Fibrinogen was incubated with human α-thrombin (0.5 U/mL, final concentration) in the presence of bovine fibrinogen fragment D (1 µmol/L).

†Percent fibrinogen cleavage is calculated by the following formula: FP-A measured × 100/FP-A predicted.

‡The maximum concentration of fibrin is considered to be equal to the concentration of fibrinogen × percent fibrinogen cleavage/100.

§The percent fibrin polymer formation is determined spectrophotometrically by measuring light absorbance at 350 nm of a suspension of thrombin-cleaved fibrinogen (see Materials and Methods).

‖Total fibrin polymer is calculated by the formula: maximum fibrin polymer × percent polymer/100.

¶Concentration of fibrin monomer is calculated by the following formula: [maximum fibrin − fibrinogen] × (percent cleavage/100) × percent polymer/100.

platelet-bound fibrin monomer required to mediate enhanced plt-vWF binding to platelets is 45 µg/10^{10} platelets. Plt-vWF binding increases only when bound fibrin monomer exceeds this value.

DISCUSSION

These experiments indicate that fibrin monomer mediates plt-vWF binding to the glycocalicin portion of platelet GPIb. The initial observation showed that fibrin, when present in small concentrations, resulted in increased surface expression of plt-vWF on thrombin-stimulated platelets. Confirmation that this effect was specific for fibrin was demonstrated by the inability of other purified proteins (eg, bovine serum albumin and human fibronectin) to enhance plt-vWF binding (Fig 1B). The ability of fibronectin to interact with platelets was confirmed by the inhibition of plt-vWF binding to platelets when fibronectin is present at high concentrations (Fig 1B). Studies measuring the generation of FP-A or using collagen as the platelet agonist confirmed that fibrin and not fibrinogen was responsible for the enhanced plt-vWF binding to platelets.

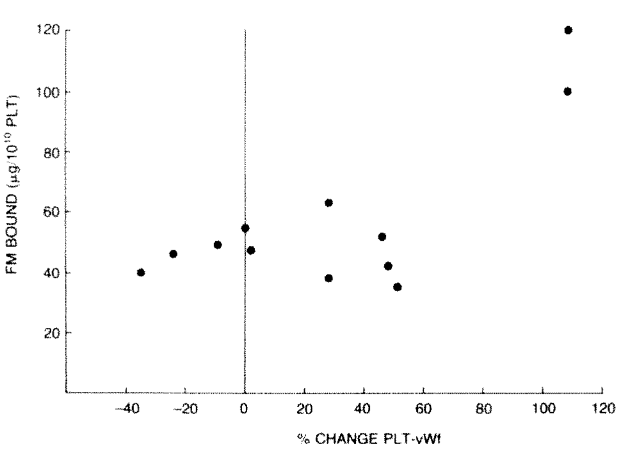

Fig 3. Graph of bound fibrin monomer v percent change in plt-vWF binding. Each point represents the mean of three points. The best fit for this curve is a three-parameter hyperbolic function with the equation $1/Y = A + Bx$ where $Y = FM$ (fibrin monomer) bound, x = percent change in plt-vWF, $A = 0.0207 \pm 0.0015$, and $B = 0.000109 \pm 0.000015$. The y-intercept by this equation is 44.9 ± 6.3. P value for curve fit < .001 by the F test.

Studies with the GPRP tetrapeptide, which prevents both fibrin polymerization[18] and fibrin/fibrinogen binding to platelet GPIIb/IIIa,[11,19] demonstrated that binding of the fibrin to the platelet is necessary to induce plt-vWF binding (Figs 1, 2, and 3). Fibrin polymerization is inhibited by either the GPRP tetrapeptide or the fragment D isolated from fibrinogen.[20] However, the binding of the fibrin monomer to the platelet surface is prevented by the GPRP tetrapeptide, whereas fragment D does not interfere with fibrin binding to platelets (Fig 2). The importance of this difference is critical. These experiments demonstrate that fibrin monomer must bind to the platelet surface to have any effect on plt-vWF binding, ie, fragment D enhances plt-vWF binding whereas GPRP has no effect (Fig 1).

The studies using a monoclonal antibody directed against GPIb and a monospecific anti-glycocalicin (α-GC) antiserum suggest that the glycocalicin portion of GPIb serves as the receptor for fibrin monomer–induced plt-vWF binding. Further evidence that GPIb serves as the receptor site for fibrin monomer–induced plt-vWF binding are the results of the studies with Bernard-Soulier platelets in which fibrin monomer does not increase plt-vWF binding while fibrin(ogen) inhibits plt-vWF binding. The degree of inhibition is quite similar to that observed with normal platelets incubated with the α-GC antiserum. These data are consistent with our earlier studies demonstrating binding of released plt-vWF to platelet GPIIb/IIIa[6] and demonstrate the inhibition of this binding in the presence of polymerized fibrin. These data along with the results obtained when fibrin polymerization is prevented by fibrinogen fragment D suggest that fibrin polymer is the form of fibrin that binds to GPIIb/IIIa and that fibrin monomer (or very small fibrin oligomers) binds to GPIb.

In experiments designed to test whether GPIb serves as a receptor for fibrin monomer, we used platelets in which the vWF binding site on GPIb was occupied by monoclonal antibody 6D1 or by plasma vWF. In these studies, fibrin(ogen) binding to GPIIb/IIIa is completely blocked by monoclonal antibody 10E5. The finding of a significant reduction in the binding of fibrin to these platelets indicates that a site on the glycocalicin portion of GPIb is involved in the binding of fibrin monomer to platelets. Furthermore, by the use of platelets in which plasma vWF is bound to GPIb in the presence of ristocetin we were able to determine that surface-bound vWF does not serve as a receptor for fibrin or fibrin monomer. This suggests that a vWF–fibrin monomer complex does not form on the platelet surface, and if such a complex formation is an important step in the binding of plt-vWF to the platelet GPIb, the complex must form before the vWF binds to the platelet. Because fibrin binding is not completely inhibited in these experiments, our data suggest that either the site on glycocalicin to which fibrin monomer binds is not identical to that for vWF or that there are additional non-GPIb, nonGPIIb/IIIa binding sites for fibrin monomer on the platelet surface.

Our results indicating enhanced binding of fibrin monomer to platelets are consistent with earlier studies by Niewiarowski et al[21,22] who demonstrated binding of polymerizing fibrin but not native fibrinogen or fully polymerized fibrin to washed platelets. The recent report of Loscalzo and et al[12] that documents binding of plasma vWF and purified glycocalicin to immobilized fibrin monomer shows that plasma vWF enhances platelet incorporation into polymerizing fibrin. They suggest that a vWF–fibrin monomer complex is formed that subsequently binds to platelet glycocalicin. These studies in concert with our observations suggest that the mechanism of enhanced plt-vWF binding in the presence of low concentrations of fibrinogen involves the binding of fibrin monomer to the glycocalicin portion of platelet GPIb. Our studies showing inhibition of plt-vWF binding in the presence of the GPRP tetrapeptide suggest that fibrin monomer binding to platelets is required to induce plt-vWF binding to platelets. We have shown that an epitope on glycocalicin serves as the receptor for this fibrin monomer–dependent binding of plt-vWF.

The clinical significance of this phenomenon is speculative at this time, although the recent finding of Michelson et al[23] localizing the ristocetin-dependent plasma vWF binding site on GPIb to glycocalicin suggests that fibrin monomer–induced binding of plt-vWF to glycocalicin may have a function similar to that described for the binding of plasma vWF to platelets in the presence of ristocetin. Under conditions that may favor fibrin monomer formation (eg, disseminated intravascular coagulation, the environment within an evolving thrombus) platelet adhesion may be maximized by this process of fibrin monomer–induced plt-vWF binding. Inasmuch as we do not find increased fibrin monomer binding to platelets with plasma vWF prebound to GPI (Fig 2), we believe that vWF bound to GPIb is not the receptor for fibrin monomer binding. The platelet receptor for fibrin monomer is not determined in this study. However, from our data, we propose the following model: fibrin monomer is formed and binds initially to the platelet, possibly at a site near the vWF binding site on GPIb. This interaction results in a conformational change in the glycocalicin portion of GPIb, which allows the binding of vWF to its receptor on GPIb. An alternative possibility involves the binding of a fibrin monomer–vWF complex to the platelet GPIb through the binding of the fibrin monomer component of the complex to the platelet.

ACKNOWLEDGMENT

The authors wish to thank Drs Elemer Mihalyi and Margaret Rick for their helpful suggestions and Dr Mihalyi for his kind gift of bovine fibrinogen fragment D.

Interleukin-2 Production and Response to Interleukin-2 by Peripheral Blood Mononuclear Cells From Patients After Bone Marrow Transplantation: II. Patients Receiving Soybean Lectin–Separated and T Cell–Depleted Bone Marrow

By Karl Welte, Carolyn A. Keever, Janet Levick, Mary Ann Bonilla, Vincent J. Merluzzi, Roland Mertelsmann, Robert Evans, and Richard J. O'Reilly

The ability of peripheral blood mononuclear cells (PBMC) to produce and respond to interleukin-2 (IL-2) was evaluated in 50 recipients of HLA-identical bone marrow (BM) depleted of mature T cells by soybean agglutination and E rosetting (SBA$^-$E$^-$BM). In contrast to our previous findings in recipients of unfractionated marrow, during weeks 3 to 7 post-SBA$^-$E$^-$BM transplantation (BMT), PBMC from the majority of patients spontaneously released IL-2 into the culture medium. This IL-2 was not produced by Leu-11$^+$ natural killer cells, which were found to be predominant in the circulation at this time, but by T11$^+$, T3$^+$, Ia antigen-bearing T cells. The IL-2 production could be enhanced by coculture with host PBMC frozen before transplant but not by stimulation with mitogenic amounts of OKT3 antibody, thus suggesting an in vivo activation of donor T cells or their precursors by host tissue. Spontaneous IL-2 production was inversely proportional to the number of circulating peripheral blood lymphocytes and ceased after 7 to 8 weeks post-SBA$^-$E$^-$BMT in most of the patients. In patients whose cells had ceased to produce IL-2 spontaneously or never produced this cytokine, neither coculture with host cells nor stimulation with OKT3 antibody thereafter induced IL-2 release through the first year posttransplant. Proliferative responses to exogenous IL-2 after stimulation with OKT3 antibody remained abnormal for up to 6 months post-SBA$^-$E$^-$BMT, unlike the responses of PBMC from recipients of conventional BM, which responded normally by 1 month post-BMT. However, the upregulation of IL-2 receptor expression by exogenous IL-2 was found to be comparable to normal controls when tested as early as 3 weeks post-SBA$^-$E$^-$BMT. Therefore, the immunologic recovery of proliferative responses to IL-2 and the appearance of cells regulating in vivo activation of T cells appear to be more delayed in patients receiving T cell–depleted BMT. Similar to patients receiving conventional BMT, however, the ability to produce IL-2 after mitogenic stimulation remains depressed for up to 1 year after transplantation.

IT HAS BEEN WELL DOCUMENTED that patients after bone marrow transplantation (BMT) demonstrate severe deficiences of cellular and humoral immunity.[1-6] The inability to produce normal amounts of interleukin-2 (IL-2) is considered to be one possible mechanism for deficient immune function post-BMT.[7-12]

IL-2 is one of the major cytokines responsible for clonal expansion and function of T cells,[13-15] natural killer (NK) cells,[16-18] and lymphokine activated killer cells in vitro and in vivo.[19,20] Defective mitogen-induced IL-2 production has been documented in several immunodeficiency states including severe combined immunodeficiency, acquired immunodeficiency syndrome, and common variable immunodeficiency.[14] We previously reported[10] that when using OKT3 antibody as a T cell–specifc mitogen[21-23] peripheral blood mononuclear cells (PBMC) from patients receiving allogeneic, HLA-identical unfractionated bone marrow (BM) were deficient in their production of IL-2 up to 18 months post-BMT. This defective IL-2 production was associated with severely depressed proliferative responses to OKT3. However, in the presence of exogenous IL-2, PBMC from the majority of patients showed normal proliferation.[10]

Relatively little is known about the immune function of PBMC from patients with leukemia after receiving T cell–depleted BMT. In our center, a technique was developed to remove from BM mature blood cells including T lymphocytes by soybean agglutination and subsequent E rosette depletion (SBA$^-$E$^-$BMT).[24,25] The enriched source of hematopoietic progenitor cells isolated by this procedure is adequate to ensure full engraftment of all cellular BM elements and recovery of marrow function.[25] Such grafts prevent acute and chronic forms of graft-*v*-host disease (GvHD) posttransplant in both HLA-identical and HLA-nonidentical recipients.[25,26] The kinetics of hematopoietic recovery do not differ significantly from that in patients receiving unfractionated BM. However, as shown in this study, the pattern of reconstitution of T cell subpopulations and T cell functions in the first 3 months after BMT is different from those in patients receiving unfractionated BMT.[10]

We have sequentially examined PBMC from patients receiving T cell–depleted BMT for (*a*) their ability to produce IL-2, (*b*) their IL-2 receptor expression, and (*c*) their ability to proliferate in response to mitogen with and without the addition of IL-2.

MATERIALS AND METHODS

Patients and controls. The study group consisted of 50 recipients of SBA$^-$E$^-$, allogeneic, HLA-identical BM: 13 patients with acute lymphoblastic leukemia in first, second, or third remission; two patients with non-Hodgkin's lymphoma; 13 patients with acute myeloid leukemia in first or second remission; 19 patients with

chronic myelogenous leukemia; and three patients with myelodysplastic syndrome. Pretransplant conditioning was with cyclophosphamide (60 mg/kg/d for two days) and hyperfractionated total body irradiation (1,320 rad or 1,440 rad). No drug prophylaxis was administered posttransplant to prevent GvHD. All patients tested in this series achieved durable engraftment confirmed by cytogenetics and full hematopoietic reconstitution.

Forty-three patients were tested at least once during weeks 3 to 7 post-BMT, and 26 of the 43 patients were tested more than once (two to five times) during this time period. Of the 43 patients, 35 patients subsequently were tested one or more times during weeks 8 to 14 post-BMT. Seven additional patients were tested for the first time during this time period. Eighteen patients in the study were repeatedly tested up to 1 year post-BMT. Normal controls consisted of 51 laboratory personnel aged 20 to 45 years.

The protocol for this study was subject to initial approval and subsequent annual review by the human subject review committee of Memorial Sloan Kettering Cancer Center. All participants in the study signed committee approved consent forms.

Monoclonal antibodies. OKT3, OKT4, OKT8, and OKT11 monoclonal antibodies (MoAbs) were purchased from Ortho Pharmaceuticals (Raritan, NJ). Leu-11b antibody was purchased from Becton Dickinson, (Mountain View, CA). Leu-2, Leu-3, Leu-4, and Leu-5 antibodies were generated as culture supernatants in our laboratory by one of us (Dr R. Evans). The hybrid line secreting Leu-7 was obtained from the American Tissue Culture Collection (Rockville, MD). Anti-Tac MoAb (ascites fluid) was kindly provided by Dr T. Waldmann, National Institutes of Health, Bethesda, MD; NKH1 MoAb by Drs R. Schmidt and J. Ritz, Dana Farber Cancer Center, Boston; and PL8 (anti-HLA class II) by Dr K. Horibe, Memorial Sloan-Kettering Cancer Center, NY.

Cell preparations. PBMC from patients or healthy human volunteers were separated by density gradient centrifugation on Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) and were kept in RPMI 1640 supplemented with 2 mmol/L L-glutamine, 50 U/mL penicillin, 50 μg/mL streptomycin, and 10% heat-inactivated fetal calf serum (FCS) during all subsequent incubation and washing procedures. Adherent cells were removed by incubation on Falcon tissue culture dishes (no. 3003, Falcon Labware, Oxnard, CA) as described[23] and are referred to as peripheral blood lymphocytes (PBL). In some experiments E^+ cells were separated from PBMC by rosetting with neuraminidase-treated sheep erythrocytes as described.[27]

Analysis of T cell surface antigens. Immunofluorescence analyses were performed on a FACS IV (Becton Dickinson). PBMC (10^6 cells) were incubated with appropriate dilutions of MoAb (1:4 for culture supernatants, 1:10,000 for anti-Tac, 1:40 for all other antibodies) for 40 minutes at 4°C, washed twice, and then incubated with a 1:40 dilution of affinity-purified goat antimouse IgG, $F(Ab')_2$-fluorescein isothiocyanate (FITC) (Cappel Laboratories, Cochranville, PA) in the same way. After washing twice, the cells were suspended in 1 mL phosphate-buffered saline for analysis. All incubations and centrifugation steps were done at 4°C. Background fluorescence was determined by using a supernatant containing an IgG1κ protein of diluted normal mouse serum instead of the first antibody.

Proliferation assay. The separated PBMC (1×10^6 cells/mL) or E^+ cells (supplemented with 10% macrophages, 1×10^6 cells/mL) were incubated in triplicate cultures (no. 3596 culture plates, Costar, Inc, Cambridge, MA) in the presence or absence of OKT3 antibody, in the presence and absence of phorbol-myristate-acetate (PMA), and in the presence or absence of exogenous IL-2 in a total volume of 200 μL. The concentrations used were OKT3, 2.5 ng/mL; PMA, 2.5 ng/mL; and IL-2, 20 U/mL. After 72 hours, the cultures were pulsed for four hours with ^3H-thymidine (0.5 μCi/well, New England Nuclear, Boston) and proliferation measured as described previously.[10,23]

Assay for IL-2 production and IL-2 activity. Identical cultures (see Proliferation Assay, in the absence of exogenous IL-2) were incubated for 24 hours, and 100 μL of supernatant was removed to be assayed for IL-2 activity. IL-2 was measured by using the assay previously described by Gillis et al.[28] Units of IL-2 activity were determined by using an IL-2 standard provided by the National Institutes of Health Biological Response Modifers Program.

BM separation and IL-2 production by $SBA^-E^-BM^-$. Donor BM cells were enriched for progenitor cells and depleted of mature blood cells including T lymphocytes by using soybean agglutinin and E rosetting by a method originally developed by Reisner et al.[24,25] The SBA^-E^-BM cells were incubated at 10^6 cells/mL in RPMI 1640 supplemented with 10% FCS in the absence and presence of OKT3 antibody (2.5 ng/mL). After incubation at 37°C for 24 hours, supernatants of the cells were collected and tested for IL-2 activity as described.[28,29]

IL-2 source. For this study we used human recombinant IL-2, kindly provided by CETUS, Emeryville, CA.[30] In some of the studies highly purified IL-2 (hpIL-2) was used in parallel, which was purified from lymphocyte-conditioned medium (Lymphocult, Biotest, Fairfield, NJ) as described.[29] Recombinant IL-2 and hpIL-2 gave qualitatively and quantitatively identical results in these experiments. Therefore, results are detailed for recombinant IL-2 only.

Antibody plus complement depletions. PBL were treated with MoAb plus complement (C') to remove selected populations of cells. All of the MoAbs used were free of sodium azide. The cells were resuspended in 0.1 mL/10^6 cells of antibody or medium alone. The optimum dilution established for OKT3, OKT11, OKT4, and OKT8 was 1:20; Leu-11b, 1:50, NKH-1, 1:125; and PL8, 1:2. After a 60-minute incubation at 4°C the cells were centrifuged, and the MoAb was decanted. A volume of 0.5 mL of a pretested dilution (1:5) of low-toxicity rabbit C' (Pel-Freez, Rogers, AR) was added, and incubation was continued at 22°C for 60 minutes. The cells were washed twice with RPMI-10% FCS, counted, and adjusted to the same volume as the C' control (cells incubated with C' but without MoAb) before culturing. PBL that had been incubated overnight at 37°C to shed bound antibodies were restrained with directly FITC conjugated antibodies to monitor T cell depletion. Less than 5% of the relevant population could be detected. PBL that had been depleted of Leu-11^+ or NKH-1^+ cells had no lytic activity to K562 in four-hour, ^{51}Cr release assays.

Mixed cell culture. Mixed cell cultures were performed in RPMI 1640 plus 10% FCS. Responder cells (10^5 cells) were cocultured with irradiated, previously frozen pretransplant PBMC (10^5 cells) from the patients or their donors at 37°C and 5% CO_2 for 72 hours. The supernatant was removed and tested for the presence of IL-2. Controls included responders incubated without stimulators and irradiated stimulators incubated alone. In one experiment, mixed cell cultures between irradiated donor SBA^-E^-BM cells (obtained on the day of transplant) and pretransplant patient PBMC and donor PBMC were performed.

Statistical analysis. Statistical evaluation was performed by using the nonparametric two-sample rank test (Mann-Whitney test).

RESULTS

PBMC from patients 3 to 7 weeks post-BMT were cocultured with medium alone, PMA, OKT3, and a combination of T3 and PMA, and the amount of IL-2 secreted into the medium was measured. The results in Fig 1 show that unlike

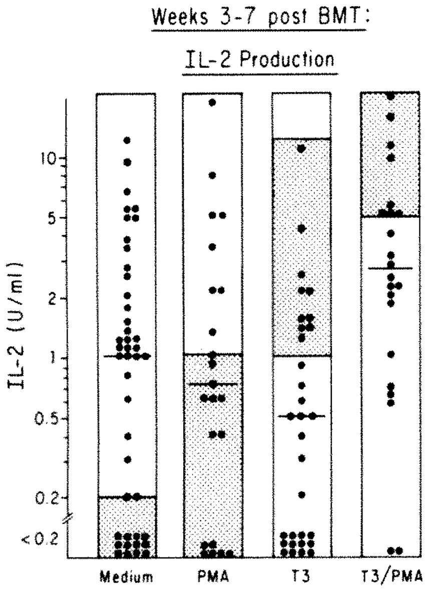

Fig 1. IL-2 production by PBMC from patients 3 to 7 weeks post-BMT. PBMC from patients were cultured (10^6 cells/mL) in RPMI 1640 and 10% FCS in the absence (medium) or presence of stimulators: PMA, 2.5 ng/mL; T3 (OKT3), 2.5 ng/mL; or PMA plus T3. After 24 hours the supernatants were tested for IL-2 activities. The results are shown for each patient only once at the time of maximal IL-2 release without stimulator (medium). The shaded area represents the 100% range of normal donors (n = 51). ———, median.

*Spontaneous IL-2 production after 24 hours of culture.

†PBMC obtained from patients at the indicated times post-BMT were cultured for 72 hours in medium (RPMI 1640 plus 10% FCS) or cocultured with host or donor PBMC cryopreserved pretransplantation. Secreted IL-2 was measured as described in Materials and Methods. Results are expressed as units of IL-2/mL supernatant.

‡Data are units of IL-2/mL.

normal controls PBMC from 31 of 43 patients spontaneously secreted detectable amounts of IL-2 (0.2 to 12 U/mL; median, 1.0 U/mL) into the medium ($P < .001$). The addition of PMA (2.5 ng/mL) or OKT3 antibody (2.5 ng/mL) to the medium did not increase IL-2 production. OKT3 plus PMA, however, increased production, but the levels achieved were below the normal range of the control group ($P < .01$), which is shown as the shaded area (100% range). The IL-2 produced by PBMC from patients after OKT3 stimulation was no greater than the spontaneous IL-2 production. All eight of the patients whose PBMC produced normal amounts of IL-2 after stimulation with OKT3 plus PMA were also spontaneous IL-2 producers (>1 U/mL).

Table 1 shows results from cocultures between weeks 3 to 7 posttranspant PBMC and irradiated pretransplant host PBMC and donor PBMC, respectively. Spontaneous IL-2 production was measured on days 1 and 3 of culture, and stimulated IL-2 production was measured on day 3. Compared with day 1, spontaneous IL-2 production on day 3 of culture was unchanged in two experiments, increased in three experiments, and decreased in four experiments. In eight of ten experiments, irradiated pretransplant host PBMC stimulated higher production of IL-2 than that seen in medium alone (day 3). In three of five experiments donor PBMC also increased the production of IL-2 compared with the medium alone, but in only one patient (no. 526) was this production greater (11 U/mL) than that stimulated by coculture with pretransplant host cells (9.4 U/mL). In contrast, when the donor's own PBMC were cultured alone or with irradiated prestransplant host cells, no detectable IL-2 was produced. Furthermore, irradiated host or donor stimulator cells incubated alone (data not shown) did not generate IL-2.

Cultures of SBA$^-$E$^-$BM specimens from 40 donors in medium alone or in the presence of OKT3 (2.5 ng/mL) did not result in the release of detectable amounts of IL-2. In contrast, unfractionated BM (n = 16) under the same conditions released IL-2 (1 to 4 U/mL) when stimulated with OKT3, which indicated the presence of T cells in the unfractionated marrow sample.

Mixed cell cultures using irradiated donor SBA$^-$E$^-$BM cells as stimulators and host pretransplant PBMC or PBMC as responders also did not result in IL-2 production, which indicated that the donor SBA$^-$E$^-$ marrow does not contain cell populations capable of stimulating IL-2 production by either the donor or the HLA-identical host. As expected, however, the SBA$^-$E$^-$BM fraction was able to induce IL-2 production by a third-party control PBMC (data not shown).

Phenotype of the T cells during weeks 3 to 7 post-BMT. Phenotyping of PBMC from patients was performed at the same post-BMT time as IL-2 production was measured. Most striking was the consistently high percentage of cells with the NK-associated antigens (Leu-11 and Leu-7). Leu-5$^+$ (CD2) cells were consistently in significant excess of Leu-4$^+$ (CD3) cells, which suggested the presence of cells with the Leu-4$^-$, Leu-5$^+$, Leu-11$^+$ or NK cell phenotype as reported by others.[6] It is also possible, however, that the discrepancy between Leu-4$^+$ and Leu-5$^+$ cells reflects the presence of immature prethymic Leu-5$^+$, Leu-4$^-$, Leu-3$^-$, Leu-2$^-$ cells (Table 2).

The phenotype of PBMC from patients who did or did not spontaneously generate IL-2 was not different with the

exception of an increased level of Tac^+ cells in the spontaneous IL-2–producing patients (10% ± 5% Tac^+ cells). This difference compared with normal controls was significant ($P < .01$).

Phenotype of the IL-2–producing cells. MoAb plus C′ treatment of PBL from spontaneous IL-2 producers showed reduced IL-2 production when T11, T3, and Ia plus C′ were used. The results from five patients tested at different times post-BMT are shown in Table 3. Surprisingly, Leu-7, Leu-11b, or NKH1 plus C′ treatment of PBL did not reduce the IL-2 production in any experiment, which suggested that although this population of cells predominates at this time the cells producing IL-2 were not NK cells. T4 or T8 plus C′ treatment of PBL had only minor effects on the IL-2 production.

IL-2 is able to induce its own receptor on PBMC from patients after BMT. In five patients (3 to 7 weeks post-BMT) we studied the ability of IL-2 to upregulate its own receptor expression on PBMC as has been shown for normal PBMC[31,32] (Table 4). The percentage of Tac+ PBMC before culture was between 7% and 9%. Culturing the PBMC from these five patients without mitogenic stimulation but in the presence of IL-2 (100 U/mL) led to an increase of the

3	8	27
4	8	26
5	9	17
Median (range)	8 (7-9)	26 (17-33)

PBMC obtained from patient 3 to 7 weeks post-BMT were cultured for three to four days in medium (RPMI 1640 plus 10% FCS) in the presence of recombinant IL-2 (100 U/mL). Tac antigen expression was measured as described in Material and Methods. A healthy control tested at the same time under the same conditions had 0% Tac+ cells at day 0 and 21% Tac+ cells at day 4.

percentage of Tac+ cells from 8% (7% to 9%) to 26% (17% to 35%) at days 3 to 4 in culture. PBMC from a simultaneously tested normal control increased from 0% to 21% Tac+ cells at day 4.

The kinetics of spontaneous IL-2 production. As shown in Table 5, the maximal spontaneous IL-2 production occurred during the first 7 weeks post-BMT. After 8 weeks and at later times post-BMT, the majority of patients no longer spontaneously produced IL-2, and the pattern of mitogen-induced IL-2 production became more similar to that of patients receiving unfractionated BMT.[10] The amount of spontaneous IL-2 produced by any one patient during the first 7 weeks post-BMT varied considerately (Fig 1). We were interested to determine the time course and factors that may affect production by PBMC from the patients under study. In Fig 2, we have detailed the course of IL-2 production along with WBC and lymphocyte recovery of six patients who represent different patterns of spontaneous IL-2 production. Patient A (Fig 2A) spontaneously produced IL-2 from weeks 3 to 6 post-BMT, whereas patient E (Fig 2E) never produced detectable amounts of IL-2 during this period. Patients B, C, D, and F (Fig 2B, 2C, 2D, 2F) produced IL-2 only for a short period of time (up to week 5 post-BMT). As can be seen, the spontaneous IL-2 production was inversely correlated with the recovery of the number of WBC and absolute lymphocyte count (ALC): patients E and F, who experienced a rapid recovery of WBC, either did not produce IL-2 spontaneously (2E) or produced it only very early post-BMT (3 weeks; Fig 2F). In contrast, patients A and B, who experienced a slower return of WBC, had a high level of spontaneous IL-2 production for a protracted period post-BMT.

The inverse correlation between ALC and the amount of IL-2 produced in vitro by PBMC was examined for all tests (n = 85) performed on patients (n = 43) between weeks 3 and 7 post-BMT. High spontaneous IL-2 producers (>3 U/mL) were found only in the group with ALC <500/μL. The difference in spontaneous IL-2 production between patients with ALC <500/μL was statistically significant ($P < .001$).

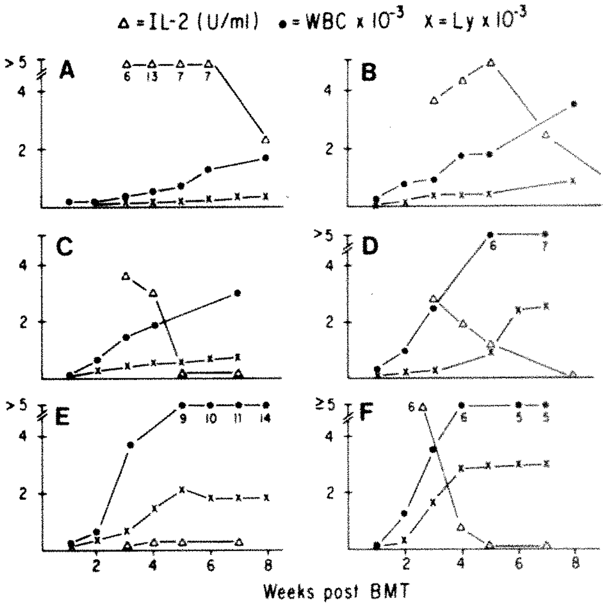

Fig 2. Time course of spontaneous IL-2 production (△), WBC recovery (●), and absolute lymphocyte number (x) in six representative patients tested more than three times during the first 7 weeks post-BMT. The numbers below the symbols point out the exact values when higher than or equal to 5.

Patients A, C, and E were also tested for the percentage of Tac+ cells; patient A was 13% at week 4, 11% at week 5, 5% at week 7, and 2% at week 8. In patient C the percentage of Tac+ cells was 9% at week 4 and 4% at both weeks 5 and 6. In patient E 2% of PBMC were Tac+ at week 4, 3% at week 5, and 0% at week 8. These data suggest a good correlation between the development and decline of spontaneous IL-2–producing cells and IL-2 receptor–positive cells in those patients tested.

The normal control values are also shown as shaded areas (100% range) in Fig 1 for IL-2 production and in Fig 3 for proliferation.

tion of lymphocytes from 13 of 36 patients tested during weeks 3 to 7 post-BMT was significantly greater than PBMC from controls ($P < .01$) (Fig 3). All of these 13 patients were spontaneous IL-2 producers. Exogenous IL-2 increased the proliferation of PBMC from the majority of patients, which is consistent with the increased levels of IL-2 receptors. This IL-2–induced proliferation was also significantly different from the normal control group ($P < .001$). OKT3-induced proliferation, however, was low during weeks 3 to 7 post-BMT compared with controls, both in the absence and in the presence of IL-2 ($P < .001$). PMA was not able to increase the proliferation in the medium control or in the presence of OKT3 (Table 5).

A summary of IL-2 production and proliferative responses with and without IL-2 of PBMC from patients tested at intervals up to 1 year post-BMT is shown in Table 5. The pattern of OKT3-induced proliferative response during weeks 8 to 12 was similar to that seen during weeks 3 to 7. Statistical analysis comparing data from controls with patients up to 26 weeks post-BMT showed significant differences in all values tested ($P < .01$). Six to 12 months after BMT (weeks 27 to 52), the proliferative response to OKT3 antibody was still defective in the majority of patients (median, 19,000 cpm). However, the proliferative response by PBMC stimulated with OKT3 in the presence of exogenous IL-2 was within the normal range for all patients tested later than 27 weeks post-BMT.

DISCUSSION

In a previous study we found that patients conditioned with the same regimen as described here who received unfractionated HLA-identical BM demonstrated low proliferative response to mitogens and produced little or no IL-2 up to 18 months post-BMT in response to OKT3 antibody. Exogenous IL-2, however, was able to restore the mitogen responses to within the normal range of healthy controls as early as 1 month post-BMT.[10] Similar results are seen when using PBMC from recipients of HLA-identical SBA^-E^-BM when tested later than 6 months post-BMT. However, there were substantial differences during the early posttransplant period. Between 3 and 7 weeks post-BMT, PBMC from the majority of patients released IL-2 into the culture medium in the absence of added stimuli, thereby suggesting in vivo stimulation of T cells, a phenomenon not observed in recipients of unfractionated marrow. Furthermore, in contrast to conventional transplant recipients, the mitogen responses of PBMC at this time and until 6 months postgrafting could not be normalized by the addition of exogenous IL-2.

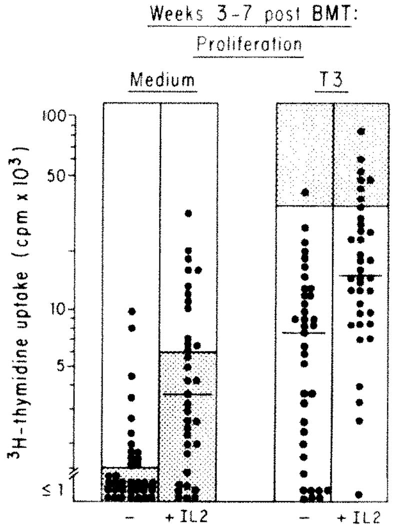

Fig 3. Spontaneous or OKT3-induced proliferation of PBMC from patients 3 to 7 weeks post-BMT in the presence or absence of exogenous IL-2 (20 U/mL). Cell proliferation was measured by ^{3}H-thymidine uptake on day 3 of culture. The shaded area represents the 100% range of normal donors (n = 51). ———, median.

The cell source of the spontaneous IL-2 production observed in recipients of T cell–depleted marrow grafts has heretofore not been defined. Brenner et al[33] recently reported that recipients of HLA-matched marrow grafts depleted of T cells with mouse MoAbs spontaneously produce IL-2, B cell differentiation factor, and γ-interferon early posttransplant. Cells in a Percoll gradient fraction enriched for large granular lymphocytes were responsible for this production, and the authors suggested that NK cells were the source of these cytokines. However, clear identification of the producer cells was not reported.

We as well as others[5,6] show a predominant population of cells with an NK phenotype developing early post-BMT. We have also found that these cells function normally in NK and lymphokine activated killer cell (LAK) assays.[34,35] However, our current studies indicate that these NK cells are not the source of spontaneously produced IL-2. C′ plus antibody lysis using Leu-11 or NKH1 antibodies did not abolish the spontaneous IL-2 release; rather, it increased IL-2 production from the remaining PBL, which suggested a possible suppressor activity of NK cells on the producer cells. Antibody plus C′ treatment of fresh PBL indicated that the IL-2–producing cell was a $T3^+$, $T11^+$, $T8^-$, Ia^+ T cell. Antibody to T4 plus C′ had a variable inhibiting effect on IL-2 production, perhaps due to a low density of the antigen on producer cells. These T cells are likely already activated because the proportion of Tac^+ T cells and spontaneous proliferation of lymphocytes from patients who spontaneously produce IL-2 was increased when compared with cells from either normal controls or patients who did not generate IL-2 spontaneously. IL-2 receptors are only expressed on T cells either activated by antigen/mitogen or stimulated by IL-2[31,32]

The stimulus provoking spontaneous IL-2 production by T cells emerging early after SBA^-E^-BMT is still unclear. In our studies, production of IL-2 by T lymphocytes emerging 3 to 7 weeks post-BMT could not be augmented by stimulation with the mitogen OKT3. The IL-2 detected in supernatants of PBMC after T3 stimulation could be accounted for by spontaneously released IL-2 because it was not increased compared with the medium control. PMA, a diacylglycerol analogue that is a potent stimulator of protein kinase C, was also not able to increase the production of IL-2. PMA in combination with the T3 antibody, however, did increase IL-2 production, which indicated that given optimal stimuli the cells were capable of producing higher, although still suboptimal, amounts of IL-2. When compared with a healthy control group ($n = 51$), the amounts of T3- and T3/PMA-induced IL-2 produced by PBMC from the patients up to 7 weeks post-BMT were well below the normal range. Our study thus indicates that T cells developing in patients early after receiving SBA$^-$E$^-$BMT are deficient in their response to mitogens as measured by lymphocyte proliferation and IL-2 production. Therefore, either the mechanism that leads to spontaneous IL-2 production has to be a very potent activator of T cells, or it activates only a subpopulation of immature T cells that do not respond to mitogens.

Given the data we have accrued to date, at least three hypotheses can be proposed to account for this spontaneous IL-2 production: (*a*) the IL-2–producing cells are residual radioresistant host T cells reactive against donor marrow whose growth and activity is normally inhibited by mature T cells in the donor marrow inoculum, (*b*) the production is by mature cells within the graft responding to minor alloantigen differences of the host, or (*c*) spontaneous IL-2 production reflects the activity of donor T cells developing within the host from early precursors in the SBA$^-$E$^-$ marrow inoculum. It is unlikely that the IL-2 production is by host cells because karyotype as well as DNA restriction length polymorphisms have indicated a clear predominance of donor-derived cells in most patients at this stage posttransplant. Furthermore, in mixed cell cultures, the generation of IL-2 at levels in excess of spontaneous production was observed with coculture of patient PBMC with irradiated host rather than donor PBMC stimulations in two thirds of the cases tested (Table 1).

Stimulation of SBA$^-$E$^-$ marrow fractions with mitogen or with host cells failed to induce IL-2 production, which rendered it unlikely that mature cells within the inoculum are the IL-2–producing cell. Most likely is the third hypothesis; indeed, persistence of spontaneous IL-2 production was inversely correlated with the temporal course of early lymphoid and hematopoietic reconstitution.

The phenotype of these IL-2–producing cells and their early development and rapid decline resembles what has been described by Lattime and Stutman in the early ontogeny of T cells in mice.[36] They described the transient presence of T cells bearing a helper phenotype that generate IL-2 in response to autologous Ia antigens present on accessory cells within the thymus. With maturation, these cells are depleted from the thymus and can be detected only as a minor population of lymphocytes in the adult spleen. Cells of a similar phenotype capable of proliferative but not cytotoxic responses to host Ia antigens have also been observed transiently in the thymus and spleens of lethally irradiated mice that have been reconstituted with T cell–depleted, H-2–incompatible marrow.[37,38]

We tested the response of PBMC from the patients post-SBA$^-$E$^-$BMT to exogenously added IL-2 in two assay systems: (*a*) spontaneous and mitogen-induced proliferation and (*b*) regulation of the IL-2 receptor expression by IL-2. Our results suggest that T cells from SBA$^-$E$^-$BMT recipients have a delayed response to OKT3 in the presence of exogenous IL-2 compared with those from patients receiving conventional BMT.[10] Although PBMC from all recipients of unfractionated BM proliferated normally to OKT3 plus IL-2 as early as 1 month post-BMT,[10] recipients of SBA$^-$E$^-$BM required as long as 6 months to regain normal proliferation under the same experimental conditions (Table 5). PMA as a costimulator did not significantly increase the T3-induced proliferation of PBMC from recipients of SBA$^-$E$^-$BMT.

The increased IL-2 receptor expression of freshly obtained patient PBMC is shown in Table 2. The ability of IL-2 to induce its own receptor on T cells from patients up to 7 weeks post-BMT was also tested. As reported for normal T cells,[31,32] IL-2 was able to upregulate the IL-2 receptor expression as judged by staining with the Tac MoAb in all patients tested. The highest percentage of Tac$^+$ cells was detected at days 2 to 3 of culture in IL-2–containing medium. This finding is of interest in that it suggests that even though the T cells are unable to proliferate normally in response to IL-2 the pathway of IL-2–stimulated IL-2 receptor induction seems to be intact. Alternatively, it is possible that NK cells, which represent a high percentage of the lymphocytes detected early after BMT, are able to respond to IL-2 with increased expression of the IL-2 receptor.

The clinical importance of our finding both early and late post–T cell–depleted grafts remains to be determined. The patients studied in this series all achieved durable engraftment. Only two patients developed clinical evidence of GvHD. Each of these patients did produce increased levels of IL-2 early posttransplant. However, other patients without GvHD produced comparable levels. Current prospective analyses performed on patients receiving T cell–depleted or unfractionated marrow grafts as part of a randomized trial should determine whether our findings of early spontaneous IL-2 production and delayed regeneration of IL-2–responsive T cell functions are correlated with clinical events such as graft rejection, which complicate T cell–depleted grafts, or with other posttransplant complications such as recurrent infection or leukemia relapse.

ACKNOWLEDGMENT

We would like to thank Drs J. Brochstein, H. Castro-Malaspina, B. Cunningham, D. Emanuel, N. Flomenberg, N. Kernan, and J. Laver for allowing us to study their patients; Lorna Barnett, Azita Mairzadeh, and Karen Pekle for excellent technical assistance; Andrej Polivka for statistical analysis; and Mary Sullivan for providing us with the blood samples.

Risk of AIDS for Recipients of Blood Components From Donors Who Subsequently Developed AIDS

By Herbert A. Perkins, Susan Samson, Jane Garner, Dean Echenberg, James R. Allen, Morton Cowan, and Jay A. Levy

Reported cases of acquired immunodeficiency syndrome (AIDS) in San Francisco as of March 31, 1986, include 92 individuals who had donated blood subsequent to 1978. Their donated blood components had been transfused into 406 different recipients. The current status of 336 of these recipients was ascertained as of April 1, 1986. Of these, 223 had died at the time of our first contact, almost all as a result of the condition for which they were transfused. Seven had developed AIDS; five of these died, two before entry into the study and three subsequently. Forty-six additional living recipients were interviewed and evaluated. Seven had the AIDS-related complex, 18 had antibody to the human immunodeficiency virus (HIV) but were otherwise healthy, and 19 had no detectable anti-HIV. Two had risk factors other than transfusion. The frequency of infection of the recipient decreased as the time interval between transfusion and the diagnosis of AIDS in the donor increased. This information should be useful when counseling patients who have been transfused with blood components from donors later found to be infected with HIV.

© 1987 by Grune & Stratton, Inc.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) is caused by a virus or a group of related viruses designated lymphadenopathy-associated virus[1] human T cell lymphotropic virus, type III,[2] or AIDS-associated retrovirus.[3] Recently an international committee has recommended that these viruses be named human immunodeficiency viruses (HIV).[4] HIV can be transmitted to patients by transfusion of blood components from donors who are carriers of the virus. Although most of these carrier donors appear healthy when subsequently examined, virus can usually be cultured from their peripheral blood lymphocytes.[5] Other HIV-infected donors have later developed symptoms, signs, and laboratory test results consistent with AIDS-related complex (ARC),[6] and a small proportion subsequently meet the criteria for a diagnosis of AIDS as defined by the Centers for Disease Control (CDC).[7] Before 1983 it was not recognized that persons from groups at high risk for AIDS should be excluded as blood donors, whereas it is now evident that substantial numbers of cases of AIDS occurred in this country as early as 1979, with a few cases occurring even earlier.

The three national blood bank organizations (American Association of Blood Banks, American Red Cross, and Council of Community Blood Centers) have endorsed a statement that recipients should be notified when a donor of a blood component that they have received subsequently develops AIDS.[8] Interviewers of patients with AIDS should always ask whether they had donated blood for transfusion. If so, the center where the blood was donated should be notified. Often this procedure is done through the local health department.

Ultimately the recipient is informed of the potential exposure, and the patient's first concern will be about the likelihood that he or she may develop AIDS. This report presents information on the risk of becoming infected with HIV and of developing AIDS for recipients of blood components whose donors subsequently develop AIDS. It is likely that the findings apply equally well when the donor remains healthy but anti-HIV is detected. The majority of donors with Western blot–confirmed anti-HIV (over 90% in our experience) have cells in their blood from which HIV can be cultured.

PATIENT SELECTION AND METHODS

The Irwin Memorial Blood Bank collects blood from volunteer donors in San Francisco and seven other counties of northern California. More than 100,000 donations have been given yearly for the past 7 years. As of March 31, 1986, 1,870 cases of AIDS had been reported to the San Francisco Department of Public Health, which has resulted in the highest per capita incidence of any major city in this country. The first case of AIDS associated with receipt of a blood transfusion was reported from San Francisco in December 1982.[9,10] The blood donor developed AIDS 9 months after the blood had been given. In December 1982, the Irwin Memorial Blood Bank and the San Francisco Department of Public Health agreed to share information so that they could identify all possible AIDS patients who had donated blood at an Irwin facility subsequent to 1978.

The list of AIDS patients reported to the San Francisco Department of Public Health was compared at regular intervals with the blood bank files to identify the dates of donation, the blood components made from each donation, and the hospitals to which the components were dispensed. The hospital contacted the physician who ordered the blood or the current personal physician of the recipient. The physician informed the patient that he or she may have been exposed to the AIDS agent through transfusion. The physician was also requested to ask his or her patient to participate in this current investigation. With permission of the personal physician, the recipient was contacted, provided with information about the study, and asked for written consent to be included in the study after the nature of the procedures had been fully explained. The protocol and the consent forms were approved by the University of California San Francisco Committee on Human Research.

Each consenting recipient was interveiwed by an experienced member of the blood bank epidemiology staff to determine whether there was any evidence that he or she had a risk factor for AIDS

apart from transfusion. Such patients were eliminated from the final analysis. The interview, which included a brief physical examination, also searched for evidence of AIDS or ARC. Blood samples were taken for laboratory tests. T cell subset analysis was done in the first 13 cases by fluorescent microscopy using OKT4 and OKT8 monoclonal antibodies (Ortho Pharmaceutical Corp, Raritan, NJ) and in the remainder by flow cytometry using Leu-3 and Leu-2 monoclonal antibodies (Becton Dickinson, Mountain View, CA) in a Becton Dickinson FACS Analyzer. Mitogen stimulation of lymphocytes with phytohemagglutinin (PHA) was done in most cases. Mixed lymphocyte cultures (MLC) were attempted in the first 13 cases and stimulation with pokeweed mitogen (PWM) in the remainder. β_2-Microglobulin levels were measured by an enzyme immunoassay microtiter technique using reagents supplied by Pharmacia Fine Chemicals (Piscataway, NJ). Commercially available Abbott kits (Abbott Laboratories, Abbott Park, IL) were used for the hepatitis tests, and anticytomegalovirus (CMV) antibody was detected by reverse passive latex agglutination (BBL Microbiology Systems, Cockeyesville, MD). Serological tests for antibody to HIV were performed by licensed enzyme immunoassay (EIA) methods at the blood bank. The Abbott EIA method was used in all cases; ENI (Electronucleonics, Columbia, MD) and Genetic Systems (Seattle, WA) methods also were used when there were discrepancies with other tests. Other tests for anti-HIV in all cases were the immunofluorescent antiglobulin slide test (IFA) at the University of California, San Francisco (UCSF)[3] and the immunoblot (IB) (Western blot) technique at CDC and UCSF.[11] Antibody was considered to be present if both IFA and IB were positive and to be absent if both IFA and IB were negative.

Although the majority of recipients had consistent results in their multiple tests for antibody to HIV, discrepancies between IFA and IB reports were initially noted in six of the 53 cases (11%). Criteria for the IB were not standardized initially, but later a gp41 band was required for a positive reaction, and with multiple blinded replicates, the two laboratories ultimately reported identical results.

RESULTS

Clinical status of the recipients. As of March 31, 1986, the San Francisco Department of Public Health list of 1,870 reported cases of AIDS meeting requirements of the CDC definition included 90 previous donors from the Irwin Memorial Blood Bank. Two additional donors from a neighboring blood bank were included early in the investigation; subsequently, only Irwin donors were followed. Most donations had been separated into components, each of which had been given to a different recipient, and most of the donors had given blood multiple times since 1978. The total number of patients who had received the components under investigation was 406. Of these, 223 (54.9%) were deceased at the time of our first contact with their physician. According to the records, almost all of these died as a result of the illness for which they were transfused, but two cases of AIDS had been recognized. In the rest, no evidence for HIV infection had been noted clinically or (when done) at autopsy, but it had rarely been considered in the differential diagnosis. The most common indications for transfusion of the deceased patients were gastrointestinal bleeding, leukemia, and cardiac surgery. The most common cause of death was leukemia, but death of unknown cause was equally common. The average interval between transfusion and death was 10 months. Of the remaining recipients, 113 (27.8%) were alive, and the status of 70 (17.2%) has not yet been determined. Information on the clinical status of the 223 dead and 113 living recipients was obtained from their personal physicians.

Seven of these recipients had developed AIDS, two died before initiation of this study and three between entry into this study and preparation of this report. Two were still alive at the time of this report. We interviewed and evaluated 46 additional recipients who were alive at the time of our initial contact. These were all of the living recipients who lived within several hundred miles of us and for whom permission had been obtained to participate in the study. Table 1 summarizes the data obtained concerning these 53 recipients. Eight of the recipients had signs, symptoms, and laboratory test results consistent with ARC.[6] The remaining 38 recipients appeared to be healthy, but 19 of them had antibody to HIV in their sera, and in the other 19 no antibody could be detected. The percentage of potentially exposed recipients for whom evidence of infection was obtained was thus 62% (33/53). Two of the living recipients (one with ARC and one with anti-HIV only) acknowledged having other risk factors for AIDS; therefore, they will be eliminated from further analysis. Case no. 14 had had repeated sexual contacts with a bisexual male whose antibody status is unknown. Case no. 33 gave a history of using drugs by injection.

Although there was a wide distribution of recipient ages in all four groups, of the four recipients aged 10 or less, one had AIDS, and three had ARC. Of the five recipients aged 80 or older, two had AIDS, and two had ARC. There was no clear effect of the sex of the recipient on susceptibility to infection or disease. Although 13 of the 31 infected individuals were female and only four of 20 noninfected individuals were female, the differences are not statistically significant. The most common indications for transfusion were cardiac surgery (20 cases), orthopedic surgery, (7 cases) and gastrointestinal bleeding (7 cases), all conditions that tend to require large amounts of blood. There was no obvious correlation between the condition prompting transfusion and the occurrence of infection or AIDS in the recipient, although the numbers are too small for meaningful statistical analysis. Diseases commonly associated with immunologic depression were not encountered among the living patients we investigated. It should be noted that they would not have been reported to us as AIDS cases because the CDC definition excluded them.

Among those patients who were alive when first seen, the death rate was highest in those with AIDS, was much lower in those with ARC and with antibody only, and was zero in those without antibody. These statements are based on the patient status when we first attempted to contact them. The numbers of RBC, platelet, and fresh frozen plasma components were all significantly greater for recipients who developed AIDS, but not if patient no. 3 is omitted. Patient no. 3 received many platelet transfusions and repeated therapeutic plasmapheresis for idiopathic thrombocytopenic purpura. HIV infection was not suspected in this case before the transfusions. There were no differences in the numbers of components transfused between those patients with ARC, those with antibody only, and those without detectable

*Normal range.

antiviral antibody. All three types of components had been provided by the donors who later developed AIDS. RBC had been given to 21 infected recipients and 13 not infected; platelets to eight and seven, respectively; and fresh frozen plasma to two each.

Table 2 relates the recipient's chance of infection or disease to the time interval between the transfusion and the diagnosis of AIDS in the donor. In six of the seven cases where the recipient developed AIDS, the donor was recognized to have AIDS within 22 months. Infection of the recipient was apparent in 90% of the cases where the donor developed AIDS within a year, in 62% when the donor's AIDS was recognized between 1 and 4 years, in 20% of those with an interval between 4 and 5 years, and in neither of the two cases where the interval was over 5 years. Although it seems obvious that the longer the interval between transfusion and the diagnosis of AIDS in the donor, the less likely the donor was infected when the blood was taken, it should be noted that the differences in Table 2 lack statistical significance.

Laboratory data. Of the seven cases of AIDS, two had no detectable antibody by IB. Case no. 1 (our original case of transfusion-associated AIDS)[10] was tested by IB alone. Case no. 5 was positive in the Abbott EIA, negative by Genetic Systems EIA, and negative by IFA and IB and was therefore considered to be a false-positive by the Abbott method. All tests on the ARC cases were consistently positive. In case no. 36 three EIA tests were reactive (Abbott, ENI, and Genetic Systems), but both IFA and IB were nonreactive. Based on the latter two test results and the known propensity of EIA tests to result in false-positives, this result is assumed also to be an EIA false-positive.

A low WBC count was more common in the AIDS and ARC groups. The absolute lymphocyte count was progressively lower from the antibody-negative to the antibody-positive groups to those with ARC to those with AIDS, but it is noteworthy that three of the 15 measured in the antibody-negative group (20%) had levels below 1,500/μL. Helper/suppressor ratios were below 1.0 in all of the AIDS cases and in more than 80% of those with ARC or with anti-HIV antibody alone. They were also low in 25% of those who were negative for anti-HIV antibody. Stimulation indexes with PHA, PWM, and MLC did not correlate with the category into which the patient fell. β_2-Microglobulin levels were high in all of the AIDS cases, but they were abnormal in more recipients who had anti-HIV antibody alone than in those with ARC. Moreover, 40% of those negative for antiviral antibody had an elevated β_2-microglobulin level.

Table 2. Effect of the Time Between Blood Donation and the Development of AIDS in the Donor on the Risk of Infection in the Transfused Recipient

Months	AIDS	ARC	Asymptomatic With Anti-HIV	No Anti-HIV
0-12	4	2	3	1
13-24	2	1	4	7
25-36	0	1	6	4
37-48	1	3	3	2
49-60	0	0	2	3
>60	0	0	0	2

The laboratory tests were performed at a mean interval of 26 months after transfusion (range, 10 to 43) in the patients with AIDS, 38 months (range, 12 to 71) with ARC, 32 months (range, 9 to 60) with anti-HIV only, and 43 months (23 to 78) in the patients with no antibody to the virus detected.

DISCUSSION

Our observations on previous recipients of blood components from donors who later developed AIDS demonstrate that these recipients are at relatively high risk of developing AIDS themselves or of being infected by HIV. Of 336 recipients whose current status is known, seven (2%) have developed AIDS. Of 46 living recipients who do not have AIDS, 24 have antibody to HIV (52%), and seven of these meet the criteria for ARC.

The blood components transfused from the donors who developed AIDS included all routine components. This fact confirms the prevous CDC report that AIDS can be transmitted by whole blood, RBC and platelet concentrates, and fresh frozen plasma.[12] There is no evidence in this small series that any of these components is more likely to transmit AIDS than the others.

Infection occurred after transfusion of even a single unit (case nos. 9 and 19), but in general our patients received relatively large amounts of blood components. Recipients who developed AIDS received more components on the average than those with ARC, with anti-HIV only, or with no evidence for infection; but the difference is not significant if the atypical case 3 is omitted. Curran et al[12] have already shown that recipients with AIDS tended to receive large numbers of blood components and have reasoned that the more donors to whom a recipient is exposed, the greater the possibility of receiving an infected unit. This is undoubtedly true, but in contrast to the study of Curran et al where the recipients were selected because they had developed AIDS, the recipients in our study were selected because they had received a component from a donor who developed AIDS. Moreover, we have to explain why antibody-negative recipients had received an equally large number of components. The most likely explanation for our results is that a single specified component, no matter how selected, is more likely to have been given to a patient who received large numbers of components than to a recipient of one or two components. Whatever the explanation, the relatively large number of components given to these patients could act as a cofactor for the development of AIDS in view of the well-established immunosuppressive effects of blood transfusion.[13]

That two thirds of the recipients we identified were already dead when we first attempted to contact them can also be explained by our case selection method and should not be interpreted to be the typical fate of all transfusion recipients. Patients who receive large amounts of blood are more likely to have conditions that result in early demise. There was no evidence in the medical records that this excess of early deaths was related to AIDS. Our assumption that they were an artifact of the method of case selection requires comparison with a control group of recipients selected by identifying a donor who was not infected with HIV. Such control studies are underway.

The absolute lymphocyte count and, to a lesser degree, the total WBC count were lowest in AIDS cases compared with those with ARC, were less often low in antibody-only cases, and were most often normal in the antibody-negative group. Helper-suppressor ratios were low in all AIDS cases, in 80% of antibody-positive cases (whether or not ARC was present), but also in 25% of antibody-negative cases. Obviously, in this group of subjects ill enough to require previous transfusions, a low helper-suppressor ratio is even less indicative of AIDS or HIV infection than it is in a healthier population. Functional lymphocyte stimulation tests showed a very poor correlation with the presence or absence of HIV infection or the stage of disease and would appear to be of no help in this type of patient who has other reasons for abnormal results in these procedures. β_2-Microglobulin, which has been suggested as a test that might indicate the likelihood of overt AIDS occurring,[14] also appears to be of little help in this situation because of the high frequency of abnormal results in patients with no evidence of infection by the AIDS virus, presumably a result of coexisting illnesses.

Hepatitis B tests were usually negative in these patients, in contrast to their high rate of positive results among the more common high-risk groups for AIDS. Homosexually active males and intravenous drug users are very likely to have been exposed to hepatitis B virus. Blood transfusion recipients are exposed far less often because all donor blood is tested for hepatitis B antigen, and positive units are discarded. In contrast to the results with hepatitis B tests, our blood recipents had a very high frequency of antibody to CMV (34/40, or 85%) compared with the 51% rate of positive results among our blood donors. This finding suggests that exposure to CMV is very likely to occur during blood transfusions, but the numbers are small, and the recipients were generally older than most blood donors. The frequency of anti-CMV increases with the age of the subject. It is noteworthy that the frequency of anti-CMV antibody did not correlate with the presence or extent of HIV infection in view of the common hypothesis that infection with CMV may be a cofactor that increases susceptibility to the AIDS virus.[15]

The most useful prognostic indicators for these recipients were the time interval from transfusion until the donor was diagnosed as having AIDS and the age of the recipient. Recipients below age 11 or over age 79 were much more likely to develop overt disease than those of intermediate ages. This latter finding may reflect the state of the immune system at these ages. The shorter the time interval between the transfusion and the onset of AIDS in the donor, the more likely the donor was to be infected already at the time the blood was given, and the more likely, therefore, that the recipient would have antibody as a sign of infection. Moreover, the occurrence of disease as well as infection appears to be more likely the shorter the interval (Table 2).

ACKNOWLEDGMENT

Dr Howard Goldman, Dr Serl Rosenschein, and Deborah McSmith assisted in contacting and interviewing recipients. Dr Selma Dritz was responsible for the initial agreement by the San Francisco Health Department to allow the blood bank to compare the list of AIDS victims against its blood donor files. Dr Arthur Ammann recognized the first case of transfusion-associated AIDS[10] and was responsible for immunologic studies in the early phase of this investigation.

Limiting-Dilution Analysis of the Effects of Colony-Stimulating Factors, Phytohemagglutinin, and Hydrocortisone on Hematopoietic Progenitor Cell Growth

By Yoichi Takaue, Christopher L. Reading, Aaron J. Roome, Karel A. Dicke, Sharon Tindle,
Meena Chandran, and Barbara Devaraj

The effects of colony-stimulating factors (CSFs), phytohemagglutinin (PHA), and hydrocortisone on the growth of human bone marrow hematopoietic progenitor cells (granulocyte-macrophage; GM) were analyzed in a limiting-dilution assay (LDA). Both low-density bone marrow cells separated by discontinuous Percoll gradients and a T cell–depleted and progenitor-enriched cell fraction obtained by the combination of counterflow elutriation centrifugation and Percoll gradients were examined in LDA. GCT (monocytoid cell line–conditioned medium containing GM-CSF), human placenta-conditioned medium, bladder carcinoma cell line 5637–conditioned medium (containing GM- and G-CSF), and recombinant CSF (G-CSF) directly induced proliferation of progenitors with single-hit kinetics. In some instances, however, PHA-stimulated lymphocyte-conditioned medium (containing G- and GM-CSF) showed deviation from single-hit kinetics, which demonstrated the presence of factor(s) suppressive to progenitor growth. In a T cell–depleted, progenitor-enriched fraction, PHA alone was found to suppress progenitor growth at a level as low as 100 ng/mL. The addition of hydrocortisone (10^{-6} mol/L) increased the progenitor frequency but suppressed progenitor growth at 10^{-4} mol/L. LDA appears to be a valuable method for exploring mechanisms of factors regulating hematopoietic cell growth.

© 1987 by Grune & Stratton, Inc.

GRANULOCYTE-MACROPHAGE (GM) colony-stimulating factors (CSFs) are glycoproteins that regulate growth and differentiation of GM progenitors.[1] Agar and methylcellulose colony assays have been used to evaluate the effects of CSF,[2,3] to monitor purification of committed hematopoietic progenitors,[4-10] and to represent a correlate of hematopoietic restoration potential of bone marrow (BM) aspirates.

Colony assays in semisolid media have aided the understanding of hematopoiesis, but they have limitations. The different preparations of CSFs used and the criteria used to define clonal growth make colony results from various laboratories difficult to compare. Agar or methylcellulose may disrupt cellular and extracellular matrix interactions that play a role in hematopoietic proliferation and differentiation.[11,12] These assays are not linear except at relatively high cell concentrations,[13-15] and under these conditions, the number of colonies obtained may be influenced by helper or suppressor accessory cell functions. To conclude that a factor has a direct effect on progenitors, it should be demonstrated that the observed colony growth is based on single-hit kinetics (ie, the factor is affecting only one cell type and not operating via an accessory cell). In these culture systems, assessment of the effect of CSFs on progenitor growth requires purified progenitors.[16] However, human hematopoietic progenitor purification is time and labor intensive and has met with only limited success.[17]

Limiting-dilution analysis has been used to enumerate murine hematopoietic progenitors,[18,19] and recently, we have developed a quantitative assay of human BM GM progenitors by limiting-dilution assay (LDA).[20] This method was shown to detect approximately three times more total progenitors than methylcellulose colony assays. LDA offers the potential for examining mechanisms of factors regulating progenitor growth in vitro and, hence, is an ideal method for resolving several of the aforementioned problems. Using this method, we have evaluated the stimulatory activities of CSFs on progenitor growth by using low-density BM cell fractions from Percoll gradients. The effects of phytohemagglutinin (PHA) and hydrocortisone (HC) on progenitor growth were also analyzed with a T cell–depleted and progenitor-enriched fraction that was obtained by the combination of counterflow elutriation centrifugation (elutriation)[21] and Percoll gradient separation.[22] We have found that a human giant cell tumor line (GCT), human placenta–conditioned medium (HPCM), bladder carcinoma–conditioned medium (BCM), and recombinant CSF can stimulate the growth of hematopoietic progenitors independent of the effects of accessory cells. PHA suppressed CSF-stimulated progenitor growth, and HC increased the progenitor frequency at 10^{-6} mol/L. This analysis allows evaluation of various agents that affect hematopoietic cell growth in vitro.

MATERIALS AND METHODS

BM Cell Fractionation

BM aspirates were fractionated to enrich for mononuclear cells as previously described.[22] Without this enrichment, it was difficult to detect colonies because of the greater number of nonproliferating cells. Briefly, BM was aspirated from normal donors after obtaining informed consent. Cells were centrifuged at 600 g for 25 minutes, and buffy coat cells (BMBC) were collected. A stock solution of 100% Percoll was prepared by diluting Percoll (Sigma Chemical Co, St Louis) with 1/10 volume of 10× phosphate-buffered saline (PBS). The 100% solution was then diluted with Dulbecco's PBS (GIBCO, Grand Island, NY) to obtain 60% and 40% Percoll

solutions. BMBC were layered over a 8-mL gradient consisting of 4-mL layers of 60% and 40% Percoll (Sigma) in 15-mL polystyrene tubes (Becton Dickinson, Oxnard, CA). These were centrifuged for 20 minutes at 750 g. Cells in the 40/60 Percoll interphase were aspirated and washed twice with Hank's balanced salt solution supplemented with 1% fetal bovine serum (FBS). The 40/60 Percoll fraction is depleted of erythrocytes, granulocytes, platelets, and nucleated red cells and enriched in immature blasts.[22] Cells thus obtained (Fr 40/60) were used to study the effect of CSFs on progenitor growth.

LDA of Progenitors

LDA was performed as previously described.[20] Briefly, BM cells were resuspended in Dulbecco's modified Eagle's medium (DMEM) supplemented with 2.6×10^{-2} mol/L $NaHCO_3$, 1.8×10^{-2} mol/L HEPES, 3×10^{-5} mol/L hypoxanthine, 3×10^{-6} mol/L thymidine, 10^{-3} mol/L pyruvate, 5×10^{-5} mol/L 2-mercaptoethanol, 10^{-4} mol/L minimal essential medium (MEM) nonessential amino acids (GIBCO), 15% FBS, and CSF at various concentrations. For the study of CSFs, 10^{-6} mol/L HC sodium succinate (Elkins-Sinn, Inc, Cherry Hill, NJ) was added to the medium to suppress the growth of residual T cell clones. The cell suspension was mixed by pipetting and placed in 60-well microplates (Flow Laboratories, McLean, VA) at seven to nine cell densities (10 to 400 cells/10 μL/well). Each dilution consisted of one or two plates (60 to 120 wells). The plates were then incubated in a humidified atmosphere (37°C, 5% CO_2 in air), and the medium was replaced every other day. After 10 days the number of cells in the largest cluster of blasts in each well was counted by using an inverted microscope. Control wells were incubated without CSFs.

Statistical Analysis

Linear regression analysis was applied to the limiting dilution data to calculate the best slope.[23,24] The resulting straight line allowed calculation of the progenitor frequency. Confidence intervals for the slope were calculated by using a form of Student's *t* test. Conformance of the data to linearity was tested by using a chi-square analysis; a probability $P > .05$ indicated single-hit kinetics, thus demonstrating the activity of a single limiting cell type.

Morphological Evaluation

The cells were examined morphologically by using Wright's stained cytocentrifuge preparations (Shandon Products, Astmoor, England). To minimize distortions, slides were also made by unit gravity sedimentation. This was especially useful in examination of immature blasts.[25] The slides were also analyzed for nonspecific esterase, naphthol-AS-D-chloroacetate esterase, and myeloperoxidase (Sigma) by following the manufacturer's instructions.

CSFs

Five types of CSFs were evaluated at various concentrations. HPCM, prepared by the method of Burgess et al,[26] was tested at 1% to 20%. PHA-stimulated leukocyte-conditioned medium (PHA-LCM) was prepared by using the method of Iscove et al[27] with minor modifications. Normal donor peripheral mononuclear cells were cultured at 2×10^6 cells/mL in DMEM with 7.5% FBS and 7.5% human AB serum in the presence of PHA (10 μg/mL, Sigma) at 37°C, 5% CO_2 for four days. The medium was harvested, filtered, and tested at 1% to 10%, with and without 1 U/mL erythropoietin (Epo; Connaught, Toronto, Ontario, Canada). A single lot of the culture medium of GCT[28] (GIBCO) was used at 1% to 20%. Conditioned medium of human bladder carcinoma cell line 5637 (kindly provided by Dr Fogh, Memorial Sloan-Kettering Cancer Center)[29] was tested at 0.5% to 10%. The 5637 cells were cultured in RPMI 1640 supplemented with 10% FBS, and the medium was harvested every three or four days, filtered, and stored at 4°C. Recombinant CSF, provided by Dr Souza, Amgen, Inc (Thousand Oaks, CA), was tested at 10 to 500 U/mL.

Effects of PHA and HC on Progenitor Growth

PHA-M (Sigma) was diluted with supplemented DMEM. HC sodium succinate was prepared according to the manufacturer's instructions and then diluted with supplemented DMEM. The LDA was performed as earlier by using cells from elutriation and Percoll gradient centrifugation (Fr 3:40/60 cells) with the addition of PHA or HC. When testing PHA, no HC was added to the culture. Fresh PHA (0.01 to 10 μg/mL) and HC (10^{-9} to 10^{-4} mol/L) were prepared for each experiment.

RESULTS

Composition of Cells After Percoll Separation and Elutriation of BMBC

The cell recovery in Fr 40/60 from the Percoll gradient was 11.2% of the initial BMBC layer. The average cell composition in this fraction was in agreement with our previous study[22]: 18.7% unclassified blasts plus myeloblasts, 2.4% promyelocytes, 3.7% myelocytes plus metamyelocytes, 15.4% granulocytes, 9.1% erythroblasts, 13.7% monocytes or macrophages, and 39% lymphocytes.

For testing T cell–active agents for their direct effects on progenitors, T cells were eliminated by elutriation of BMBC cells before the Percoll gradient. After elutriation, the highest cell count was observed in the large cell fraction (Fr3), which contained about 60% of the input cells, most of them having the morphology of myelomonocytic cells. When this fraction was further separated by discontinuous Percoll gradient centrifugation, the 40%/60% layer (Fr: 3,40/60) contained 50% to 80% blasts and promyelocytes and was five- to ninefold enriched for progenitor activities over the BMBC layer.[21] By limiting-dilution analysis, we have shown

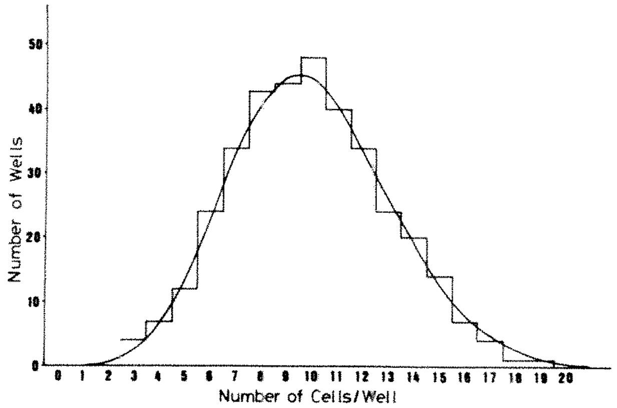

Fig 1. The actual distribution of cells in each well (bars) and the expected Poisson distribution (line) were shown. In this experiment, cells were plated at 10 cells/well in 360 wells, and three hours ater, the number of cells in each well was counted by using an inverted microscope. In a separate experiment, the actual distribution of cells at one cell/well was also tested. In both experiments, the observed distribution conformed to the Poisson distribution.

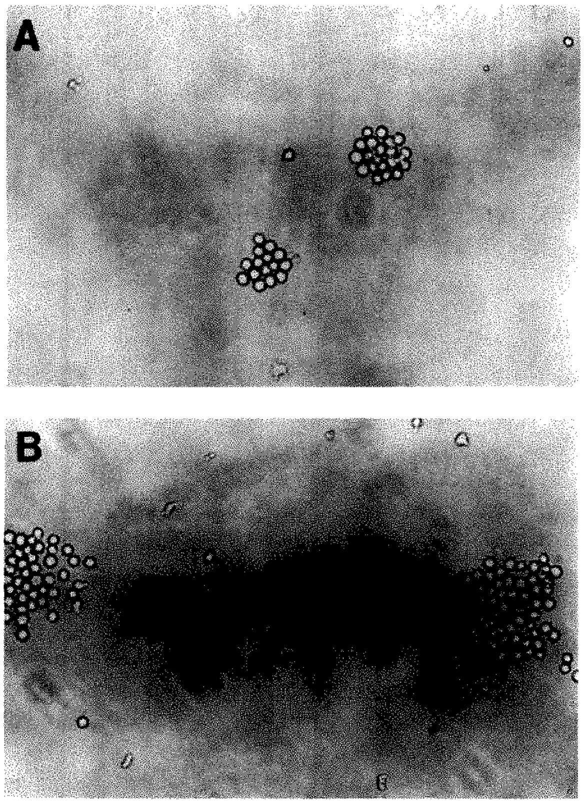

Fig 2. Examples of colonies in microwells examined by phase-contrast microscopy at day 10 of culture: (A) ≥10 cells, and (B) ≥40 cells colonies.

that this fraction contains only 1/3,000 to 1/10,000 T cells.[21]

LDA of the Growth of BM Cells

For the statistical approaches used in this analysis to be valid, it was necessary to demonstrate that the cell suspension was uniform (ie, did not contain clumps that would be scored as colonies) and could be distributed in the 10-μL wells by filling the plates (ie, the cells did not sediment into the wells from the additional volume above the wells during the plating). We verified the actual number of cells remaining in each well after distributing a known cell concentration into the microwell plates (Fig 1). In this experiment, the cells were plated at 1,000 cells/mL, and a typical Poisson distribution[30] was confirmed with a peak at ten cells per well. Cells were also plated at 100 cells/mL in 180 wells, and the cell distribution was examined in the same way; the percentage of wells that contained no cells was 36% (66/180). This is close to the result predicted by the zero term of the Poisson distribution (37% negative wells). Thus, the statistical vehicles used for the analyses were appropriate.

Clones of proliferating cells were distinguished from the nondividing cells remaining in the wells by their larger size, refractile surface by phase-contrast microscopy, and homogeneous appearance (Fig 2). Nonproliferating cells and aggregates usually disappeared by the seventh day of culture. We also investigated the optimum duration of growth for the analysis. The data obtained at day 10 showed the highest progenitor frequencies with narrowest confidence intervals in the linear regression analysis; therefore, cultures were scored on day 10. By day 14, the cells had usually degenerated, and colonies could not be scored.

Before determining the degree to which various factors influence growth of progenitors in vitro, it was necessary to establish the criteria to be used in scoring a well as positive for growth. No colonies consisting of more than eight cells were formed in wells with Fr 40/60 cells cultured without CSF or in wells with 500 purified T lymphocytes. Initially, assays were scored using multiple criteria (≥8, ≥10, ≥20, ≥30, and ≥40 cells/colony). When more than one colony was present, only the largest colony in each well was scored. When the confidence intervals were compared for each criteria, the criterion ≥10 cells was determined to be the most reliable. Calculated frequencies of progenitors cultured with 10% GCT and scored by the different criteria from eight different donors are shown in Table 1.

The estimated frequency of progenitor cells was obtained by analyzing the relationship between the number of cells plated per well and the percentage of wells found to be negative for cell growth. According to the zero term of the Poisson distribution, each well may be considered to contain an average of one precursor when 37% of a series of replicate wells are negative. In previous experiments using 10% GCT, it was shown that each criterion including ≥8, ≥10, ≥20, ≥30, and ≥40 cells/colony demonstrated single-hit kinetics,

Table 1. GM Progenitor Frequencies in LDA

	Number of Cells/Colony*

Abbreviation: ND, not determined.

*In each experiment, the same plates were scored five times by using criteria from ≥8 to ≥40 cells to define a colony. Precursor frequencies were determined as described in the test for each criterion. Data are given as the mean precursor frequencies for each criterion ± SD.

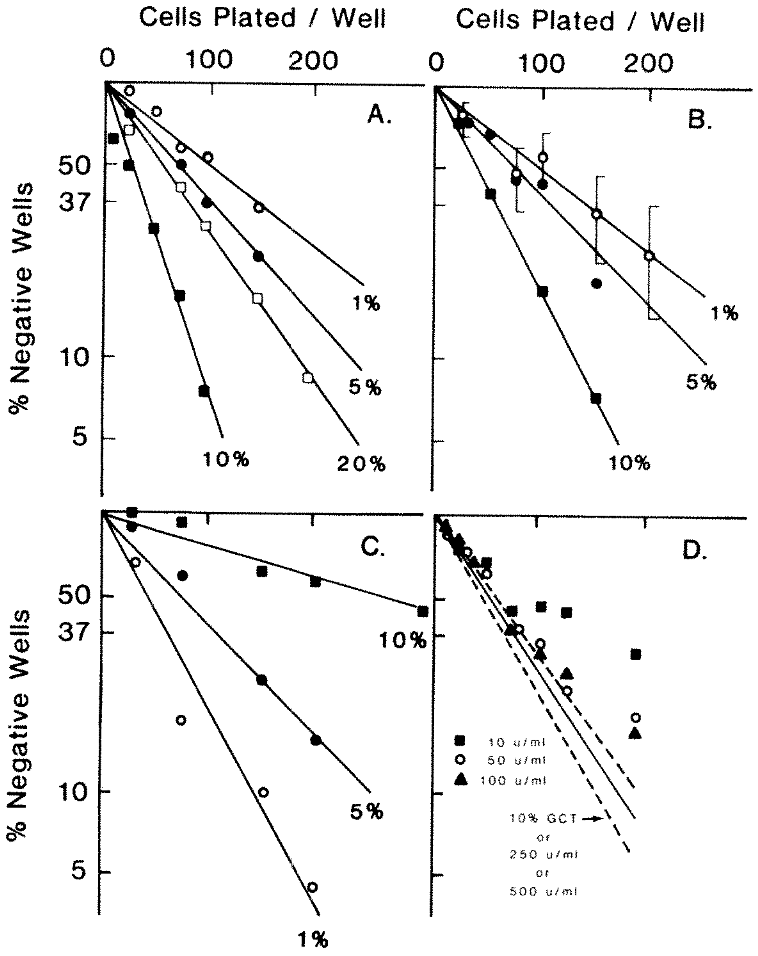

Fig 3. Representative results obtained from LDA of progenitors with CSFs. Each CSF was tested with three to four different donors. (A) GCT. A nonlinear response was observed in one of four donors at 1%. (B) HPCM. A nonlinear response was observed in one of four patients at 1%. (C) BCM. Nonlinear responses were observed in one of three donors at 0.5% and one of three patients at 10%. (D) Recombinant CSF: Approximately the same progenitor frequency was obtained with either 250 or 500 U/mL. Both of these results were within the confidence intervals for a parallel assay with 10% GCT. For clarity, only one line is shown. The progenitor frequency was slightly decreased with 50 and 100 U/mL, and single-hit kinetics were not observed with 10 U/mL in three donors.

thereby indicating that only one cell type was limiting in the culture system. Thus, no helper or suppressor accessory cell function affecting progenitor growth was observed under these conditions.

Screening of CSFs on Progenitor Growth

GCT. In the absence of a source of CSF, no colonies were observed. In most experiments, GCT supported progenitor cell growth with single-hit kinetics at various concentrations (1% to 20%); however, the highest frequency was observed with a concentration of 10%. The dose response of progenitor growth demonstrated normal biologic variation from donor to donor, but a representative experiment is demonstrated in Fig 3A. When progenitor frequency was compared with that of other CSFs, GCT usually yielded the highest frequency (Table 2). The colony-forming cells harvested from cultures containing GCT showed both myeloid (86%) and macrophage-monocyte (14%) differentiation (Table 3).

HPCM. A similar trend was observed in cultures containing HPCM. Progenitor growth with single-hit kinetics was supported by HPCM, and maximum progenitor yields were observed at 5% or 10% concentration (Fig 3B). Lower

Table 2. Progenitor Frequencies in LDA Cultured With Different CSFs

Experiment	10% GCT	10% HPCM	5% PHA-LCM	1% BCM
1	1/99	1/124	ND	ND
2	1/143	1/176	1/225	ND
3	1/39	1/167	ND	ND
4	1/59	1/57	1/118	1/99
5	1/44	1/28	1/71	1/57
6	1/132	ND	ND	1/171

In each experiment, cells from a single marrow sample were stimulated with the indicted sources of CSFs, and the progenitor frequencies were determined as described in the text by using the criterion ≥10 cells/colony.

Table 3. Effect of Different CSFs on Progenitor Maturation

	Differential Counts (%)			
Factor	Promye/Blast*	Juvenile	Polys	Macrophage/Monocyte
GCT	50	14.5	21.3	14.3
HPCM	75	9.1	11.2	4.4
PHA-LCM	53	11	8.3	28
BCM	55	8.2	20.3	16.3

BM mononuclear cells were stimulated with various sources of CSF as described in the footnote to Table 2, representative wells were harvested at day 10 and pooled, and differential morphological examinations were performed. The average results of three to four experiments are shown.

*Promye/Blasts include immature blasts, myeloblasts and promyelocytes. Juvenile myeloid cells include myelocytes and metamyelocytes. Polys are polymorphonuclear leukocytes.

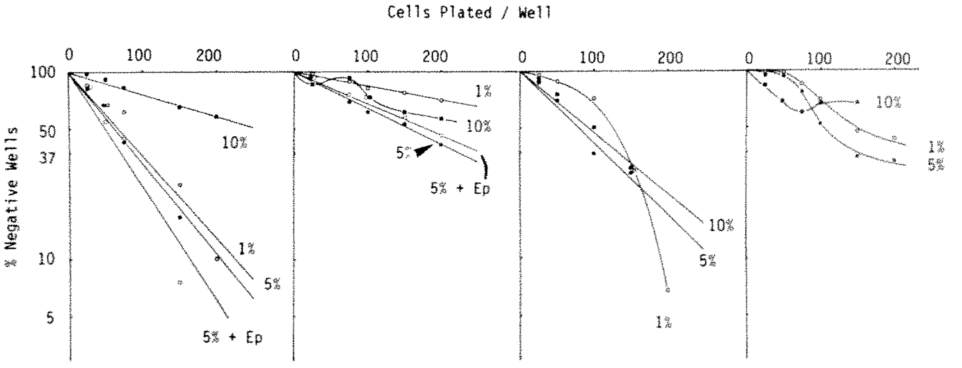

Fig 4. LDA of progenitors with PHA-LCM. Derivation from linearity were observed in several experiments.

levels appeared to be limiting, and in one donor, the response to 1% HPCM deviated from linearity.

BCM. Cell growth with single-hit kinetics was also usually observed with BCM (Fig 3C). The maximum progenitor yield was always obtained with 1% BCM. A nonlinear response was seen in one donor at the lowest concentration (0.5%) and in one donor at the highest concentration (10%). Because of the ability of a 1% concentration of BCM to yield about the same progenitor frequency obtained with other CSFs, the synergistic effect with GCT was evaluated by adding 1% BCM to 10% GCT in the culture. The progenitor yield remained almost the same as with GCT alone (data not shown).

Recombinant CSF. In three experiments, cultures containing 250 or 500 U/mL recombinant CSF yielded a linear response with approximately the same frequency of progenitors as 10% GCT. A slightly decreased frequency was obtained at 50 and 100 U/mL, and 10 U/mL failed to yield a linear response. Thus, as in experiments with GCT, HPCM, and BCM, the CSFs directly stimulated progenitor growth independent of accessory cell populations.

PHA-LCM. In some cases, PHA-LCM supported cell growth with single-hit kinetics, although the progenitor frequency was usually low compared with the frequency obtained by 10% GCT (Fig 4). No significant change in the progenitor frequency was observed after the addition of erythropoietin, nor was there any development of erythroid cultures. In some cases, however, the presence of suppressor or helper effects was evident as deviations from linearity. Thus, the results of progenitor growth with PHA-LCM were unpredictable. In wells containing PHA-LCM, aggregates of cells were often observed, which suggested the presence of residual lectin. Consequently, the effect of PHA alone was investigated.

Effect of PHA and HC on T Cell–Depleted BM Cells

PHA. As shown in Fig 5, PHA-containing medium showed suppressive action on progenitor growth at levels as low as 0.1 μg/mL, whereas at least 5 μg/mL of PHA was required to stimulate ^{3}H-thymidine uptake with lymphocytes (data not shown). In cultures containing higher concentrations of PHA, cells tended to form aggregates. These were distinguishable from myelomonocytic cells colonies by morphology.

HC. HC was found to have an enhancing effect on progenitor growth at concentrations from 10^{-7} to 10^{-6} mol/L (Fig 6). The addition of HC at this concentration increased the progenitor frequency with single-hit kinetics. A concentration of 10^{-4} mol/L always resulted in suppression, and the effect of a 10^{-5} mol/L concentration was subject to variable responses with different donors. Colonies from cultures without HC tended to be smaller and showed signs of early degeneration.

Morphological Evaluation

Evaluation of cells from wells containing colonies by cytochemistry with myeloperoxidase, AS-D-chloroacetate esterase, and nonspecific esterase staining demonstrated a myelomonocytic lineage (data not shown). Colonies from cells cultured with different CSFs were also evaluated morphologically. No significant difference of CSFs on progenitor

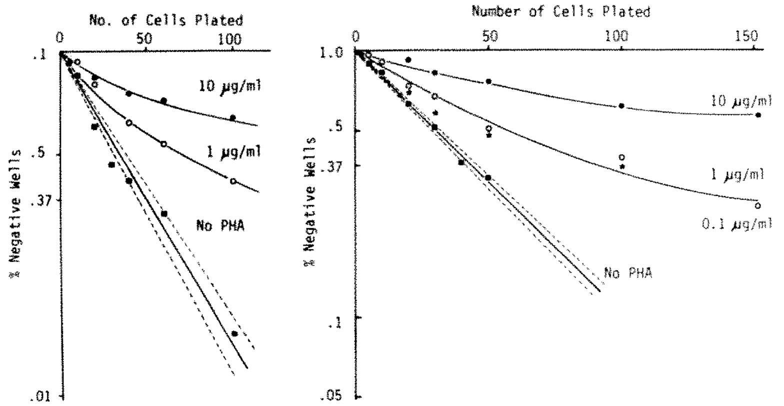

Fig 5. LDA in progenitors with PHA-M plus 10% GCT. A similar suppression was observed in two additional experiments.

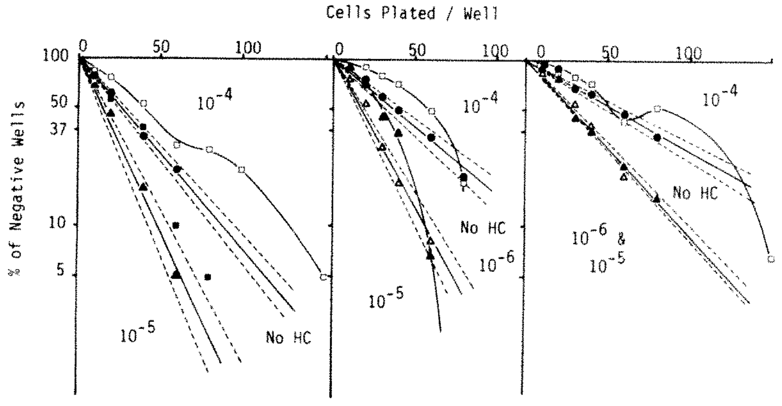

Fig 6. LDA of progenitors with HC. Lower concentrations increased precursor frequency, whereas higher concentrations showed deviations from linearity.

maturation was observed, as shown in Table 3. Erythroid maturation was not observed, even in the presence of erythropoietin.

DISCUSSION

LDA is a quantitative method to determine the frequency of progenitor cells responsive to stimulatory factors in a given population of cells. LDA has proved to be a useful measure for evaluating the factors regulating growth of immunocompetent cells.[21,31-34] To analyze responding GM precursors in a sample that contains mixed cell populations, it is important to exclude the possible effects of other cell types such as monocytes and T lymphocytes on progenitor growth. This can be accomplished because LDA can identify helper or suppressive effects. When the number of cells plated per well is plotted *v* the log of the percent nonresponding wells, linearity indicates that clonal growth of progenitors is unaffected by the cells present and only dependent on the presence or absence of a progenitor. Deviation from linearity indicates the presence of accessory cell populations that have helping or suppressing influences on progenitor growth. In the presence of suppressor cells, plating increasing numbers of cells per well results in an apparent decreasing frequency of progenitors. Hence, we adapted LDA to liquid suspension human GM progenitor cultures to establish an assay for the evaluation of factors regulating hematopoiesis.

Murine hematopoietic progenitors have been assayed in microwell cultures after isolation by fluorescence-activated cell sorting.[35,36] When using an increase in cell number as a response to CSF, accessory cell effects could not be ruled out.[36] LDA of murine BM and spleen GM progenitors without definition of the criteria for clonal growth was hampered by highly variable confidence intervals.[18]

In semisolid culture systems, various criteria have been used to define clonal growth, and the biologic implications of these criteria have not been established. In this study, we have evaluated different criteria for defining clonal growth of progenitors. Most of the criteria used in methylcellulose colony assays (eg, ≥8 cells or ≥40 cells) can also be used in our system. Among them, the criterion ≥10 cells appeared to provide the most consistent results and was used to compare the effect of factors on progenitor growth. We speculate that the larger colonies may represent more primitive progenitors with a greater proliferation potential, whereas the smaller colonies may represent more differentiated cells.

The different responses to CSFs observed in this study suggest that the LDA might measure a different set of progenitors than the semisolid colony assays. In LDA, the best progenitor yield was almost always obtained from cultures containing 10% GCT. BCM and recombinant CSF produced almost the same number of progenitors, but in some instances, PHA-LCM did not. On the contrary, the use of GCT in methylcellulose usually yielded a smaller number of colonies (CFU-GM plus BFU-E plus CFU-GEMM) compared with PHA-LCM (data not shown). For clonal culture of primitive hematopoietic precursors, PHA-LCM was considered to be essential. However, this does not seem to be true in Dexter-type long-term BM culture in which primitive progenitors can be enumerated. Fewer mixed colonies were obtained with 10% PHA-LCM than with 7.5% in semisolid culture.[6,37] Thus, our results indicate that the crude preparation of PHA-LCM cannot be used reproducibly in LDA.

In previous reports, PHA was added to soft agar or methylcellulose cultures to study the effect of activated T cells on progenitor growth. The addition of PHA was thought to promote burst colony formation.[38] In agar culture systems, the addition of PHA alone to T cell–depleted marrow cells was reported to have had no effect on GM progenitor growth at a concentration of 20 μg/mL.[39] Additionally, PHA-stimulated conditioned medium has been used to stimulate the growth of progenitor cells in semisolid and liquid suspension cultures.[40] In LDA, however, a suppressive effect of PHA on progenitor growth was observed at levels as low as 0.1 μg/mL.

HC prevents the growth and function of T cells[41-43] and increases marrow granulocyte production in long-term BM culture.[44] However, reports on the effect of glucocorticosteroids on granulopoiesis in short-term culture systems have been contradictory. Suda et al[45] reported that the addition of HC (10^{-6} mol/L) to T cell– and phagocyte-depleted BM cells increased the number of granulocyte colonies but decreased macrophage colonies in agar culture. Enhanced formation of granulocyte colonies was also observed after the addition of HC in agar[46] and in a diffusion chamber culture system.[47] Slovick et al,[48] however, reported that the addition of 10^{-6} mol/L HC did not significantly change the total number of GM-CFC in agar culture. Cheng et al[43] also noted that the growth of granulocytic colonies in agar was not affected by the presence of up to 10^{-4} mol/L HC. In this study, HC was shown for the first time to have a direct enhancing function on progenitor cell growth in short-term suspension cultures at concentrations of 10^{-7} to 10^{-6} mol/L. Cells cultured with HC also formed larger colonies and tended to be more homogeneous and round, similar to findings reported by Barr et al.[49] We found the use of HC to prevent T cell growth in our assay system to be critical because the possible concomitant growth of T cells may be mistaken for or interfere with GM progenitor growth. The precise action of HC on progenitor cell growth is still unclear; however, LDA provides an approach for further investigation.

Optimum concentrations of CSFs for progenitor growth have been previously reported[50,51] that suggest that promotion of clonal growth by conditioned media is regulated by a balance between stimulators and inhibitors. Thus, the decrease in progenitor frequencies in wells cultured with 1%, 5%, and 20% GCT may be due to a deficiency of CSF at lower concentrations and to the presence of growth-inhibitory substances at higher concentrations. In this respect, LDA has proved to be a reasonable approach for investigation of the mechanism of action of these factors.

Lymphoma Cell Line (FL-18) and Epstein-Barr Virus–Carrying Cell Line (FL-18-EB) Obtained From a Patient With Follicular Lymphoma: Monoclonal Derivation and Different Properties

By Shoichi Doi, Hitoshi Ohno, Eiji Tatsumi, Yuu Arita, Hiroshi Kamesaki, Shirou Fukuhara, Masaru Nishikori, Hiroshi Miwa, Kenkichi Kita, Masakazu Hatanaka, Tasuku Honjo, Hiroshi Fujii, and Haruto Uchino

A novel cell line, FL-18, was established from the pleural effusion of a patient with follicular small cleaved cell lymphoma. At the same time, an Epstein-Barr virus (EBV) nuclear antigen (EBNA)-postive cell line, FL-18-EB, was established from the EBV-infected culture of the same pleural effusion cells. Both cell lines had the same monoclonal surface immunoglobulin (IgGκ), and they had the same karyotype as that of the fresh pleural effusion cells in which a reciprocal translocation between the long arm of chromosomes 14 and 18 [t(14;18)(q32;q21)] was detected. Gene rearrangement analysis of immunoglobulin heavy-chain gene (J_H) and κ light-chain gene (Jκ) showed the same rearranged configurations in the two cell lines; however, some morphological and phenotypic differences were found. The FL-18-EB cells, which were morphologically similar to common EBNA-positive lymphoblastoid cell lines of normal B cell origin at the initial phase of culture, were larger than the FL-18 cells and contained multinucleated giant cells. The FL-18 cells lacked cytoplasmic immunoglobulin and were positive for common acute lymphoblastic leukemia antigen (CALLA), whereas the FL-18-EB cells had cytoplasmic immunoglobulin and were negative for CALLA. Thus, the phenotype of FL-18-EB seems to be a result of a shift by EBV infection to a more mature stage in the B cell differentiation pathway than that of FL-18. The paired availability of EBV-free and EBV-infected cell lines of a neoplastic clone is unique and valuable in considering EBV infectibility of neoplastic B cells and resultant phenotypic changes.

©1987 by Grune & Stratton, Inc.

THE TARGET CELL REPERTOIRE of Epstein-Barr virus (EBV) has been studied in terms of EBV nuclear antigen (EBNA) inducibility or the occurrence of transformation by using human neoplastic B cells from diseases such as chronic lymphocytic leukemia,[1-4] prolymphocytic leukemia, and Waldenström's macroglobulinemia.[5] Indeed, a few lymphoid cell lines were considered to carry EBV and definite chromosome aberrations indicative of neoplastic origin,[1,2,5] although some authors insisted that EBV-infected neoplastic cells were not transformed in most cases.[2,6] Further convincing evidence has not been shown regarding the derivation of the alleged EBV-carrying human neoplastic B cell lines.

There is now general agreement that endemic Burkitt's lymphoma cells harbor EBV, whereas nonendemic ones are commonly EBV-free.[7] Two groups have successfully converted EBV-free nonendemic Burkitt's lymphoma cell lines into EBV-carrying ones by EBV infection in vitro.[8,9] Klein et al concluded that EBV infection shifted a nonendemic Burkitt's lymphoma line (Ramos) into a more "activated stage."[10] Notably, however, little is known about EBV infectibility of non-Burkitt's lymphoma cells. We describe here a follicular lymphoma cell line (FL-18) and an EBV-carrying cell line (FL-18-EB) established from the same source. They have the same karyotype and the same pattern of immunoglobulin gene rearrangement; however, they are distinct in terms of morphology and phenotype, probably resulting from the EBV infection itself.

MATERIALS AND METHODS

Case report. A 68-year-old Japanese male noted cervical lymph node swelling in August 1980. Lymph node biopsy in February 1982 revealed follicular small cleaved cell lymphoma.[11] He received combined chemotherapy and achieved complete remission. A pleural effusion developed in July 1984. Cell lines were established from the culture of the pleural effusion cells collected at this time. The patient gave informed consent. He died in November 1984.

Preparation of EBV, infection in vitro, and establishment of the cell lines. Preparation of EBV and infection in vitro were performed as previously reported.[3] Briefly, the culture supernatants of B95-8 cells were centrifuged for two hours at 15,000 g. The pellet was diluted with a nonconcentrated culture supernatant. The pleural effusion cells were washed twice in phosphate-buffered saline and then were cultured in RPMI 1640 medium supplemented with 10% heat-inactivated fetal calf serum (FCS). Two weeks later, continuous cell growth was observed, and the established cell line was designated FL-18. At the same time, 10^7 pleural effusion cells were incubated with 0.4 mL of the EBV for 90 minutes at 37°C. The infected cells were washed twice and cultured in the same manner as the untreated culture. They also showed continuous growth and were found to be positive for EBNA 2 months later. This EBNA-positive cell line was designated FL-18-EB. The FL-18 cells were infected in vitro in the same way as the fresh pleural effusion cells. The presence or absence of EBNA-positive cells was tested once a week until 3 months after the infection. The same experiment was repeated three times.

Cytochemical examination, cell surface marker analysis, and EBNA. The pleural, FL-18, and FL-18-EB cells were examined with peroxidase (POX), α-naphthyl acetate esterase (NAE),[12] naphthol AS-D chloroacetate esterase (CAE),[12] and PAS.[13] Spontaneous rosette formation with sheep erythrocytes (E rosette), receptors for the Fc portion of IgG (Fcγ receptor) and receptors for complement (C3b and C3d receptor) were examined as previously described.[14-16] Surface and cytoplasmic immunoglobulin (Ig) was tested by the

direct immunofluorescence method. Reactivities with monoclonal antibodies were tested by the indirect immunofluorescence method. Monoclonal antibodies used in this study consisted of OKIa-1 for the HLA-DR antigen, B1,[17] B2,[18] J5 for common acute lymphoblastic leukemia antigen (CALLA),[19] Leu-1,[20] PCA-1,[21] EBVCS-4,[22] EBVCS-5,[22] and OKT9.[23] EBNA was tested according to the method of Reedman and Klein.[24]

Cytogenetic study. The pleural effusion cells were processed after short-term culture (24 hours) in RPMI 1640 medium supplemented with 20% FCS at 37°C. The cells were harvested after a 60-minute incubation with Colcemid and then treated with 0.075 mol/L KCl for 20 minutes before they were fixed in methanol acetic acid (3:1). Metaphases were banded by trypsin-Giemsa (G-band).[25] Chromosome analysis of the cultured FL-18 and FL-18-EB cells was done 6 months after the initiation of the culture. Metaphase preparation was performed when the cells showed exponential proliferation. Processing and banding methods were the same as those of the pleural effusion cells.

Gene rearrangement analysis of Ig heavy chain and light chain. Genomic DNA was extracted from the THP-1 (for control), FL-18, and FL-18-EB cells as previously described[26] and digested with *Bam*HI. The digested DNA was fractionated by agarose gel electrophoresis and transferred to nitrocellulose paper according to the method of Southern.[27] The 3.4-kilobase (kb) *Eco*RI-*Hin*dIII fragment of the joining region of the heavy-chain gene and the 2-kb *Sac*I-*Sac*I fragment of the joining region of the κ chain gene were used as J_H and $J\kappa$ probes. The nick-translated ^{32}P-labeled probes were hybridized to the nitrocellulose filters and visualized on autoradiograms.

RESULTS

Morphological findings. Cytocentrifuged smears of the FL-18 and FL-18-EB cells are shown in Fig 1. The pleural effusion cells were small cleaved lymphoid cells that were morphologically the same as the lymph node cells with a diagnosis of follicular lymphoma. The FL-18 cells were also small to medium in size. The FL-18-EB cells, however, were larger than the FL-18 cells and contained multinucleated giant cells. The FL-18-EB cells were indistinguishable from the cells of common lymphoblastoid cell line of normal B cell origin at the early phase of the culture because the FL-18-EB cells formed firm clumps and exhibited pseudopods.[28]

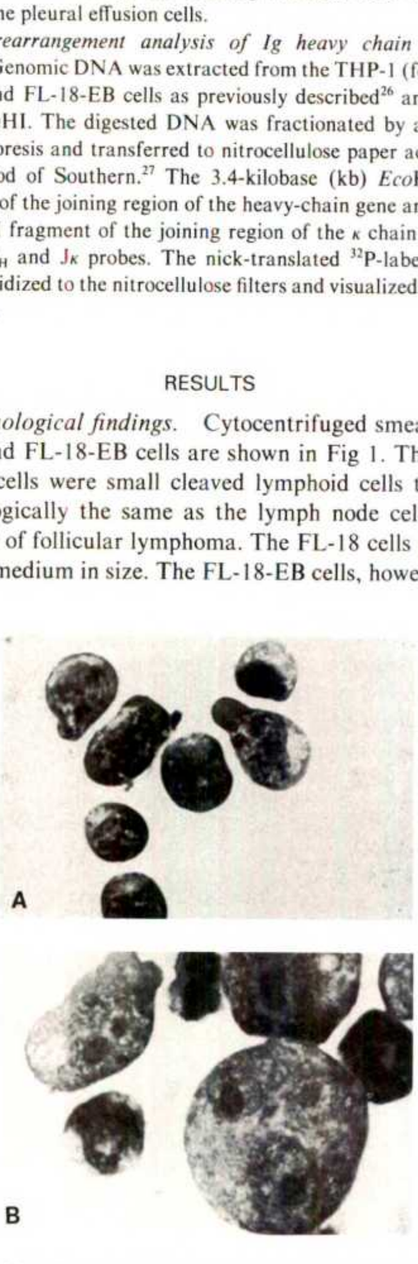

Fig 1. May-Giemsa stain of cytocentrifuged smears of (A) FL-18 and (B) FL-18-EB.

Cytochemical examination, surface marker analysis, and EBNA. Table 1 shows the results of cytochemistry and cell surface phenotype including reactivities with the monoclonal antibodies and EBNA. The pleural, FL-18, and FL-18-EB cells were all negative for POX, NAE, or CAE. The FL-18-EB cells were positive for PAS, although the pleural effusion cells and FL-18 cells were negative. The fresh pleural effusion cells were positive for HLA-DR and B1 and were negative for E rosette or Leu-1, whereas surface Ig was not detected. B2 was not tested in the pleural effusion cells. The FL-18 cells were also positive for HLA-DR and B1. Unlike the pleural effusion cells, the FL-18 cells had surface Ig (IgGκ) and were positive for CALLA. They expressed the B2 antigen only to a limited degree. The pleural effusion cells and the FL-18 cells were negative for EBNA. Virtually all of the cells of FL-18-EB were positive for EBNA. They were also positive for HLA-DR and B1 and had monoclonal surface Ig (IgGκ). They had cytoplasmic Ig and expressed the B2 antigen in a major population. They were negative for CALLA. Neither of the two cell lines was reactive with PCA-1. EBVCS-4 and -5, which have been reported to react specifically with common lymphoblastoid cell lines of B cell origin, reacted with FL-18-EB but not with FL-18.

Cytogenetic study. Table 2 shows the results of the chromosome analysis of the fresh pleural, FL-18, and FL-

Table 2. Summary of the Karyotype of the Pleural Effusion Cells, FL-18, and FL-18-EB

Pleural effusion cells	49, XY, +X, +7, +12, dir ins(13;8) (q14;q22q24), t(8;22) (q24;q13), t(14;18) (q32;21)
FL-18	49, XY, +7, +12, −17, +del(X) (p11), del(6) (p11), dir ins(13;8) (q14;q22q24), t(8;22) (q24;q13), t(14;18) (q32;q21), +der(17)t(17;?) (q23;?)
FL-18-EB	49, XY, +X, +7, +12, dir ins(13;8) (q14;q22q24), t(8;22) (q24;q13), t(14;18) (q32;q21) (Tetraploid) 94, XX, −Y, 4n±{+7, +7, +12, +12}, 2x dir ins(13;8) (q14;q22q24), 2x t(8;22) (q24;q13), 2x t(14;18) (q32;q21)

18-EB cells. The fresh lymphoma cells were hyperdiploid, and the modal chromosome number was 49 with gains of chromosomes 7, 12, and an X. They showed a reciprocal translocation between the long arms of chromosomes 14 and 18 [t(14;18)(q32;q21)]. In addition, complex chromosome rearrangements involving nos. 8, 13, and 22 were observed. FL-18 also had a 14q+ marker chromosome that was the result of a translocation between nos. 14 and 18. The modal karyotype was the same as that of the pleural effusion cells. In some cells, however, additional abnormal chromosomes such as 6p−, 17q+, and Xp− were found. The modal karyotype of FL-18-EB was the same as that of the fresh lymphoma cells. The additional abnormal chromosomes observed in FL-18 were not found in FL-18-EB. Fifty percent of the karyotypes of FL-18-EB showed a tetraploid genome. None of the FL-18-EB cells showed a normal karyotype.

Gene rearrangement analysis of Ig heavy chain and light chain. Fig 2 shows the gene rearrangement analysis of Ig heavy chain and κ chain when using *Bam*HI as a restriction endonuclease. Two clonally rearranged bands in the analysis using J_H as a probe and one rearranged band in that using $J\kappa$ were observed at the same positions in FL-18 and FL-18-EB. The pleural effusion cells were not available for this study.

In vitro infection of FL-18 with EBV. Virtually no EBNA-positive cells were induced among the treated FL-18 cells.

DISCUSSION

FL-18 is thought to be derived from the lymphoma cells in the pleural effusion of a patient with follicular small cleaved cell lymphoma because it carried the same karyotype as that of the pleural effusion cells and was negative for EBNA. Cytogenetically, FL-18 had a reciprocal translocation between the long arms of chromosomes 14 and 18 [t(14;18)(q32;q21)], which is known to be specific for follicular lymphoma.[29] The details of the karyotype of FL-18 have been reported previously.[30] FL-18 had monoclonal surface Ig globulin (IgGκ), although no surface or cytoplasmic Ig was detected in the pleural effusion cells.

We also established an EBV-carrying cell line, FL-18-EB. It is unlikely that FL-18-EB is a common lymphoblastoid cell line derived from normal B cell in the pleural effusion because FL-18-EB had the same karyotype and monoclonal Ig as FL-18. Moreover, Ig gene rearrangement analysis

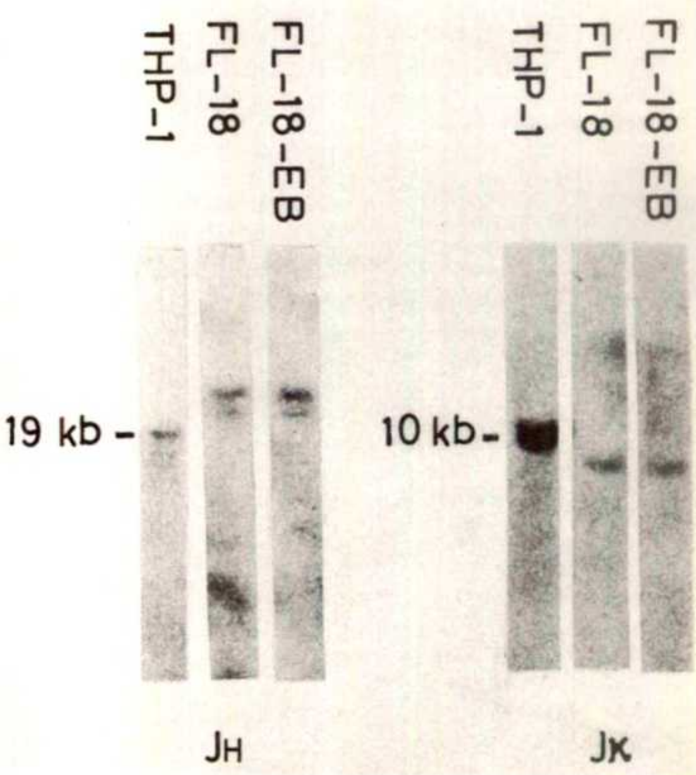

Fig 2. Southern blot analysis of DNA from THP-1 (for control), FL-18, and FL-18-EB when using J_H and $J\kappa$ as probes. The germlines of 19 kb and 10 kb are indicated respectively. Rearranged bands are demonstrated at the same positions in FL-18 and FL-18-EB.

using J_H and J_κ as probes revealed the same rearranged bands in the two cell lines, thereby indicating their clonal identify.

Several morphological and phenotypic differences were found between FL-18 and FL-18-EB. Unlike the FL-18 cells, the FL-18-EB cells were larger and contained multinucleated giant cells. At the early stage of passage, the FL-18-EB cells were morphologically indistinguishable from common lymphoblastoid cell lines of normal B cell origin. Some investigators have described similar changes accompanying EBV transformation of neoplastic B cells. Karande et al reported that EBV-transformed chronic lymphocytic leukemia cells were morphologically similar to common lymphoblastoid cell lines.[1] Fresen and zur Hausen also reported that their EBV-infected BJAB cells contained multinucleated gaint cells.[9] In addition, the expression of the EBVCS-4– or -5–determined antigen can be regarded as a feature shared by common lymphoblastoid cell lines with FL-18-EB but not with FL-18. It should be noted that the antigen is not related specifically to EBV infection of the cell lines because Raji cells do not express this antigen.

The FL-18-EB cells expressed the B2 antigen, whereas the FL-18 cells hardly did. The C3d receptor detected with B2 is thought to be a receptor molecule for EBV.[31-33] The augumentation of the C3d receptor on the FL-18-EB cells may be a result of EBV infection as has been described.[10] Alternatively, EBV may have infected the C3d receptor–positive subpopulation of the fresh lymphoma cells, thereby leading to the generation of FL-18-EB, although the extent to which the fresh cells expressed the B2 antigen is unknown. The FL-18 cells lacked cytoplasmic Ig and were positive for CALLA, whereas the FL-18-EB cells had cytoplasmic Ig and did not express CALLA. It is generally thought that, in the differentiation from B cells to plasma cells, cytoplasmic Ig appears and surface Ig fades away.[34] CALLA, which is expressed on most of the precursors of B cells such as common ALL and a part of B cells, disappears in the differentiation of B cells.[34] Therefore, FL-18-EB seems to be closer to plasma cells than FL-18 is, although the FL-18-EB cells did not react with PCA-1, which is thought to be specific for plasma cells.[21] These phenotypic differences are probably due to EBV infection itself rather than to the clonal difference of the two cell lines. To confirm the effect of EBV infection on the lymphoma cells, we tried to infect the FL-18 cells with EBV in vitro. No EBNA-positive cells were induced in any experiments. However, further studies are necessary to prove the absence of the infectibility.

The FL-18 and FL-18-EB cell lines may be of value for examining two isogenic cell lines at slightly different stages of maturation.

Identification and Characterization of a Unique Subpopulation (CALLA/CD10-Negative) of Human Neutrophils Manifesting a Heightened Chemotactic Response to Activated Complement

By Robert T. McCormack, Robert D. Nelson, Dennis E. Chenoweth, and Tucker W. LeBien

We have previously demonstrated that human neutrophils synthesize the common acute lymphoblastic leukemia antigen (CALLA/CD10). To determine whether CALLA/CD10-positive and -negative neutrophils have similar or distinct functional attributes, we sorted normal peripheral blood neutrophils for CALLA/CD10 expression and compared their chemotactic ability. Surprisingly, the low-frequency (~5%), CALLA/CD10-negative neutrophils displayed a dramatically heightened chemotactic response to activated complement (C′) that was (*a*) specific for C′, (*b*) not observed with other minor subpopulations of neutrophils, (*c*) not due to previous activation in vivo or in vitro, and (*d*) apparently not due to an increase in C5a receptors. These results underscore the concept of neutrophil heterogeneity and prompt the hypothesis that CALLA/CD10-negative neutrophils may participate in an inflammatory response to trauma involving complement activation.

©1987 by Grune & Stratton, Inc.

THE PHENOTYPIC AND FUNCTIONAL heterogeneity of peripheral blood mononuclear cells has been largely defined by using monoclonal antibodies.[1,2] Functional heterogeneity of human polymorphonucleated neutrophils was intially suggested over 60 years ago,[3] and more recent studies have documented heterogeneity of neutrophil function,[4-13] density,[14,15] and RNA/protein biosynthesis.[16] Monoclonal antibodies have also been applied in further attempts to unravel heterogeneity of neutrophil origin and function.[17-24]

The common acute lymphoblastic leukemia antigen (CALLA/CD10) is a 95-kD cell surface molecule originally characterized on ALL cells by Greaves et al.[25] CALLA/CD10 has subsequently been identified on normal and malignant cells of both hematopoietic and nonhematopoietic origin,[26-34] including neutrophils.[35,36] We have recently confirmed and extended the observations of others[35,36] by showing that neutrophils synthesize and insert CALLA/CD10 into their membranes.[37] However, blocking studies with the anti-CALLA/CD10 monoclonal antibody BA-3 failed to ascribe any role for CALLA/CD10 in neutrophil function.[37]

In the experiments reported herein, we have identified a rare subpopulation (~5%) of segmented peripheral blood neutrophils from normal donors characterized by (*a*) an absence of cell surface CALLA/CD10 and (*b*) the presence of a heightened chemotactic responsiveness to activated complement (C′). The potential biologic significance of our results is discussed.

MATERIALS AND METHODS

Monoclonal antibodies. The anti-CALLA/CD10 monoclonal antibody BA-3 is an IgG2b antibody that was produced and characterized in this laboratory.[26] AHN-1 is an IgM monoclonal antibody that recognizes a 150/105-kD complex on neutrophils[38] and was kindly provided by Dr Keith Skubitz, University of Minnesota. OkM-1, a monoclonal antibody that recognizes the C3bi receptor,[39] was purchased as a fluorescein isothiocyanate conjugate (FITC-MO-1) from Coulter Diagnostics, Hialeah, FL.

Purification of neutrophils. Peripheral blood neutrophils were purified from heparinized whole blood by using Ficoll-Hypaque centrifugation followed by hypotonic lysis of erythrocytes. Final preparations contained >95% neutrophils, with the remainder of the cells being contaminating eosinophils and basophils.

Immunofluorescence analysis and cell sorting. Neutrophils were stained with monoclonal antibodies and analyzed by indirect immunofluorescence as previously described.[37] Cell sorting of peripheral blood neutrophils was accomplished by using a fluorescence-activated cell sorter (FACS IV, Becton Dickinson, Mountain View, CA) equipped with a 5-W argon ion laser. The distribution of CALLA/CD10-positive and -negative neutrophils was determined on each donor, and the fluorescent gains were adjusted to collect positive and negative cells. At a sort rate of 3 to 4 × 10^3 cells/s, we could collect enough CALLA/CD10-negative neutrophils for functional studies in four hours. When the percentage of CALLA/CD10-negative peripheral blood neutrophils was less than 5% of the total neutrophils stained, the gains were increased to 5% of the total cells to facilitate the sorting time. CALLA/CD10-positive and -negative neutrophils were collected into 15-mL conical tubes containing phosphate-buffered saline (pH 7.2) with 2.5% fetal bovine serum and 0.02% sodium azide (PBS-F). The tubes were shaken periodically to keep the neutrophils in suspension. After sorting, the cells were washed twice in PBS-F, counted, and assayed for chemotactic function. A sample from each CALLA/CD10-positive and -negative fraction was removed and examined for cell morphology by using Wright-Giemsa staining. Four populations of cells from each donor were examined for chemotaxis: (*a*) unstained, unsorted cells that served as a control for the effects of sorting on chemotaxis; (*b*) cells stained with BA-3 and FITC–goat antimouse (GAM) but not sorted to control for the effects of antibody binding on chemotaxis; (*c*) cells stained and sorted as CALLA/CD10-positive; and (*d*) cells stained and sorted as CALLA/CD10-negative. Unstained, unsorted and stained, unsorted cells were held on ice during the sort to minimize lability.

The aforementioned procedure was also followed for sorting AHN-1–positive and –negative peripheral blood neutrophils with the following exception: only two populations of cells were prepared for each donor, unstained/unsorted cells and AHN-1–negative cells (see Results).

Unsorted, purified neutrophils were subjected to two-color flow cytometric analysis to determine the relationship between expression of CALLA/CD10 and C5a receptors. Neutrophils at 1×10^6/mL were first stained with FITC-C5a for 25 minutes at room temperature at a final C5a concentration of 5 or 50 nmol/L.[40] The cells were washed once with PBS-F and sequentially stained with BA-3 or control ascitic fluid (both 1:100), GAM-biotin (Boeringer Mannheim Biochemicals, Indianapolis) at 7.5 µg/mL, and 5 µL stock phycoerythrin-avidin (Becton Dickinson), all for 30 minutes at 4°C in a final volume of 100 µL interspersed with two washes in PBS-F. Two-color analysis was conducted with a FACS 440 analyzer (Becton Dickinson) with a 488-nm excitation wavelength from an argon laser. FITC and phycoerythrin emission wavelengths were detected by using 535-20 and 575-15 dichroic interference filters, respectively. Phycoerythrin emission detection was corrected for stray FITC emission, and the results were analyzed on a Consort 40 computer (Becton Dickinson) using a DISP2D program.

To examine the relationship between CALLA/CD10 and C3bi receptor expression, neutrophils were sorted into CALLA/CD10-positive and -negative fractions by using BA-3, GAM-biotin and phycoerythrin-avidin. Sorted cells were washed twice with PBS-F, and CALLA/CD10-positive and -negative and unsorted cells were then stained with FITC–MO-1 according to the manufacturer's instructions. The cells were then examined for green fluorescence.

Chemotaxis. Chemotaxis was performed by the agarose method of Nelson et al[41] with gelatin as a protein source. Serum collected from the same donor whose neutrophils were being assayed served as an eventual source of C′. *N*-Formyl-methionyl-leucyl-phenylalanine (F-mlp, Pierce Biochemicals, Rockford, IL) was used at a final concentration of 5×10^{-5} mg/mL.

Statistics. The two-tailed Student's test was used as a test for statistical significance.

RESULTS

Chemotaxis and random migration of CALLA/CD10-positive and CALLA/CD10-negative peripheral blood neutrophils. We[37] and others[35,36] have previously reported that ~95% of normal peripheral blood neutrophils express CALLA/CD10. To determine the relationship between CALLA/CD10 expression and neutrophil function, we sorted peripheral blood neutrophils from six normal donors into CALLA/CD10-positive and -negative populations and tested for chemotactic response to C′ and F-mlp. The results in Table 1 show that there was no significant difference in the chemotactic response to C′ between unstained/unsorted, stained/unsorted, and sorted CALLA/CD10-positive cells. The slight inhibition observed in the stained/unsorted and sorted CALLA/CD10-positive cells is consistent with other data from this laboratory indicating that BA-3 has a slight inhibitory effect on chemotaxis.[37] In striking contrast, the chemotactic response of CALLA/CD10-negative cells toward C′ (5.52 ± 0.99) was significantly greater than that of either CALLA/CD10-positive cells (3.19 ± 1.48, $P < .001$) or unstained/unsorted cells (3.68 ± 1.51, $P < .001$). Differences between CALLA/CD10-negative neutrophils and unstained/unsorted neutrophils are most meaningful because the latter population represents the true migratory capacity of neutrophils in vitro. CALLA/CD10-negative neutrophils from male and female donors were equally responsive to C′ (data not shown). The heightened chemotactic response of CALLA/CD10-negative cells was only observed for C′. There were no significant differences in the chemotactic response to F-mlp or in random migration among the cell populations tested. The similarity in chemotaxis to C′ of unstained/unsorted, stained/unsorted, and CALLA/CD10-positive cells in addition to the absence of differences in chemotaxis to F-mlp of all populations tested indicates that the cell sorting procedure was not unduly detrimental to chemotaxis.

Table 1. Chemotactic Response of CALLA/CD10-Positive and CALLA/CD10-Negative Peripheral Blood Neutrophils

Cells		Stimulus		
Stained	Sorted	C′	F-mlp	RM
–	–	3.68 ± 1.51[*]	3.93 ± 0.80	1.67 ± 0.36
+	–	3.22 ± 1.72	3.70 ± 1.92	1.62 ± 0.37
+	CALLA/CD10+	3.19 ± 1.48	3.98 ± 0.80	1.61 ± 0.38
+	CALLA/CD10−	5.52 ± 0.99	4.10 ± 0.74	1.93 ± 0.52

Neutrophils were separated into CALLA/CD10-positive or -negative fractions by using a FACS IV and tested for chemotaxis. CALLA/CD10-negative cells were assayed in duplicate or triplicate for each chemoattractant, depending upon cell yield. All other populations were assayed in triplicate.

Abbreviation: RM, random migration.

[*] Means ± SD of the chemotactic response (measured in centimeters) from six donors (three males, three females).

Figure 1 is a composite of micrographs showing CALLA/CD10-positive (Fig 1A, C) and CALLA/CD10-negative (Fig 1B, D) neutrophils migrating in response to C′ in the agarose assay. These micrographs provide direct evidence that the predominant CALLA/CD10-negative cells exhibiting a heightened chemotactic response to C′ were segmented neutrophils that were morphologically indistinguishable from CALLA/CD10-positive neutrophils. Furthermore, there were no CALLA/CD10-positive neutrophils contaminating the CALLA/CD10-negative population when checked by immunofluorescence microscopy. Contaminating CALLA/CD10-negative eosinophils and basophils constituted less than 6% of the CALLA/CD10-negative cell population and did not contribute to the leading migratory front. CALLA/CD10-positive cells were composed entirely of mature neutrophils. There were no consistent differences observed in the number of cells constituting the leading front (as shown in the micrograph) in the CALLA/CD10-positive or -negative populations.

Specificity of the heightened chemotactic response. To determine whether the heightened chemotactic response to C′ was unique to CALLA/CD10-negative neutrophils, neutrophils were sorted according to reactivity with the monoclonal antibody AHN-1. AHN-1 is a neutrophil-specific antibody recognizing an antigen that, like CALLA/CD10, is expressed on 95% of peripheral blood neutrophils. Because AHN-1 has been shown to inhibit neutrophil chemotaxis,[42] only two populations of neutrophils were tested: unstained/unsorted and AHN-1–negative. Results in Table 2 show that, unlike CALLA/CD10-negative neutrophils, AHN-

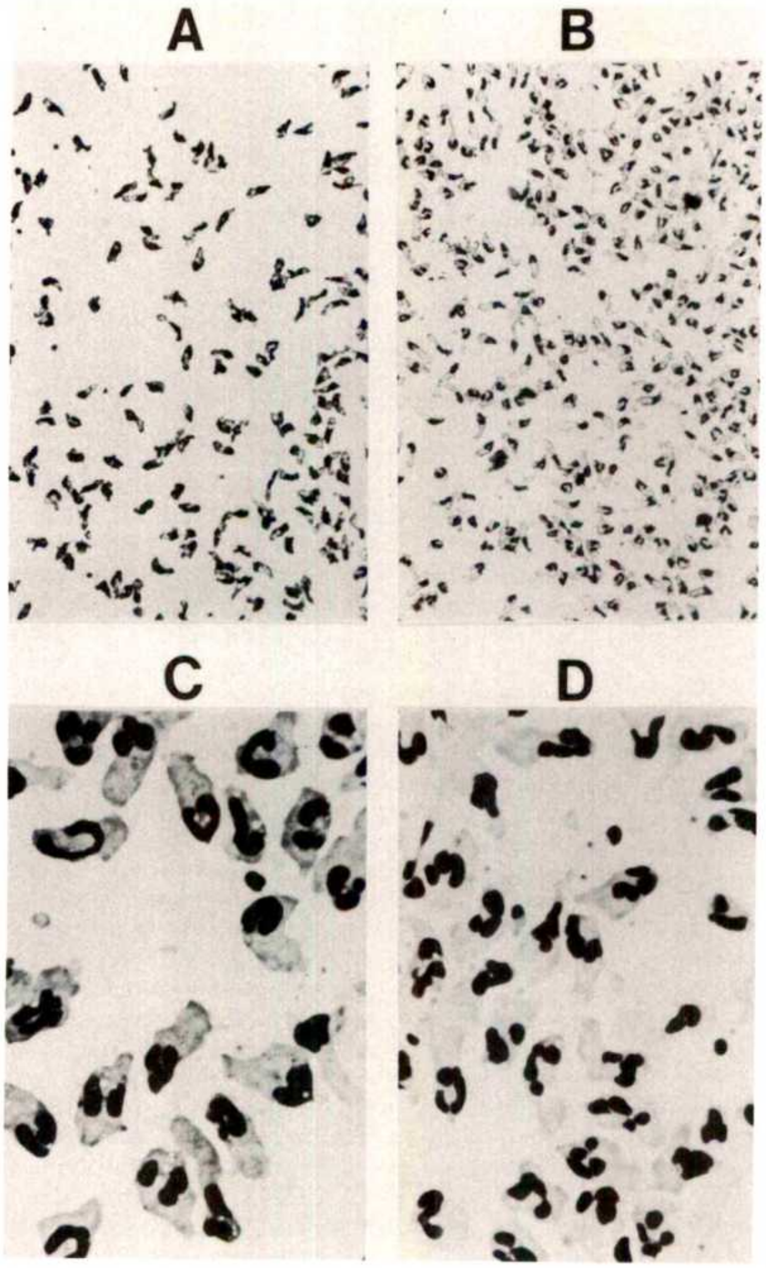

Fig 1. Light micrographs of CALLA/CD10-positive (A, C) and negative (B, D) neutrophils migrating in response to C′ in the agarose assay. (Panels A and B, original magnification × 10; panels C and D original magnification × 100 of cells at the leading migratory front; the chemoattractant is to the left in all photographs.

1–negative neutrophils did not exhibit a heightened chemotactic response to C′ (2.02 ± 0.05) when compared with unstained/unsorted neutrophils (2.72 ± 0.48). Indeed, AHN-1–negative neutrophils were less responsive to both C′ and F-mlp.

Relationship between CALLA/CD10 and C5a receptor expression on peripheral blood neutrophils. To determine whether the heightened chemotactic response to C′ was due to increased C5a receptors on CALLA/CD10-negative cells, we performed two-color flow cytometric analysis on purified neutrophils by using FITC-C5a and BA-3 plus GAM-biotin and phycoerythrin-avidin as described in Materials and Methods. Figure 2 is a representative contour plot from one of three normal donors tested by using 50 nmol/L FITC-C5a. The vast majority of neutrophils (95%) coexpressed CALLA/CD10 and C5a receptors as shown in the upper right quadrant. CALLA/CD10-negative, C5a receptor–positive and CALLA/CD10-negative, C5a receptor–negative cells each represented 2% to 3% of the total cells analyzed as shown in the lower right and lower left quadrants, respectively. It is apparent that no distinct population of CALLA/CD10-negative neutrophils express C5a receptor levels greater than CALLA/CD10-positive neutrophils, although there is some heterogeneity in C5a receptor levels in CALLA/CD10-negative neutrophils. Similar results were obtained from two other donors when using 5 and 50 nmol/L FITC-C5a. We conclude that the heightened chemotactic response of CALLA/CD10-negative neutrophils to C′ is not attributable to increased numbers of C5a receptors on CALLA/CD10-negative neutrophils.

Table 2. Chemotactic Response of AHN-1-Positive and AHN-1-Negative Peripheral Blood Neutrophils

Cells		Stimulus		
Stained	Sorted	C′	F-mlp	RM
–	–	2.72 ± 0.48*	3.43 ± 0.32	1.19 ± 0.10

Neutrophils were separated into AHN-1-positive or -negative fractions by using a FACS IV, and the AHN-1-negative cells were tested for chemotaxis.

*Means ± SD of the chemotactic response (measured in centimeters) from three donors.

Relationship between CALLA/CD10 and C3bi receptor expression on peripheral blood neutrophils. One possible explanation for the increased chemotactic response displayed by CALLA/CD10-negative neutrophils is that these cells were preactivated, either in vivo or in vitro (as a consequence of sorting). We therefore sorted neutrophils into CALLA/CD10-positive and -negative populations and examined each for C3bi receptor expression, a receptor previously shown to dramatically increase after neutrophil activation.[43] Ninety-eight percent of sorted, CALLA/CD10-positive neutrophils were C3bi receptor-positive with a mean channel of 620. Eighty-seven percent of sorted, CALLA/CD10-negative neutrophils were C3bi receptor-positive with a mean channel of 607. Unstained, unsorted neutrophils from the same donor were 89% C3bi receptor-positive with a mean channel of 619. These results confirmed data obtained from three donors when using two-color analysis to compare CALLA/CD10 and C3bi receptor expression (data not shown). Taken collectively, these results indicate that the heightened chemotactic response of CALLA/CD10-negative neutrophils to C′ is not due to significant selective activation before chemotactic analysis.

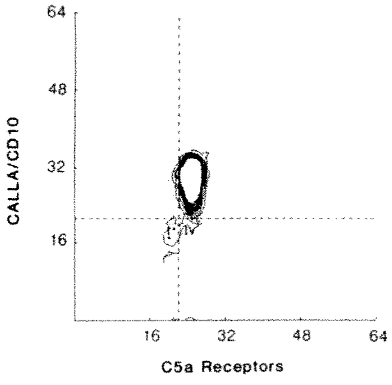

Fig 2. Two-color flow cytometric contour plot of human peripheral blood neutrophils analyzed for expression of CALLA/CD10 (y-axis) and C5a receptors (x-axis). Staining of neutrophils was conducted as described in Materials and Methods with 50 nmol/L FITC-C5a. Based on background staining the contour plot was divided into quadrants representing CALLA/CD10-positive/C5a receptor-negative neutrophils (upper left quadrant), CALLA/CD10-positive/C5a receptor-positive neutrophils (upper right quadrant), CALLA/CD10-negative/C5a receptor-negative neutrophils (lower left quadrant), and CALLA/CD10-negative/C5a receptor-positive neutrophils (lower right quadrant).

DISCUSSION

CALLA/CD10 is a 95 kD cell surface molecule originally identified on leukemic cells from patients with acute lymphoblastic leukemia[25] and subsequently shown to be expressed on human neutrophils.[35,36] We recently demonstrated that neutrophils actively synthesize CALLA/CD10 and also observed that leukemic cell and neutrophil CALLA/CD10 have similar if not identical protein backbones.[37] We[37] and others[36] have shown that myelopoietic CALLA/CD10 expression occurs at the level of the segmented neutrophil, 90% to 95% of segmented neutrophils being CALLA/CD10-positive. Because only 5% to 10% of segmented neutrophils are CALLA/CD10-negative, we hypothesized that these cells were possible precursors of CALLA/CD10-positive neutrophils and may be functionally immature. The experiments in Table 1 were initiated to test this hypothesis and showed, quite surprisingly, that the low-frequency, CALLA/CD10-negative neutrophils manifest a heightened chemotactic response to C′. Additionally, the isolation and analysis of a population of peripheral blood neutrophils that lack another cell surface antigen (AHN-1) did not result in a similar increased chemotactic response to C′ (Table 2). Collectively, these results document the existence of a low-frequency subpopulation of neutrophils manifesting an increase in chemotaxis toward C′ that is not demonstrable with other chemoattractants (eg, F-mlp) or minor neutrophil subpopulations.

Several explanations for the heterogeneous chemotactic responses of neutrophils have been suggested, including differences in ligand binding and cell age. The subject of ligand binding to individual cells and its relation to chemotaxis has been controversial. Harvath and Leonard[13] divided peripheral blood neutrophils into migrating and nonmigrating populations but showed that both populations bind F-mlp equally. Conversely, Seligmann et al[11] have shown that neutrophils bind fluoresceinated F-mlp in a heterogeneous manner, which offers a possible explanation for the heterogeneous chemotactic response of individual neutrophils to this ligand. Using two-color flow cytometric analysis we found no CALLA/CD10-negative neutrophil population with C5a receptor levels clearly above CALLA/CD10-positive neutrophils. These results agree with those of Van Epps and Chenoweth who found no identifiable neutrophil subpopulations with greatly increased numbers of C5a receptors.[40] Our results imply that the heightened chemotactic response to C′ of CALLA/CD10-negative cells is best explained by a postligand binding event, but we cannot exclude the possibility of subtle differences in receptor affinity between CALLA/CD10-positive and -negative neutrophils.

The concept of neutrophil heterogeneity has been reviewed,[44] but its biologic significance remains uncertain. It seems likely that the phenotypic/functional differences detected in this study and others[17-23] reflect differences in gene regulation and expression between subpopulations. Unfortunately, little is known concerning the regulation of C5a receptor expression and the signal transduction that follows binding of C5a. Because the difference in responsiveness is quantitative rather than qualitative, we must assume that CALLA/CD10-negative and -positive neutrophils are equally endowed with the necessary machinery (ie, receptors and second messengers) to manifest an effective response. However, preliminary evidence indicates that although distinct subpopulations are not identifiable by quantification of C5a receptors,[40] not all C5a receptors are associated with the cytoskelton (D.E. Chenoweth, unpublished observations). The relationship between cytoskeleton-associated/nonassociated C5a receptors and CALLA/CD10 expression requires further investigation.

The relationship between the heightened chemotactic response to C′ and the absence of surface CALLA/CD10 is unclear. The presence or absence of CALLA/CD10 may be fortuitous, or the acquisition of CALLA/CD10 may be functionally significant. The possible role of CALLA/CD10-negative neutrophils in an inflammatory response in vivo should be pursued.

ACKNOWLEDGMENT

The authors would like to thank Brad Anderson and Mike Hupke for conducting the flow cytometry cell sorting, Neil Kay for making the Veterans Administration Hospital flow system available, and Keith Shubitz for generous provision of AHN-1. They thank Anne Goldman for assistance with the statistical analyses and Carol El-Ghandour for typing the manuscript.

Peroxidase-Containing Microgranules in Human Neutrophils: Physical, Morphological, Cytochemical, and Secretory Properties

By R.T. Parmley, W.G. Rice, J.M. Kinkade Jr, C. Gilbert, and J.C. Barton

A microgranule fraction, isolated from human neutrophils by using a novel high-resolution Percoll density gradient system contained granules with the lowest density and diameter when compared with 12 other isopycnic granule fractions. Ultrastructurally, from 34% to 50% of the microgranules showed homogeneous diaminobenzidine (DAB) staining under conditions for localizing peroxidase reactivity. The presence of myeloperoxidase (MPO) was further confirmed by biochemical and spectral analysis and immunodiffusion methods. Periodate-thiocarbohydrazide-silver proteinate (PA-TCH-SP) intensely stained vicinal glycols in the matrix of greater than 97% microgranules in contrast to the weak or absent staining seen in larger primary granules. Directly sampled segmented neutrophils contained small DAB- and PA-TCH-SP-positive granules, which often appeared in clusters. These DAB-positive microgranules selectively remained within the cells after stimulation of exocytosis with the calcium ionophore A23187. The enriched DAB-positive microgranule fraction recovered from A23187-treated cells also contained lysozyme and β-glucuronidase but lacked vitamin B_{12} binding protein activity. A similar small, DAB- and PA-TCH-SP-positive granule type was also identified in normal promyelocytes and was the predominant or only granule type observed in leukemic or preleukemic myeloid cells from four patients. This study demonstrates a unique subpopulation of MPO-containing microgranules in normal and leukemic human myeloid cells that are distinguished from (other) primary granules by their extremely low density, small size, content of complex carbohydrates, and resistance to secretion.

PREVIOUS ULTRASTRUCTURAL[1-5] and biochemical studies[6-8] of human neutrophils have identified two major types of cytoplasmic granules, large myeloperoxidase (MPO)-containing primary granules and smaller secondary granules lacking peroxidase activity. However, a number of recent studies[9,10] indicate considerably more heterogeneity among the granules. Rice et al,[9] using a high-resolution Percoll density gradient system, isolated and characterized 13 granule fractions. Among the five higher-density MPO-containing granule fractions, a unique, large granule enriched in microbicidal defensin polypeptides was observed.[11] At least three different forms of MPO have been identified biochemically in human neutrophils.[12,13] These forms show differences in subunit structure and detergent extractability, which indicates differences in compartmentalization or association with granule membranes.[13] In addition, these different forms of MPO appear to be under separate secretory control and are differentially distributed among isolated granules of differing density.[14,15] Taken together, these results indicate the existence of several physically and functionally distinct MPO-containing neutrophil granules rather than a single MPO-containing granule previously termed a primary or azurophil granule.

A variety of apparently distinct small granule populations containing sulfated glycosaminoglycans, acid hydrolases,[16,17] gelatinase,[18] alkaline, phosphatase,[19] elastase,[20] and catalase[21] have been reported in biochemical and/or ultrastructural studies. Ackerman has previously observed small granule profiles (0.1 to 0.25 µm) in early promyelocytes[1] and clusters of small diaminobenzidine tetrahydrochloride (DAB)-reactive granules in metamyelocytes and segmented neutrophils[2]; however, little attention has been directed to these granules since their original description. Recently, these granules have been further characterized with the observation of microtrabeculae connecting the granules when observed by stereo high-voltage electron microscopy.[22] The present study reexamines the microgranule population in neutrophils and demonstrates that their DAB staining corresponds to the presence of MPO and that the granules differ dramatically from typical primary granules in size, density, carbohydrate cytochemistry, and response to secretory stimuli. The granules were identified in isolated neutrophil granule preparations as well as in intact neutrophils, leukemic myeloid cells, and ionophore-treated neutrophils. A preliminary report of this observation has been previously published.[23]

MATERIALS AND METHODS

Separation of granules. Concentrated samples of human neutrophils were obtained from healthy adults undergoing continuous-flow leukapheresis. Neutrophils were further purified to $>97\%$ purity after two cycles of hypotonic lysis of residual erythrocytes[24] and subsequent centrifugation through lymphocyte separation medium[25] to remove monocytes and lymphocytes. Purified cells were lysed, the granule-rich postnuclear supernatant (PNS) was prepared, and the high- (H) and low (L)-density Percoll gradients were performed as described previously by Rice et al.[9] The H and L gradients consisted of fused multiple-step preformed layers of different densities. These gradients were designed to maximize resolution of 13 isopycnic granule fractions that had been initially identified by using continuous, self-generated Percoll density gradients. The gradients were fractionated, and appropriate fractions were pooled and centrifuged for three hours at 100,000 g at 4°C in a Beckman SW50.1 rotor (Beckman Instruments, Inc, Palo Alto, CA). The granule pellet was collected, washed with phosphate buffered saline (PBS) and recentrifuged at 27,000 g for 15 minutes at 4°C in a Dupont/Sorvall (Willmington, DE) SM-24 rotor to obtain a purified granule pellet.

Assay of granule components. Granule pellets that were to be assayed for MPO were suspended in 0.3% cetyltrimethylammonium bromide in PBS, pH 7.4, and exposed to five cycles of freezing and thawing. The granule lysate was spectrophotometrically assayed for MPO activity by using guaiacol as the electron donor,[14] and an increase in 1 absorbance unit at 470 nm in one minute was defined as 1 unit of activity. Protein concentrations were measured according to Lowry et al.[26]

MPO protein was quantitated by spectroscopy. Difference spectra from 400 to 600 nm were measured in dithionite-reduced minus oxidized samples by using an Aminco DW-2a spectrophotometer (American Instrument Co, Silver Spring, MD). The samples were homogenized in 0.1% Triton X-100, and an absorbance coefficient of 75/mmol/L/cm was used to quantitate the characteristic MPO peak at 472 nm.[27] MPO in microgranules was also identified immunologically by using Ouchterlony double-immunodiffusion[28] plates and a monospecific rabbit antibody prepared against purified normal human neutrophil MPO as previously described.[12]

Activity of β-glucuronidase was measured as described elsewhere,[14] and vitamin B_{12} binding proteins were measured by the rapid charcoal assay described by Kane et al.[29] Amersham, Arlington Heights, IL, supplied the ^{57}Co-vitamin B_{12} (specific activity, 10 to 20 μCi/μg). Lysozyme activity was determined by using the lysoplate method of Osserman and Lawlor[30] with egg white lysozyme as a standard.

Electron microscopy. Granule pellets were overlayered with 30 to 40 μL human plasma and 30 to 40 μL 3% glutaraldehyde in 0.1 mol/L cacodylate buffer, pH 7.35. After ten minutes at 25°C the granule-containing plasma plug was minced and submersed in fresh glutaraldehyde-cacodylate buffer for an additional 50 minutes. The minced plug was then washed and stored in 0.1 mol/L cacodylate buffer containing 7% sucrose.

Normal bone marrow was obtained in a heparinized syringe after informed consent by needle aspiration from the posterior iliac crest of a healthy volunteer (n = 1) and from patients undergoing routine staging of solid tumors (n = 2) or evaluation of lymphoid leukemia in remission and not receiving chemotherapy (n = 2). Bone marrow samples were similarly obtained from five untreated patients with myeloid leukemia (French-American-British classification M2) and a patient with a pancytopenic, preleukemic myeloproliferative disorder. Peripheral blood was collected from healthy volunteers in heparinized syringes by routine venipuncture after informed consent. Marrow and blood samples were fixed in 3% glutaraldehyde and 0.1 mol/L cacodylate, pH 7.35, and then rinsed in 0.1 mol/L cacodylate and 7% sucrose, pH 7.35, as described previously.[17]

Samples for myeloperoxidase staining were incubated 30 minutes in substrate medium consisting of 5 mgm DAB · 4 HCl (pfs grade, Sigma Chemical Co, St. Louis) in 10 mL 0.05 mol/L Tris-HCl buffer, pH 7.6, with 0.01% H_2O_2 (added immediately before use) as described previously.[31] Control samples were incubated in medium lacking H_2O_2. Some samples were also processed (for inhibition of MPO activity) in a complete substrate medium containing 10 mol/L KCN after a 30-minute preincubation in buffer containing 10 mol/L KCN.

Bone marrow and blood samples processed for staining of vicinal glycol–containing complex carbohydrates were incubated en bloc in α-amylase for removal of glycogen as described previously,[32] whereas this step was omitted for isolated cytoplasmic granules.

Samples processed for routine morphology and peroxidase cytochemistry were postfixed in 0.1 mol/L cacodylate-buffered 1% OsO_4, whereas those processed for vicinal glycol staining were not postfixed. All samples were routinely dehydrated and embedded in Spurr's low-viscosity medium. Thin sections of morphological and peroxidase-stained samples were collected on copper grids. Morphological specimens were examined after counterstaining with methanolic uranyl acetate (UA) and lead citrate (LC), whereas peroxidase-stained specimens were examined with and without counterstaining. Thin sections of specimens processed for vicinal glycol staining were collected on stainless steel grids and stained with a periodate-thiocarbohydrazide-silver proteinate (PA-TCH-SP) method as described previously.[32,33] Specimens were examined in a Philips 301 electron microscope or a Zeiss EM109 electron microscope at an accelerating voltage of 60 kV.

Granule secretion. Neutrophils (approximately 2 × 10^7/mL) were suspended at 37°C in PBS with 1 mol/L Ca^{++} and 1 mol/L Mg^{++} with or without 1 or 10 μmol/L calcium ionophore A23187 for 45 minutes. Control samples were incubated without ionophore or with ionophore in PBS lacking Ca^{++}. The cells were then centrifuged into a pellet, fixed, and examined ultrastructurally as described earlier. Granule fractions were isolated and assayed for MPO, β-glucuronidase, lysozyme, and vitamin B_{12} binding proteins as described earlier.

RESULTS

Isolation and properties of microgranules. Monodispersed granules of the PNS from normal human neutrophils were separated on an L-type Percoll density gradient which resulted in eight low-density isopycnic granule fractions as described previously by Rice et al.[9] The lowest density fraction, L1, was isolated and recentrifuged on an identical L-gradient, which resulted in remigration to its original characteristic isopycnic density (mean density, 1.046 ± 0.003 g/mL; n = 25 experiments). The majority of granules in the L1 fraction appeared homogeneously electron dense in UA-LC–stained morphological preparations (Fig 1). Morphometric analysis yielded a mean granule diameter of 0.15 ± 0.04, 0.14 ± 0.05, and 0.11 ± 0.05 μm for UA-LC–, DAB-, and PA-TCH-SP–stained specimens, respectively, and indicated that the L1 granule fraction consisted of a novel class of microgranules. In each granule preparation, 100 consecutively identified granules were scored in ran-

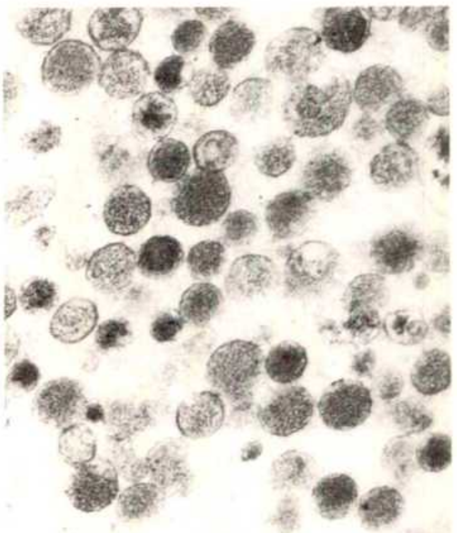

Fig 1. Ultrastructurally, the majority of granules in the L1 granule fraction appear diffusely stained with UA and LC and are variably electron dense. Bar, 1 μm.

domly selected photographs. All membrane-bound structures were scored, which would include tangential sections. Such scoring was used to prevent observer bias. Although repeat experiments did not clearly demonstrate a significant difference in diameter of PA-TCH-SP–stained preparations, the tendency for smaller size in these preparations may be related to the lack of OsO_4 postfixation before dehydration.

When the microgranules were reacted for peroxidase by using a DAB ultrastructural procedure, it was found that 34% to 50% (n = 4 experiments, 200 granules scored in each experiment) of the granules demonstrated intense staining (Fig 2A), thus indicating the existence of a DAB-reactive subclass of microgranules. The presence of DAB reactivity (30-minute incubation) at pH 7.6 rather than pH 9.7 alone indicated that the reactivity was not attributable to catalase alone, which was previously described as reacting at only the higher pH.[21] No DAB reactivity was observed in granules or neutrophils incubated 30 minutes without H_2O_2 or in the presence of 10 mmol/L KCN.

Biochemically, the microgranules of fraction L1 had a specific activity for peroxidase (units per milligram protein; electron donor, guaiacol) about five times less than that of typical, large primary granules (15.6 *v* 73.0, n = 6). This accounted for approximately 3% of the total granule-associated peroxidase activity of the neutrophil. The latency of MPO in this fraction was >95% after disruption of granules with 0.1% Triton X-100, which indicated that the peroxidase was localized within an intact, membrane-bound granule.

To identify the nature of the peroxidase activity associated with the microgranules, several characteristics of this fraction were investigated. First, the reduced minus oxidized

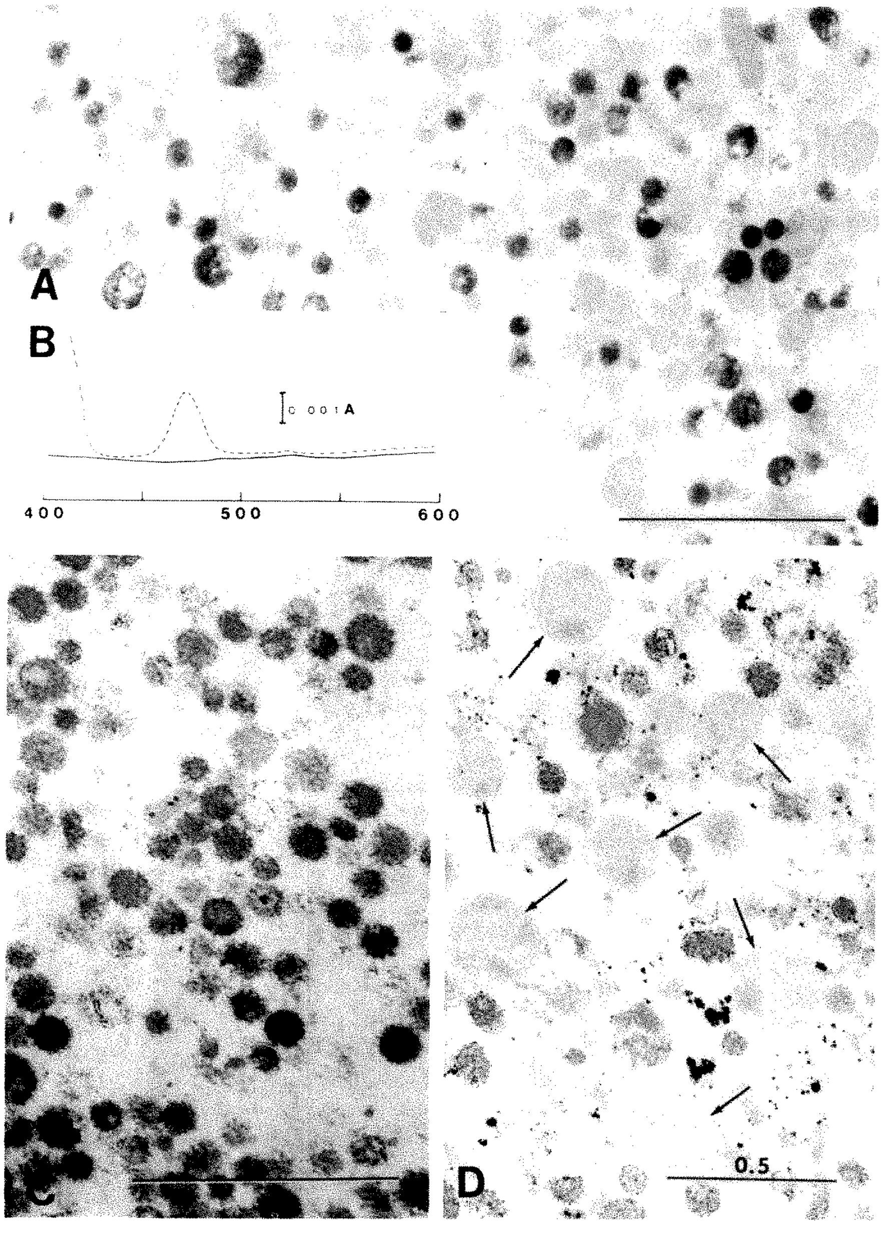

Fig 2. (A) Approximately 40% of microgranules in the L1 granule fraction demonstrate intense peroxidase reactivity after staining with DAB at pH 7.6 for 30 minutes. The thin section is not counterstained. Bar, 1 μm. (B). The reduced, minus-oxidized difference spectrum for the microgranule (L1) fraction displays a prominent absorption maximum at 472 nm, which indicates the presence of MPO. (C) PA-TCH-SP intensely stains vicinal glycol–containing complex carbohydrates in >97% of microgranules within the L1 fraction. The thin section is not counterstained. Bar, 1 μm. (D) After mixing granules from fraction L1 with granules from a typical primary granule fraction, H3, two populations of granules are seen. Microgranules demonstrate intense PA-TCH-SP staining, whereas typical primary granules are larger and essentially lack staining (arrows). The thin section is not counterstained. Bar, 0.5 μm.

difference spectrum for the microgranule fraction displayed a prominent absorption maximum at 472 nm, which indicated the presence of MPO (Fig 2B). Quantitation of the spectral data demonstrated that the microgranules contained 11 μg MPO/mg protein (range, 6 to 20; n = 3), which accounted for approximately 3% of the total granule-associated MPO on a per milligram protein basis (consistent with the enzymatic determination of MPO activity shown earlier). The absence of a trough at 430 nm due to absorption of oxidized MPO may be due to the presence of a b type cytochrome that has been reported to be colocalized with vitamin B_{12} binding protein[34]; however, because of technical difficulties in dealing with small absorbances in turbid suspensions, a definitive explanation is not possible. Interestingly, Vitamin B_{12} binding protein was concentrated in these lowest fractions,[35] and we have also confirmed the presence of the b type cytochrome in these same fractions by spectral analysis (data not shown). Second, a positive immunologic reaction for MPO was demonstrated on Ouchterlony plates when using a monospecific rabbit polyclonal anti-MPO (purified IgG fraction). Taken together, these results suggest that (*a*) the DAB reactivity seen in the ultrastructural preparations and that measured biochemically are due to the presence of MPO in the microgranule fraction and (*b*) this MPO appeared to be equivalent to that associated with typical primary granules.

Vicinal glycol–containing complex carbohydrates in the microgranule fraction stained strongly in greater than 97% of the granules when using the PA-TCH-SP procedure (Fig 2C). In marked contrast, typical, large primary granules in the denser granule fractions showed only very weak to negative PA-TCH-SP staining.[9,32] Furthermore, when isolated microgranules and larger, more dense, DAB-positive granules (fractions L1 and H3, respectively) were mixed and then stained by using the PA-TCH-SP procedure, each type of granule retained its characteristic staining pattern (Fig 2D). These results demonstrated that the peroxidase-positive microgranules were not fragments or tangential sections of the larger primary granules but belong to a newly recognized distinct subclass of MPO-containing granules that stain intensely for both peroxidase and periodate-reactive complex glycoconjugates.

Microgranules in intact normal cells. Intact neutrophil precursor cells of normal human bone marrow and mature peripheral blood neutrophils were examined ultrastructurally for the presence of microgranules. Small, intensely DAB- (Fig 3A, B) and PA-TCH-SP-reactive granules (Fig 3C) varying from 0.08 to 0.20 μm in diameter were observed

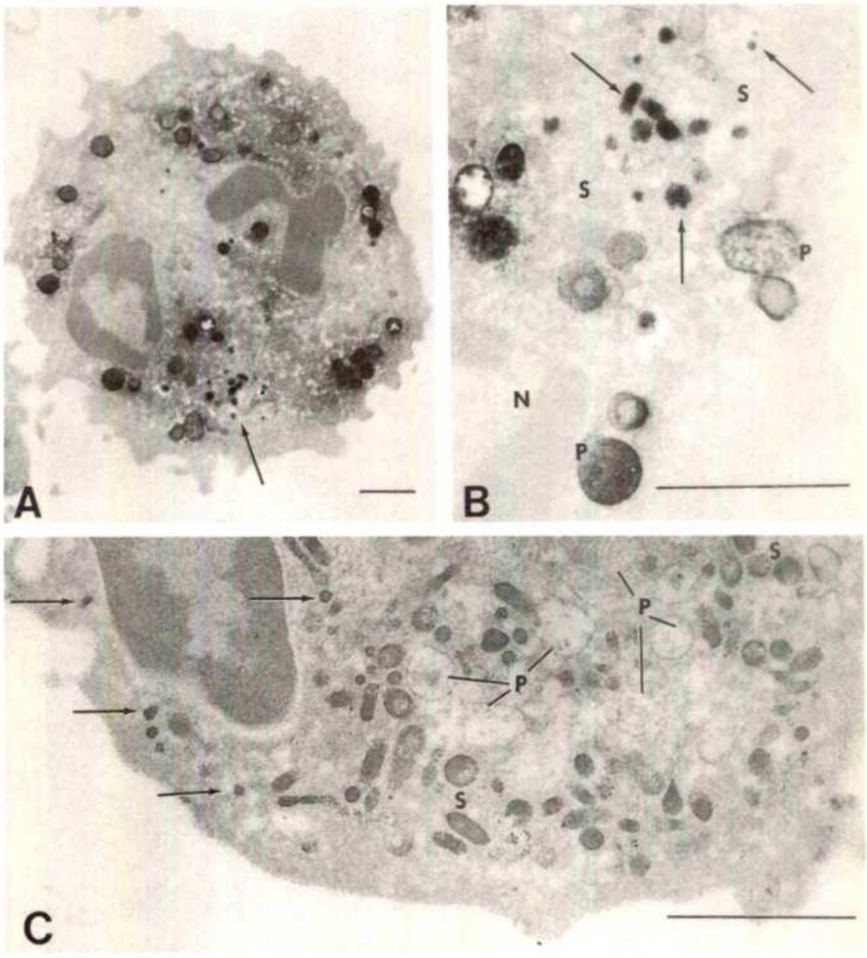

Fig 3. (A and B) Several DAB-reactive microgranules from a blood specimen are evident in a cluster (arrow, enlarged at right) in this segmented neutrophil. They are clearly smaller than larger DAB-reactive primary granules (P) and DAB-unreactive secondary granules (S); N, nuclei. The thin section is not counterstained. Bar, 1 μm. (C) PA-TCH-SP intensely stains microgranules (arrows) and secondary granules (S) of this neutrophil from a blood specimen but resulted in very weak to no staining of primary granules (P). The thin section is not counterstained. Bar, 1 μm.

at all stages of development beyond the myeloblast and appeared to correspond to the micrograules isolated from mature neutrophils. In the promyelocyte, these small granules were not readily apparent in that they were randomly dispersed and could not be easily distinguished from tangentially sectioned larger primary granules. In the myelocyte, the small granules were observed occasionally in clusters. This clustering phenomenon appeared to increase progressively with maturation. The small, DAB-reactive granules were more apparent in some profiles of fully mature neutrophils where they often appeared in clusters of three to more than ten granules. In the late (segmented) neutrophil, these clusters were observed in the central portion of the cell near the DAB-unreactive Golgi region as well as at the periphery of the cell.

Resistance of DAB-positive microgranules to secretion. Because the DAB-positive microgranules were found to be physically and chemically different from the large primary granules, the possibility they might exhibit differences in exocytosis in response to a secretory stimulus was examined. The calcium ionophore A23187 was chosen because this secretagogue has been reported to cause the differential secretion of secondary and primary granules in a dose-dependent manner (1 μmol/L and 10 μmol/L respectively).[36] Consistent with these previous reports, 1 μmol/L ionophore resulted in the loss of most DAB-negative granules and variable loss of DAB-positive granules, although DAB-positive microgranules consistently remained within the cell (Fig 4A). Again, consistent with previous reports,[37] exposure of the cells to 10 μmol/L ionophore resulted in virtually complete secretion of large (>0.20-μm-diameter) DAB-positive granules. In marked contrast the DAB-positive microgranules remained within the cells and frequently were redistributed radially to the subplasmalemmal region. These ultrastructural results were supported by Percoll density gradient centrifugation of granules prepared from 10 μmol/L ionophore-treated neutrophils in which the only visibly apparent granule fractions were the two lowest density granule fractions, L1 and L2.

Additional support for the selective retention of these MPO-containing microgranules was obtained by quantitating the distribution of MPO in isolated granule fractions from untreated and treated cells. In untreated cells, 70% of the total MPO activity was associated with the larger, high-density granules found in fractions H1 to H5, 22% with the intermediate-density fractions (L3 to L8) and 8% with the two lowest density fractions (L1 and L2). After treatment with 10 μmol/L ionophore, only fractions L1 and L2 retained significant amounts of their original MPO activity (Fig 4B); fraction L1 retained 96% ± 36% (n = 5), whereas fraction L2 retained 36% ± 10% (n = 5). In other experiments (n = 2) using neutrophils from different donors, treatment with 10 μmol/L ionophore resulted in the retention of 104% and 63% of the β-glucuronidase activity in the

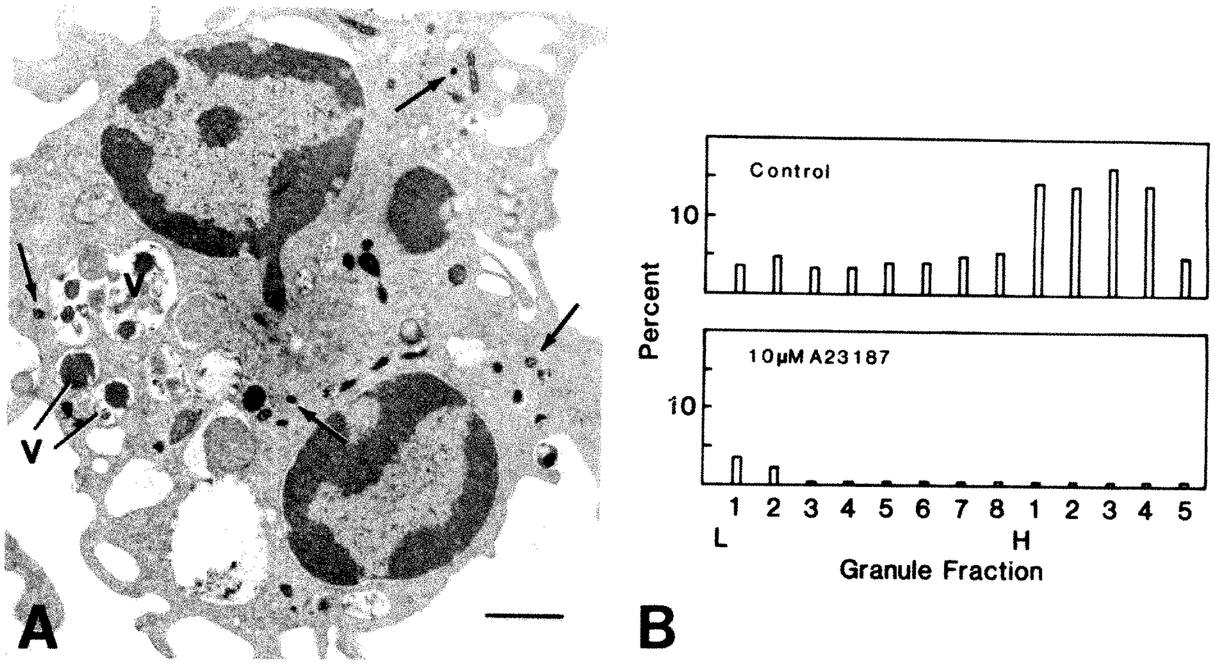

Fig 4. (A) Approximately 20% and 80% of neutrophil profiles contain predominantly DAB-reactive microgranules (arrows) after exposure to 1 and 10 μmol/L of calcium ionophore A23187 respectively (1 mmol/L sample illustrated). DAB-negative granules and large DAB-positive granules have degranulated. The granule matrices of some larger primary granules are evident in vacuoles (V) or channels into which they have degranulated. Less dense secondary granules are not evident and have presumably degranulated. The thin section is lightly counterstained with UA and LC. Bar, 1 μm. (B) Granules from untreated neutrophils (control) or from neutrophils after treatment with 10 μmol/L calcium ionophore A23187 for 45 minutes at 37°C (10 μmol/L A23187) were separated by using L and H Percoll gradients to prepare fractions L1 to L8 and H1 to H5, respectively, as previously described.[9] Granule fractions were isolated and assayed for their content of MPO. The amount of MPO activity in each fraction is expressed as a percentage of the sum of MPO activity in all fractions of control samples (ordinate). The abscissa identifies the individual granule fractions.

L1 fraction compared with control samples. Similarly, 70% and 72% of lysozyme (n = 2 experiments) was retained in the L1 fraction after 10 μmol/L A23187 compared with control values. In contrast, only 6% and 0% of vitamin B_{12} binding protein activity (n = 2 experiments) was retained in the L1 fraction after 10 μmol/L A23187 compared with simultaneous controls. The percent retention of a particular marker was based on the following control values (mean ± SD) for the L1 granule fraction derived from 2×10^8 neutrophils in both the control and ionophore-treated experiments: MPO (2.6 ± 0.6 units, n = 5), β-glucuronidase (2.0 ± 0.7 mU, n = 4), vitamin B_{12} binding proteins (28,260 ± 4,820 cpm bound, n = 3), and lysozyme (84 ng and 76 ng, n = 2). The results obtained with MPO indicated that although DAB-positive microgranules were localized primarily in fraction L1, a portion was also associated with fraction L2 (Fig 4B). Ultrastructurally, the DAB+ microgranules found in fraction L2 had identical morphometric, DAB, and PA-TCH-SP staining properties as those found in fraction L1. Granules from fraction L1 were isolated from 10 μmol/L ionophore-treated cells and were processed for ultrastructural staining using DAB. Of the remaining granules, 71% ± 8% (100 granules scored, n = 3) were DAB-positive. Mitochondria were more prominent in these preparations and were excluded from granule scoring. Thus, the DAB-positive microgranules were highly resistant to secretion relative to the larger, more typical primary granules (fractions H1 to H4), thereby demonstrating differences in secretory control between the two granule types.

Microgranules in intact leukemic myeloblasts and myelodysplastic neutrophils. Ultrastructural studies were performed on intact leukemic myeloblasts from the bone marrow of five myeloid leukemia patients (French-American-British classification M2). In three cases, the predominant granule type observed was a small, DAB- and PA-TCH-SP–reactive granule varying from 0.08 to 0.20 μm in diameter (Fig 5A, B). Auer rods, which were present in two of the patient samples, were uniformly and intensely stained with DAB and PA-TCH-SP (Fig 6). Examination of leukemic cells from two other patients with acute myelogenous leukemia (M2 classification) revealed a more heterogeneous population of DAB-positive granules; however, distinct microgranule profiles were evident.

Myelodysplastic neutrophils from a patient with a pancytopenic preleukemic syndrome (1 year prior to developing myeloid leukemia) appeared grossly abnormal in morphological preparations and completely lacked DAB-unreactive granules. Two distinct granule populations were evident in these cells, a homogeneous electron-dense and DAB-reactive large primary granule (0.25 to 0.40 μm in diameter) and a small (0.08 to 0.20 μm in diameter) electron-dense, DAB- and PA-TCH-SP–positive granule (Fig 7A, B). The small granule type outnumbered the larger primary granules and often appeared in clusters as seen in normal neutrophils. The increase in microgranules was also observed in promyelocytes and myelocytes from this patient.

DISCUSSION

The present studies identify a peroxidase-containing microgranule population in human neutrophils that is distinct from previously described primary granules. Small granule profiles have been previously identified in intact cells at the early promyelocyte stage of development.[1] Similarly, DAB-positive microgranule clusters have been observed in

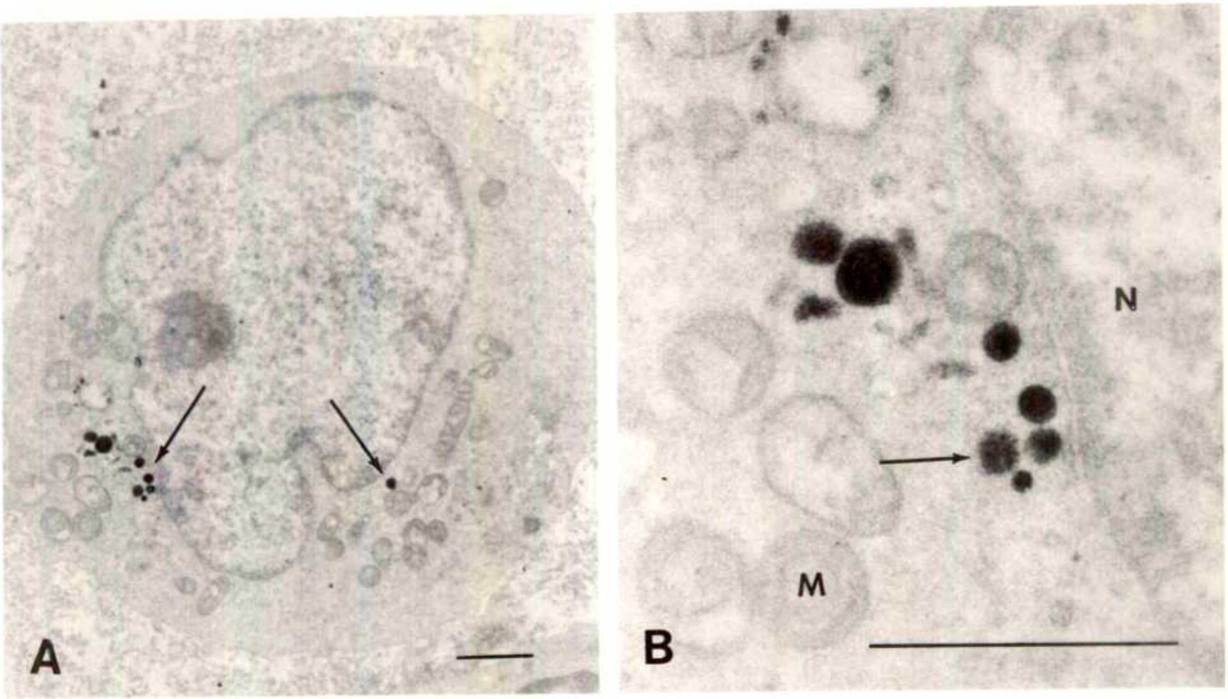

Fig 5 A, B. This leukemic myeloblast from a marrow specimen contains a cluster of small granules (arrows, enlarged in B) that stain intensely with DAB. N, nucleus; M, mitochondria. The thin section is not counterstained. Bar, 1 μm.

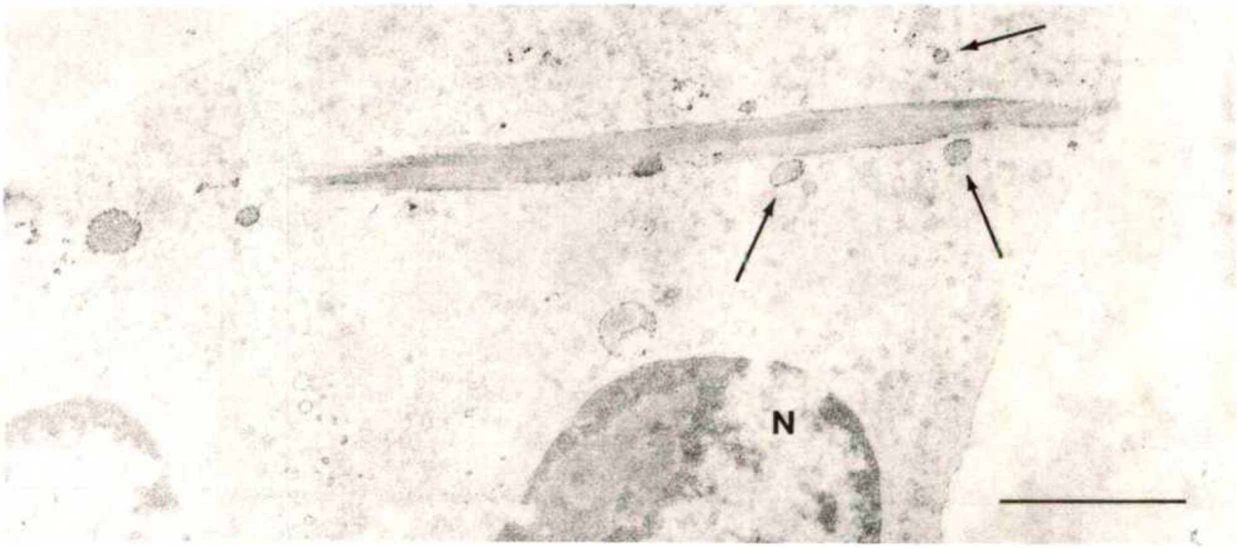

Fig 6. PA-TCH-SP intensely stains micrugranules (arrows) in this leukemic myeloblast from a marrow specimen. Many of the micrugranules are adjacent to an intensely stained Auer rod; N, nucleus. The thin section is not counterstained. Bar, 1 μm.

segmented neutrophils[2,22]; however, previous studies have not isolated the granule, defined the enzyme responsible for the DAB positivity, or examined cytochemical, physical, or secretory features of the granule. The present study establishes the existence of MPO in isolated micrugranules by using cytochemical, biochemical, and immunologic methods and provides a method for concentrating these granules from cells after ionophore-induced secretion. Biochemical analysis of the concentrated micrugranule fraction indicates that they resemble primary granules in their content of β-glucuronidase and lysozyme and lack of vitamin B_{12} binding protein activity. The DAB reactivity of micrugranules and larger

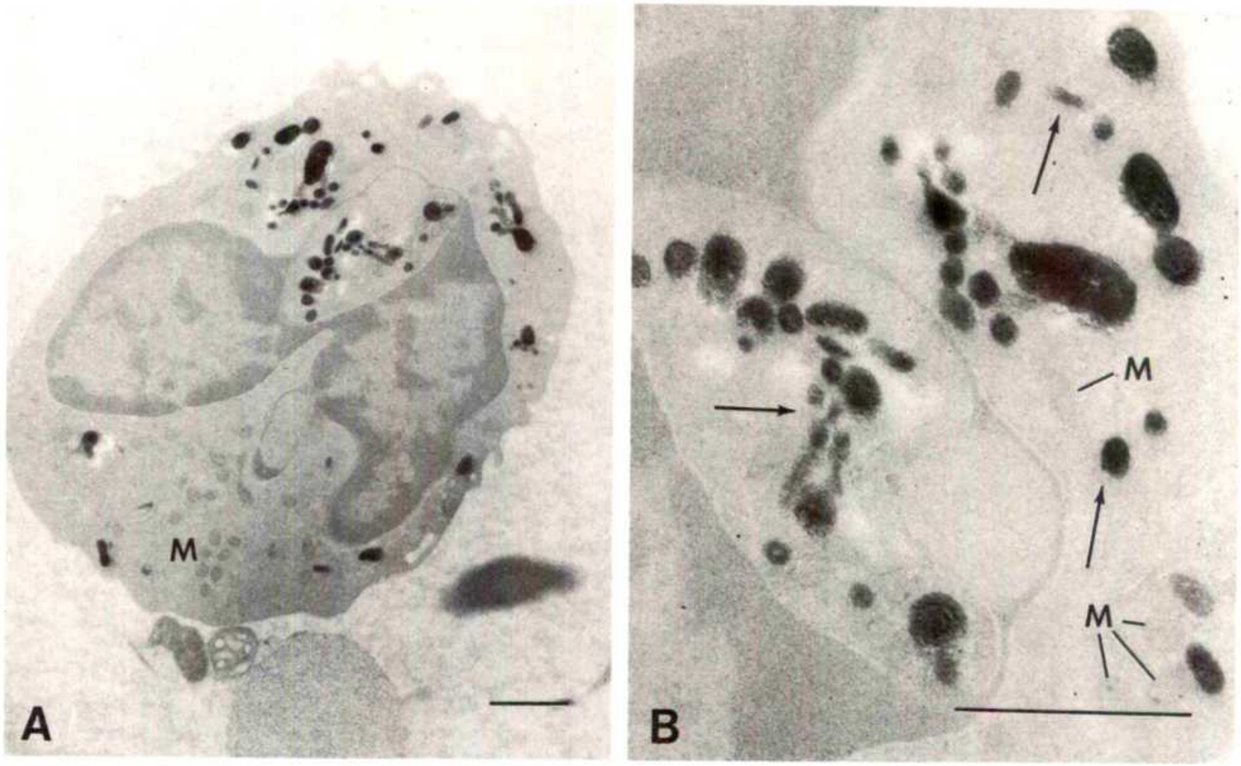

Fig 7 A, B. This segmented neutrophil from a marrow specimen of a patient with a myeloproliferative disorder contains predominantly DAB-reactive micrugranules (arrows, enlarged in B) and a few larger DAB-reactive primary granules. DAB-unreactive secondary granules are markedly decreased or absent. Numerous mitochondria (M) that lack DAB reactivity (30-minute incubation, pH 7.6) are evident. The thin section is not counterstained. Bars, 1 μm.

primary granules demonstrate that DAB reactivity and MPO content span the entire gamut of neutrophil granule size and density.

Previously described primary granules[1-5] are two to three times the size of microgranules and have considerably higher buoyant densities than do the microgranules. The intense PA-TCH-SP staining of vicinal glycols in microgranules is clearly distinct from the weak to absent staining of larger primary granules and demonstrates that microgranules also differ in content from previously described primary granules.[32] Moreover, the DAB-positive microgranules are resistant to 10 μmol/L A23187 ionophore–induced secretion, which demonstrates that these granules are under secretory control distinct from typical primary granules that were secreted under these conditions. Hence, the differences in size, density, carbohydrate content, and resistance to secretion of the DAB-positive microgranules identify them as a unique population of granules for which the terms primary or azurophil may be inappropriate, although the latter terminology has been used for all neutrophil granules with peroxidase activity.

Neutrophil granules contain several potentially DAB-reactive substances. In addition to containing at least three forms of MPO,[14,15] neutrophils also contain catalase-reactive peroxisomes,[21] which may correspond in size to the microgranules in this study. Although some of the microgranules in the lowest density fraction may, in fact, be peroxisomes, the DAB reactivity of the granules at pH 7.6, the presence of biochemically, spectrally, and immunologically demonstrable MPO in these granules, and the great abundance of these granules in some leukemic myeloblasts would appear to exclude this possibility for the DAB-reactive microgranule described in this study. Alternatively, a b-type cytochrome has been identified as a component of secondary granules and/or other small, low-density granules,[34] and cytochromes are known to be DAB-reactive.[38] The b-type cytochrome has been shown to translocate to the plasma membrane after stimulation of the cell with either a phorbol diester or the calcium ionophore A23187[34]; however, we found that stimulation of neutrophils by the ionophore did not result in secretion of the DAB-reactive microgranules. Furthermore, the abundance of similar granules in leukemic cells (presumably lacking secondary and/or cytochrome b–containing granules) also suggests that a b-type cytochrome is not responsible for the staining of microgranules in this study. Thus, the cytochemically demonstrable DAB reactivity is most consistent with the localization of MPO identified biochemically, spectrally, and immunologically in this granule fraction.

The presence of DAB-reactive microgranules in leukemic myeloblasts indicates the synthesis of at least some of these granules early in myeloid development. Conversely, the lack of DAB reactivity in Golgi lamellae and the endoplasmic reticulum beyond the myelocyte stage of development indicates that the granules are not synthesized in late neutrophils. Recent studies have suggested that microgranules are synthesized in late promyelocytes after synthesis of larger primary granules[22]; however, this hypothesis does not readily account for the previously observed synthesis of small granules (0.10 to 0.25 μm in diameter) in the earliest promyelocytes[1] and the observation in this study of abundant microgranules in some leukemic myeloblasts. Similarly, cultured myeloid leukemic HL-60 cells contain predominantly small MPO-positive granules of comparable density to the microgranules reported in this study.[9] Alternatively, the microgranules could be synthesized throughout the promyelocyte stage of development or exist as subpopulations being synthesized in early and late promyelocytes, respectively.

The microgranules were redistributed into clusters, observed both in normal and myelodysplastic neutrophils in this study. Similar clusters of DAB-reactive small granules have been observed in monocytes and have been taken to indicate functional subcompartmentalization.[39] Although clustering may represent worm-like structures in monocytes, the lack of such elongated profiles in the present study of intact neutrophils and isolated granules or in previous high-resolution electron microscopic studies of microgranules[22] indicates differences in the small DAB-reactive granules of monocytes and neutrophils. The clustering phenomenon presumably has functional significance in neutrophils and may occur in preparation for endocytosis or as a result of this process. The extreme resistance of microgranules to secretion is similar to that observed with residual bodies or secondary lysosomes[40] and may indicate prior involvement in an endocytic event. However, the lack of inclusions or ultrastructural heterogeneity within the microgranule matrix would argue against this possibility. Alternatively, the DAB-positive microgranules could represent fragmented primary granules; however, the intense PA-TCH-SP reactivity of the microgranules and the virtual lack of similar reactivity in primary granules does not support this hypothesis. The sequence of granule production has in the past correlated with resistance to granule secretion in that tertiary granules are secreted most readily,[18] followed by secondary granules[34] and primary granules. The observation of small granule profiles in the earliest promyelocytes[1] and leukemic myeloblasts in this study would suggest that these are among the first granules synthesized and the last secreted if at all.

NOTE ADDED IN PROOF

Recently, White and Krumwiede[41] have ultrastructurally demonstrated failure of peroxidase positive "vesicles" and granules to fuse with giant lysosomes in neutrophils from patients with Chédiak-Higashi Syndrome. Many of these granules were of similar size to microgranules reported in this study. We would suggest that their observation represents in vivo resistance to secretion comparable to that observed in vitro in our study.

ACKNOWLEDGMENT

We thank Drs R. Vogler, L. Winton, and the staff of the Cell Separator Department for their help in providing us with cells from patients. We also thank Drs D. Jones and C. Slife for helpful discussions during the course of this work.

The Metabolite 1α,25-Dihydroxyvitamin D_3 Enhances Lymphokine-Mediated Activation of the Oxidative Metabolism of the U937 Cell Line and Phosphorylation of a 48-kD Respiratory Burst–Associated Protein

By Rose G. Snipes, Kirk Ways, Christopher N. D'Amico, Geetha Sivam, T. Kenney Gray, and Myron S. Cohen

U937 cells respond to a variety of stimuli with increased differentiation as manifested by reduced growth, increased adherence, increased expression of several surface receptors, and increased capacity for phagocytosis and formation of reactive oxygen intermediates. In the present study the effects of lymphocyte conditioned media, recombinant interferon-γ (IFN-γ), and 1α,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) on the ability to form reactive oxygen intermediates by U937 cells were measured by using the luminol-dependent luminescence (LDL) assay. Neither $1,25(OH)_2D_3$ alone nor IFN-γ alone enhanced competence for phorbol myristate acetate–stimulated LDL. Cells were capable of moderate LDL after exposure to lymphocyte conditioned media, and this was enhanced by $1,25(OH)_2D_3$ (10^{-8} mol/L) and other vitamin D metabolites at higher concentrations. This effect was not secondary to accelerated production of myeloperoxidase, which is important in the LDL assay. Enhanced phorbol myristate acetate-stimulated phosphorylation of a 48-kd substrate was observed in ^{32}P-labeled intact cells treated with $1,25(OH)_2D_3$ alone or in combination with IFN-γ. Treatment of cells with IFN-γ or lymphocyte conditioned media did not alter phosphorylation. These results support the concept that $1,25(OH)_2D_3$ plays a role in phagocyte differentiation and activation beyond the effects of lymphokines. Protein kinase C–mediated phosphorylation reactions may be necessary for the ability of U937 cells to reduce O_2 and required for maximal activity under some conditions of incubation.

© 1987 by Grune & Stratton, Inc.

THE U937 CELL LINE is a monoblastic phagocyte precursor derived from a histiocytic lymphoma cell line.[1] U937 cells have become an important model for the study of phagocyte differentiation because they respond to a wide and surprising variety of biologic modifiers.[2]

The active metabolite of vitamin D 1α,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) has a profound effect on calcium homeostasis.[3] We and others have previously demonstrated that $1,25(OH)_2D_3$ enhances the differentiation of U937 cells as manifested by increased phagocytosis and expression of CR1 receptors.[4,5] The metabolite $1,25(OH)_2D_3$ has an additive effect with one or more lymphokines such that this combination induces adherence of the U937 cell line to plastic as well as expression of CR3 receptors.[6] Both $1,25(OH)_2D_3$ and lymphokine enhance the ability of U937 cells to reduce oxygen.[4,5,7,8] The present studies were undertaken to define the interaction of $1,25(OH)_2D_3$ and lymphokines on the differentiation of U937 cells, with emphasis on formation of reactive oxygen intermediates.

METHODS

Reagents

The metabolites $1,25(OH)_2D_3$ and 24,25-dihydroxyvitamin D_3 ($24,25(OH)_2D_3$) were a gift from Milan Uskokovic, PhD (Hoffman-LaRoche, Nutley, NJ). These metabolites were dissolved in 95% ethanol and diluted to give a final concentration of <0.1% (vol/vol) ethanol. In all experiments appropriate controls were performed to exclude an ethanol effect. The metabolite 25-hydroxyvitamin D_3 ($25(OH)D_3$) was a gift from the Upjohn Pharmaceutical Co (Kalamazoo, MI). Superoxide dismutase (SOD, Sigma Chemical Co, St Louis) was used at a final concentration of 150 U/mL. Sodium azide (Fisher Scientific Co, Fair Lawn, NJ) was used at a final concentration of 1 mmol/L. Recombinant interferon-γ (IFN-γ; Meloy Laboratories, Springfield, VA) was used to induce cell differentiation at a concentration of 1,000 U/mL. Phorbol myristate acetate (PMA, Midland Chemical Co, Brewster, NY) was diluted in Me_2SO and used at a final concentration of 100 ng/mL.

Cell Preparation and Assay

Culture conditions. U937 cells were maintained in continuous culture by passage every three days in medium consisting of Dulbecco's modified Eagle's minimal essential medium and Ham's F-12 medium (1:1; GIBCO, Grand Island, NY). The media were supplemented with 5% fetal bovine serum (GIBCO), 15 mmol/L HEPES, penicillin (100 U/mL), and streptomycin (100 μg/mL). These were considered control cells. The metabolite $1,25(OH)_2D_3$ reduced U937 cell growth[4] but did not affect viability. When experimental variables were added, the cells were resuspended at a final concentration of 10^6 cells/mL. The cells were incubated at 37°C in humidified 5% CO_2.

Lymphocyte conditioned media. These media were prepared from lymphocytes obtained from healthy human volunteer donors. Whole heparinized blood was placed on a Plasmagel (Cellular Products Inc, Buffalo) sedimentation gradient. The white cell layer was then placed over Ficoll-Hypaque as previously described.[9] The mononuclear band was washed twice at 100 g in phosphate-buffered saline. The cells were then placed in a 100 × 20-mm Petri dish (Corning Glass Works, Corning, NY) medium consisting of α-modified minimal essential medium (α-MEM, GIBCO) and the monocytes allowed to adhere for two hours. The nonadherent cells were then removed and counted by the Zaptoglobin lysis technique (Coulter Diagnostics, Hileah, FL). The cells were then suspended in α-MEM at a final concentration of 1×10^6 cells/mL in 5% pooled human serum. Phytohemagglutinin (PHA, Sigma) was added at a concentration of 5 μg/mL. The cells were incubated at 37°C in humidified 5% CO_2 for three days. The cells were then centrifuged at 250 g for ten minutes. The supernatant was collected and filtered.

Aliquots were frozen at 0°C until use. Lymphocyte conditioned media were used at concentrations of 10% to 20% (vol/vol); the lymphokine preparation was only reduced in concentration in preparations that affected cell viability. Controls included lymphocytes isolated under identical conditions with PHA added to the lymphocyte conditioned media after the three-day incubation.

Luminol-Dependent Luminescence

Measurements of chemiluminescence were made with an ATP spectrophotometer (Model 3000, SAI Technology Co, San Diego). Light intensity was monitored continuously by using a strip chart recorder (Fisher Recordall, Pittsburgh) as previously described.[10] Luminescent counts were also obtained at one-minute intervals from the digital readout of the spectrophotometer. The sensitivity was the same in all experiments (9.4). The temperature of the counting chamber was 31°C. The cell suspension was pelleted, media discarded, and cells resuspended in Hanks' balanced saline solution (HBSS) at a final concentration of 5×10^6 cells/mL. These cells remained in a 37°C water bath until use. Background counts were obtained by adding 1.0 mL of a 10^{-4} mol/L solution of luminol (Sigma) prepared in 1% bovine serum albumin to 1.0 mL of HBSS. Resting cell luminescence was obtained by adding 1.0 mL luminol to 1.0 mL of the cell suspension. Counts were obtained over a 15-minute interval. PMA (100 ng/mL) was used as a stimulus. Counts were recorded at one-minute intervals until peak luminescence was reached. Samples were examined in duplicate.

Myeloperoxidase Assay

The myeloperoxidase activity of U937 cells was determined by the *O*-dianisidine reaction as previously described.[11]

Endogenous Substrate Phosphorylation in Intact Cells

Substrate phosphorylation was determined as previously described.[12-15] After six days of exposure to the various agents, the cells were centrifuged and resuspended in Eagle's minimal essential medium with Earle's salt but without glutamine or phosphates (GIBCO) for 30 minutes. A total of 3×10^6 cells were incubated with ^{32}P, 0.25 mCi, for two hours, after which the cells were centrifuged and the supernatant was removed. After resuspension in fresh medium, the cells were exposed to vehicle (Me_2SO, 0.01%) or PMA (100 ng/mL) for ten minutes. The reaction was terminated by adding a one-third volume of a solution containing 9% (wt/vol) sodium dodecyl sulfate, 15% (wt/vol) glycerol, 30 mmol/L Tris-HCl, pH 7.8, 0.05% (wt/vol) bromophenol blue, and 6% vol/vol) mercaptoethanol. The mixture was heated to 110°C for three minutes. The samples were subjected to one-day polyacrylamide gel electrophoresis (PAGE) as described by Laemmeli.[15] The stacking and running gels were 3% and 10% acrylamide, respectively. After staining and destaining, the gels were treated with 1 mol/L potassium hydroxide for one hour at 56°C. This procedure allowed optimal visualization of PMA-dependent substrate phosphorylations. After treatment for one hour in the destaining solution, the gels were dried, and autoradiography was performed. Concurrent electrophoresis of molecular weight (mol wt) standards allowed assignments of approximate mol wts to the phosphorylated substrates. Incorporation of ^{32}P into endogenous substrates was quantitated by densitometric analysis of the autoradiogram. The autoradiograms were scanned at 600 nm with a Gilford spectrophotometer (Gilford Instrument Laboratories, Oberlin, OH).

RESULTS

Effects of $1,25(OH)_2D_3$ and Lymphocyte Conditioned Media on the O_2 Metabolism of U937 Cells

U937 cells were exposed to a variety of agents believed to be of importance in their differentiation. These included lymphokine conditioned media (harvested from cells stimulated with PHA), monoclonal IFN-γ, and $1,25(OH)_2D_3$ and other vitamin D metabolites.

Table 1 demonstrates the effects on cells examined five days after incubation with lymphocyte conditioned media alone, $1,25(OH)_2D_3$ alone, and $1,25(OH)_2D_3$ plus lymphocyte conditioned media. Cells exposed to lymphocyte conditioned media alone demonstrated an increase in luminol-dependent luminescence (LDL) in response to PMA. Cells incubated with lymphocyte conditioned media plus $1,25(OH)_2D_3$ showed a dramatic increase in LDL, whereas $1,25(OH)_2D_3$ alone did not promote LDL.

Table 1. Peak LDL (cpm × 10^3)

Conditions	Mean	SD	Increase Over Control (fold)	Number of Experiments
Background	2	.50		14
Control	2	.50		14
CM	8.5	.50	4.2	14
CM + $1,25(OH_2D_3$ (10^{-8} mol/L)	82	15.0	41	14
INF-γ, 1,000 U/mL	2	.50	0	14

CM + $24,25(OH)_2D_3$ (10^{-6} mol/L)	25	.50	12.5	3
CM + $25(OH)_2D_3$ (10^{-6} mol/L)	27	.50	13.5	3
$1,25(OH)_2D_3$	2	.50	0	14
$24,25(OH)_2D_3$	2	.50	0	3
$25(OH)D_3$	2	.50	0	3
CM + $1,25(OH)_2D_3$ + SOD	2	.20	0	10
CM + $1,25(OH)_2D_3$ + azide	18	.45	9	3

The effects of incubation of U937 cells on competence for LDL stimulated by PMA (100 ng/mL). The cells were in culture for five days before the experiments were conducted. Background refers to emission of light by media. The control for these experiments was conditioned media harvested from lymphocytes not exposed to PHA. SOD was used at a concentration of 300 U/mL. One-millimolar azide was used.

Abbreviation: CM, lymphocyte conditioned media, 20% vol/vol.

Effects of IFN-γ and $1,25(OH)_2D_3$ on O_2 Metabolism of U937 Cells

IFN-γ is a lymphokine believed critical to the differentiation and activation of monocytic phagocytes.[16] The effects of IFN-γ were compared with lymphocyte condition media, as shown in Table 1. LDL was not observed among cells treated with INF-γ alone. Treatment of cells with INF-γ plus $1,25(OH)_2D_3$ for five days enhanced competence for LDL but of less magnitude than cells treated with lymphocyte conditioned media and $1,25(OH)_2D_3$ (Table 1).

To determine whether IFN-γ resulted in the same degree of U937 cell differentiation after varied periods of incubation, the same comparisons were made among cells incubated for zero to seven days (Fig 1). At each time point the effects observed with lymphocyte conditioned media plus $1,25(OH)_2D_3$ were equivalent to or greater than the combination of $1,25(OH)_2D_3$ and IFN-γ.

Effect of Other Vitamin D Metabolites on the O_2 Metabolism of U937 Cells

The vitamin D metabolite most important for calcium homeostasis is $1,25(OH)_2D_3$.[3] Receptors for $1,25(OH)_2D_3$ have been demonstrated in human monocytes.[17] The metabolites $24,25(OH)_2D_3$ and $25(OH)D_3$ generally have lower affinity for such receptors than the active metabolite $1,25(OH)_2D_3$.[3] The effects of $1,25(OH)_2D_3$ were compared with other metabolites of vitamin D (Table 1). Neither $24,25(OH)D_3$ nor $25(OH)_2D_3$ promoted maximal competence for LDL, even when concentrations as high as 10^{-6} mol/L were used.

Effect of Adherence of U937 Cells on LDL

Lymphokine plus $1,25(OH)_2D_3$ increases U937 cell adherence from 3% to 57%.[6] To determine the role of adherence in LDL, adherent cells were removed with a rubber policeman, and PMA-stimulated LDL was measured relative to an equivalent number of cells in suspension. As shown in Table 2, LDL was greater among adherent cells than cells in suspension, which suggests that competence for LDL is a parameter of differentiation correlated with adherence.

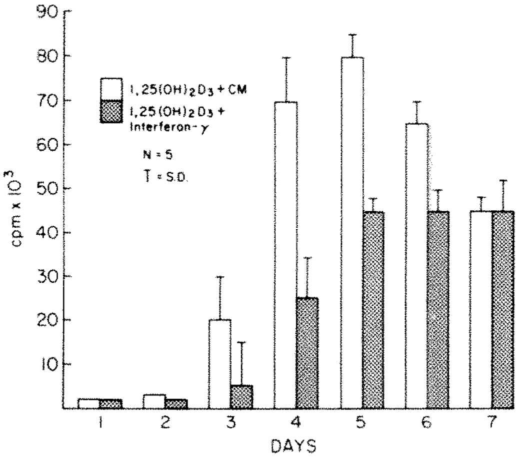

Fig 1. Comparison of $1,25(OH)_2D_3$ plus lymphocyte conditioned media or IFN-γ over seven days. Bars represent the mean and brackets the SEM of three to four separate experiments. The cells were stimulated with 100 ng/mL PMA.

Mechanism(s) of Oxygen Reduction by U937 Cells

LDL results from the interaction of luminol with several reactive oxygen intermediates.[18-21] As shown in Table 1, all light emission was eliminated by the addition of SOD to PMA-stimulated cells, thus indicating that superoxide was a critical species for this reaction. Light emission was inhibited to a lesser extent by sodium azide, which implied that a proportion of light could be attributed to the formation of hypochlorous acid, as has been reported for human neutrophils.[20] All U937 cells examined after differentiation expressed myeloperoxidase in equivalent concentrations (data not shown). These results suggest that differences in LDL related directly to the ability to form superoxide anion.

Phosphorylation of Endogenous U937 Substrates

Several recent studies have focused on protein kinase C activation and substrate phosphorylation during PMA-stimulated formation of reactive oxygen intermediates.[22-26] Specifically, PMA-stimulated phosphorylation of a substrate with an approximate mol wt of 43 to 48 kD has been associated with superoxide formation,[22,25,26] which suggests that these events are important in signal transduction. We examined the effects of $1,25(OH)_2D_3$ on phosphorylation reactions in intact cells stimulated with PMA. U937 cells incubated with 10^{-8} mol/L $1,25(OH)_2D_3$ for six days were labeled with ^{32}P and treated with PMA under conditions identical to those used to measure competence for LDL (Fig 2); longer exposure to PMA did not change these results (data not shown). When compared with control cells, $1,25(OH)_2D_3$ exposure increased PMA-dependent phosphorylation of 68- and 48-kD substrates (Fig 2). PMA-dependent phosphorylation of a 17-kD substrate was not altered by $1,25(OH)_2D_3$ pretreatment. Exposure to $1,25(OH)_2D_3$ also enhanced the non–PMA-dependent phosphorylation of a 74-kD substrate. We also examined phosphorylation in cells treated with IFN-γ, lymphocyte conditioned media, or $1,25(OH)_2D_3$ in the presence and absence of

Table 2. Peak LDL (cpm × 10^3)

Experiment	Adherent Cells	Nonadherent Cells	Percentage of Control
1	104	54	52
2	124	60	48
3	84	64	76
4	75	50	66
Mean	93	57	60.5

Cells were cultured for five days in the presence of (20%) lymphocyte conditioned media and $1,25(OH)_2D_3$ (10^{-8} mol/L), after which time nonadherent cells were prepared by gentle removal with a rubber policemen, adjusted for viability, and compared with adherent cells stimulated with PMA (100 ng/mL). Results from four separate experiments are given, and LDL of nonadherent cells is presented as a percentage of adherent cells.

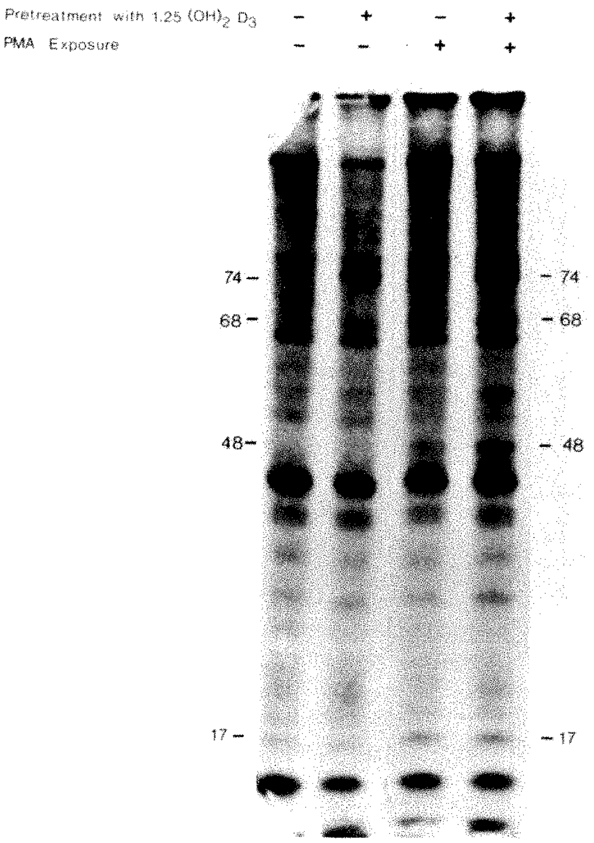

Fig 2. The effect of 1,25(OH)$_2$D$_3$ treatment on PMA-stimulated phosphorylation in ^{32}P-labeled U937 cells. After a six-day incubation with 10^{-8} mol/L 1,25(OH)$_2$D$_3$ or vehicle, the cells were labeled with ^{32}P for two hours. The ^{32}P-labeled cells were exposed to 100 ng/mL PMA for ten minutes. PMA-stimulated phosphorylation was analyzed as described in Methods. Identical results were obtained when a saturating dose of PMA was used. These data are representative of three separate experiments.

Table 3. Effects of Differentiation on 48-kD Substrate Phosphorylation of Intact Cells

Pretreatment Conditions	PMA Exposure	Substrate (48 kD) Phosphorylation (Arbitiary Units)
Vehicle (control)	−	0.53 ± 0.01 (100)*
Vehicle	+	0.68 ± 0.03 (128)
1,25(OH)$_2$D$_3$, 10^{-8} mol/L	+	0.81 ± 0.01 (154)
INF-γ, 1,000 U/mL	+	0.68 ± 0.04 (128)
1,25(OH)$_2$D$_3$ + IFN-γ	+	0.88 ± 0.14 (166)
CM, 10%	+	0.59 ± 0.13 (111)
1,25(OH)$_2$D$_3$ + CM†	+	0.89 ± 0.09 (168)

A total of 0.3×10^6 cells/mL were treated for six days under the conditions listed above. After the treatment period the cells were labeled with ^{32}P and exposed to vehicle or PMA (100 ng/mL) for ten minutes. The samples were subjected to PAGE followed by autoradiography as described in Methods. The 48-kD substrate phosphorylation was quantitated by densitometric analysis. These data represent the mean and SEM of three separate experiments.

*Percentages of 48-kD substrate phosphorylation in vehicle-treated cells not exposed to PMA are in parentheses.

†These results reflect the mean 48-kD phosphorylation of adherent and suspended cells examined on four separate occasions.

IFN-γ (Table 3, Fig 3). PMA-stimulated, 48-kD substrate phosphorylation was detected under all conditions of incubation; cells exposed to lymphocyte conditioned media or IFN-γ were not significantly different from cells treated with vehicle. In cells treated with 1,25(OH)$_2$D$_3$ alone or in combination with IFN-γ, PMA-stimulated, 48-kD substrate phosphorylation was increased relative to the other conditions examined. Concomitant exposure of cells to 1,25(OH)$_2$D$_3$ and lymphocyte conditioned media did not enhance 48-kD phosphorylation beyond that observed with 1,25(OH)$_2$D$_3$ alone (Table 3). Furthermore, no difference in 48-kD phosphorylation was detected when adherent and suspended cells (exposed to the combination of 1,25(OH)$_2$D$_3$ and lymphocyte conditioned media) were compared as described in Table 2 (data not shown). The background (PMA-independent substrate phosphorylation) was similar in all conditions examined.

DISCUSSION

The U937 cell line has provided a unique model for study of the differentiation and activation of phagocytic cells. By using this cell line it has been possible to demonstrate cell differentiation in response to a wide variety of substances.[2] The active metabolite of vitamin D is 1,25(OH)$_2$D$_3$.[3] Receptors for 1,25(OH)$_2$D$_3$ have been demonstrated in monocytic phagocytes.[17] We have previously shown that 1,25(OH)$_2$D$_3$ enhances differentiation of U937 cells as demonstrated by expression of complement receptors.[4] These effects are most dramatic when 1,25(OH)$_2$D$_3$ is combined with lymphokines.[6]

Differentiation of U937 cells also has been associated with the development of the ability of these cells to reduce oxygen, a function important if not critical for microbicidal and tumorcidal activity of mononuclear phagocytes.[27] U937 cell differentiation is associated with competence for nitroblue tetrazolium dye reduction,[5] formation of hydrogen peroxide,[7,8] and expression of LDL.[28]

The present studies were undertaken to extend our earlier observations[4,6] regarding the interaction of lymphokines and 1,25(OH)$_2$D$_3$. Consistent with these results, we observed maximal competence for LDL among cells exposed to lymphocyte conditioned media plus 1,25(OH)$_2$D$_3$. Vitamin D derivatives with less affinity for 1,25(OH)$_2$D$_3$ receptors[3] were not equivalent to 1,25(OH)$_2$D$_3$. Lymphocyte conditioned media alone acted only as a weak stimulus, and IFN-γ alone or 1,25(OH)$_2$D$_3$ alone had no effect in this system.

These results differ somewhat from reports in which U937 cells' ability to reduce O_2 could be demonstrated after their differentiation with either IFN-γ or 1,25(OH)$_2$D$_3$ alone.[5,8,28-30] However, in these studies different systems for detecting O_2 reduction were used. Also, clones of U937 cells

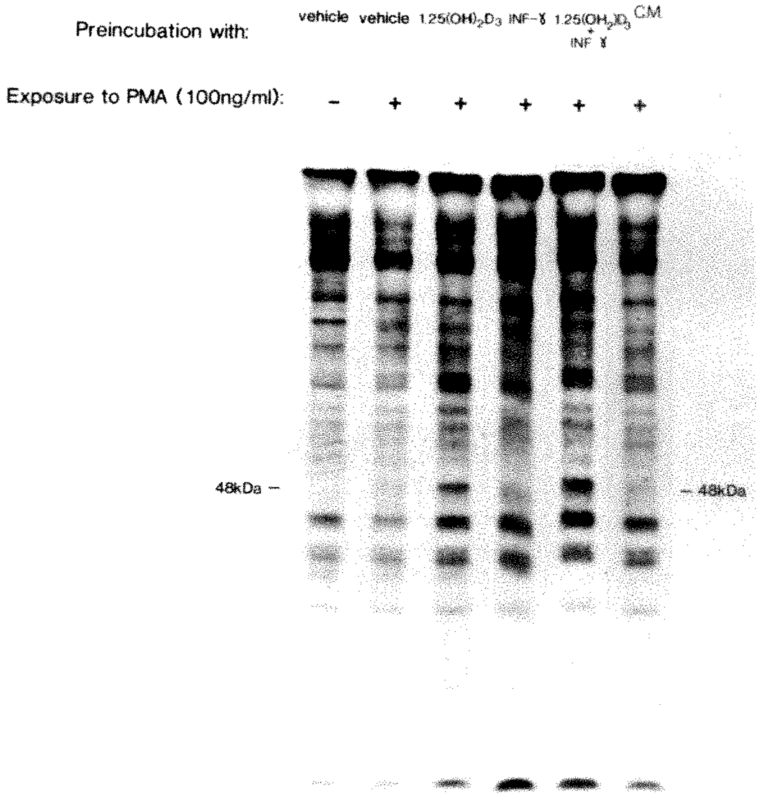

Fig 3. PMA-stimulated phosphorylation in ^{32}P-labeled intact U937 cells. After a six-day exposure to 1,25(OH)$_2$D$_3$ alone or in combination with IFN-γ, IFN-γ, or lymphocyte conditioned media (see Table 3 for specific concentrations), the cells were labeled with ^{32}P for two hours. The labeled cells were exposed to vehicle (−) or 100 ng/mL PMA (+) as shown above the autoradiogram. After ten minutes the reaction was terminated, the substrates were separated by electrophoresis and identified by autoradiography. Location of the 48-kD substrate is indicated on the side of the autoradiogram. This experiment was repeated on three separate occasions with similar results.

clearly differ in their responses to these factors. In earlier work using the same U937 clone as examined in this report we noted a minimal increase in glucose oxidation and no superoxide release among cells differentiated with 1,25(OH)$_2$D$_3$.[4]

Several different mechanisms for expression of LDL by phagocytic cells are possible.[18-21] Because light emission was eliminated by SOD, LDL could primarily be attributed to superoxide anion formation. Myeloperoxidase was present in these cells in equivalent concentration under all conditions examined, so differences in myeloperoxidase formation are unlikely to account for differences in LDL observed.[20]

Formation of superoxide by phagocytic cells involves the transfer of a single electron from NADPH to molecular oxygen.[31] This reaction is mediated by an NADPH-dependent oxidase and a unique cytochrome. PMA-mediated O_2 reduction has been linked to the transfer of protein kinase activity from the cytosol to a particulate fraction[23] and phosphorylation of 43- to 48-kD proteins.[22,25,26] A deficiency in phosphorylation of these substrates has been demonstrated in neutrophils harvested from children with some forms of chronic granulomatous disease of childhood[25,26] where the cells are unable to form superoxide. Increased superoxide formation by activated macrophages has also been related to a reduced K*m* of NADPH oxidase[31,32] and enhanced cytochrome function.[33]

We measured protein kinase C–dependent phosphorylation in U937 cells incubated under conditions known to enhance LDL. The metabolite 1,25(OH)$_2$D$_3$ enhanced maximal protein kinase C–dependent phosphorylation of a 48-kD substrate but did not permit LDL. Lymphocyte conditioned media alone led to LDL but did not enhance 48-kD phosphorylation. Phosphorylation of the 48-kD protein under conditions that allowed maximal LDL, ie, the combination of 1,25(OH)$_2$D$_3$ and lymphocyte conditioned media, was no greater than that of 1,25(OH)$_2$D$_3$ alone. Furthermore, under these conditions LDL but not phosphorylation was greater in adherent cells. These results suggest that although 48-kD phosphorylation may be required for superoxide formation in response to some stimuli the magnitude of phosphorylation cannot be correlated directly with LDL. These results do not preclude the idea that a 1,25(OH)$_2$D$_3$-mediated increase in 48-kD phosphorylation enhances other effects of lymphocyte conditioned media involved in the generation of LDL. Also, it is possible that the conditions of incubation have an effect on translocation of protein kinase C[23] or other critical cytosolic components,[31] and experiments to examine this hypothesis are in progress.

These results are consistent with our recent work showing activation of human monocyte-derived macrophages by 1,25(OH)$_2$D$_3$.[34] In these studies the concentration of 1,25(OH)$_2$D$_3$ required to produce effects was supraphysiological, although serum vitamin D binding proteins reduce the concentration of 1,25(OH)$_2$D$_3$ available to interact with the cell.[35] It seems possible that lower concentrations of 1,25(OH)$_2$D$_3$ are permissive for a variety of cell functions.

Plasminogen Activator Inhibitor 1: Development of a Radioimmunoassay and Observations on Its Plasma Concentration During Venous Occlusion and After Platelet Aggregation

By Egbert K.O. Kruithof, Grazia Nicolosa, and Fedor Bachmann

To study the effect of plasminogen activator inhibitors (PAI) on fibrinolysis it is essential to be able to specifically measure these proteins in plasma. To this end PAI-1 was purified from cortisol-stimulated HT 1080 fibrosarcoma cells and antisera raised in rabbits. The immunologic relationship of the purified inhibitor to PAI-1 in plasma and platelet extracts was established by immunoblotting and regular and reverse fibrin zymography. Furthermore, the purified product could be immunoprecipitated with antibodies to human or bovine endothelial cell-derived PAI-1. A radioimmunoassay was developed that measures both free and tissue-type plasminogen activator (t-PA)-bound PAI-1 in plasma and has an effective range of 8 to 250 ng/mL. PAI-1 antigen levels showed a twofold increase after 20 minutes of venous occlusion, partially due to hemoconcentration. Approximately one quarter of PAI-1 before and after venous occlusion is derived from platelets. After correction for hemoconcentration and the contribution of platelets to plasma PAI-1 levels, a still significant increase in PAI-1 levels was noted during venous occlusion, which suggests that the local vascular bed releases PAI-1. Concomitant with PAI-1, t-PA antigen levels increased eightfold and fibrinolytic activity 18-fold after 20 minutes of venous occlusion. PAI-1 and t-PA levels tend to augment with age: in a group of older healthy volunteers (mean age, 53 years) PAI-1 levels were twice and t-PA levels 1.7 times higher than those in a group with a mean age of 29 years. Determination of PAI-1 antigen levels before and after platelet aggregation demonstrated that 85% of PAI-1 in platelet-rich plasma is associated with platelets. The average amount of PAI-1 per platelet was 0.3 fg/platelet, ie, 4,000 molecules per platelet.

THE FIBRINOLYTIC SYSTEM in plasma is a complex enzyme cascade system that degrades fibrin and thereby contributes to the prevention of thrombotic disease. A precise regulation of this system is needed to avoid nonspecific proteolytic degradation of plasma proteins and hemostatic plugs. Plasminogen activator inhibitors (PAIs) are important modulators of fibrinolytic activity.[1-5] Two distinct PAIs have been purified and are well characterized: PAI-1[6,7] and PAI 2.[8-10] PAI-1 is found in normal plasma and platelet releasates,[11-14] whereas PAI-2 is observed in pregnancy plasma[15,16] and in leukocytes.[17-19]

In a variety of clinical conditions increased levels of PAI activity have been observed,[3,15,16,20-24] and it has been suggested that PAI activity behaves as an acute-phase reactant.[25,26] PAI activity assays, however, do not measure the total PAI content of plasma but rather the level of free, active PAI-1. To evaluate correctly the contribution of PAI-1 to fibrinolytic activity it is, therefore, essential to complement PA and PAI activity measurements with specific antigen determinations of tissue-type PA (t-PA) and PAI-1. To this end we have developed a radioimmunoassay (RIA) for PAI-1, applied this assay to the measurement of PAI-1 levels in the plasma of normal individuals before and after venous stasis, and studied the contribution of platelets to PAI-1 levels in plasma.

MATERIALS AND METHODS

Materials. Iodogen was obtained from Pierce, Oud Beijerland, The Netherlands; Na^{125}I from New England Nuclear, Dreieich, FRG; Sephadex G25, Sephadex G100, CNBr-activated Sepharose 4B, concanavalin A (Con A)-Sepharose, and protein A–Sepharose from Pharmacia Fine Chemicals, Uppsala, Sweden. All reagents for polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS-PAGE) and the peroxidase staining reagent were obtained from Bio-Rad Laboratories, Richmond, CA. The World Health Organization International Reference Preparation of human t-PA (NIBSC 83/517) was provided by Dr P.J. Gaffney from the National Institute for Biological Standards and Control, London, UK.

t-PA. Human t-PA was purified and antiserum against t-PA raised in rabbits as described.[27] The activity of the t-PA preparation used in this study was calibrated in a fibrin plate assay against that of the international reference preparation.

PAI-1. PAI-1 was purified from the conditioned medium of cortisol (10^{-7} mol/L) stimulated human fibrosarcoma (HT 1080) cells.[7] The cells were grown to confluency in Dulbecco's modified Eagle's medium (DME) supplemented with 5% fetal bovine serum in 175-cm^2 culture flasks (Corning Glass Works, Corning, NY), washed twice with phosphate buffered saline (8 g/L NaCl, 0.2 g/L KCl, 1.44 g/L $Na_2HPO_4 \cdot 2H_2O$, 0.2 g/L KH_2PO_4) and stimulated with 10^{-7} mol/L cortisol (Solu-Cortef, Upjohn, Puurs, Belgium) in DME. Five-liter batches were concentrated 20-fold in a Millipore membrane concentrator equipped with a 4,650-cm^2 Pellikon membrane and passed over a 70 mL Con A–Sepharose column.[6] After washing with 40 mL 0.05 mol/L Tris-HCl, 0.1 mol/L NaCl, pH 7.4, and 40 mL 0.05 mol/L Tris-HCl, 1 mol/L NaCl, pH 7.4, PAI-1 was eluted with 0.05 mol/L Tris-HCl, 0.5 mol/L NaCl, 0.5 mol/L methyl-α-mannoside, pH 7.4. The protein-containing fractions of the methylmannoside eluate (approximately 150 mL) were dialyzed against 2 × 4 L of deionized water and, after the addition of 0.1 vol 0.1 mol/L Tris-HCl, 0.1 mol/L NaCl, pH 8.4, passed over a 1.5-mL column of diethyl aminoethyl–Sephacel preequilibrated with 0.01 mol/L Tris-HCl, 0.01 mol/L NaCl, pH 8.4. The column was washed with 10 mL of the same buffer followed by a stepwise gradient of 0.02 to 1 mol/L NaCl in the same buffer. PAI-1, as judged from

sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), reverse fibrin zymography, and immunoblotting eluted at a NaCl concentration of 0.1 mol/L. The PAI-1–containing fractions (3 mL) were further purified by gel filtration on a 60 × 1.6-cm column of Sephadex G-100 preequilibrated with 0.05 mol/L Tris-HCl, 0.1 mol/L NaCl, and 0.0001% merthiolate, pH 7.4. The final product showed one band on reduced and nonreduced SDS-PAGE. The protein concentration of the pure product was determined by the method of Bradford.[28]

PAI-1 was radioiodinated by the iodogen technique.[29] Radioiodinated inhibitor was separated from free ^{125}I by passage over a 10-mL column of Sephadex G-25. Its specific radioactivity was between 15 and 50 nCi/ng (corresponding to 15 to 50 molecules of ^{125}I incorporated per 100 molecules of PAI-1). After radiolabeling, approximately 70% of the inhibitor had retained its ability to bind to anti–PAI-1 antibodies. Under the conditions of the RIA using different antiserum dilutions and the recommended amount of cellulose-bound donkey antibodies to rabbit IgG (Sac-Cel, Wellcome, Beckenham, UK) maximal binding was only 30% at an antiserum dilution of 1:200. This low binding was found to be due to the limited capacity of the Sac-Cel preparation. When immunopurified antibodies and twice the amount of Sac-Cel were used, 70% of the radiolabeled antigen was immunoprecipitated.

Preparation of antiserum to PAI-1. For the immunization of rabbits with PAI-1, the gel-filtered PAI-1 preparation was subjected to further purification by SDS-PAGE in a 10% gel.[30] The stained PAI-1 bands were cut out and mixed by passage through hypodermic needles of different diameter with 0.3 mL 0.2% SDS and 0.5 mL Freund's adjuvant (complete for the first immunization, incomplete for subsequent immunizations).

Total anti–PAI-1 IgG was prepared by passing 1 mL antiserum over 1 mL protein A–Sepharose. After washing with 10 mL 0.05 mol/L Tris-HCl, 0.1 mol/L NaCl, pH 7.5, the IgG was eluted with 0.1 mol/L glycine-HCl, pH 2.2. Immediately after elution the IgG solution was neutralized by addition of 0.1 vol of 1 mol/L Tris. For preparing immobilized anti–PAI-1 IgG, the IgG was dialyzed overnight against two changes of 1 L 0.1 mol/L sodium bicarbonate, pH 8.1, and coupled to 1 mL CNBr-activated Sepharose 4B.[13,16]

Immunopurified anti–PAI-1 antibodies were prepared from total IgG by immunoadsorption to immobilized PAI-1 (150 μg pure PAI-1 coupled to 300 μL CNBr-activated Sepharose) and elution with glycine-HCl as described earlier. Biotinylated anti–PAI-1 IgG was prepared from the immunopurified IgG by incubating for two hours at room temperature 200 μL IgG (0.3 mg/mL in sodium bicarbonate) with 10 μL *N*-hydroxysuccinimidobiotin (Sigma Chemical Co, St Louis; 1 mg/mL in dimethylsulfoxide). Incorporated biotin was separated from free biotin by centrifugation through a 0.6-mL spincolumn of Sephadex G-25. Immobilized immunopurified anti–PAI-1 IgG as well as control IgG was prepared either by direct coupling of 0.5 mg IgG/mL CNBr-activated Sepharose or by incubating for one hour at room temperature 10 μg IgG with 100 μL cellulose-bound donkey antibodies to rabbit IgG (Sac-Cel) followed by removal of the supernatant by centrifugation (five minutes, 1,000 g). For comparative purposes antisera to bovine PAI-1[6] and human PAI-1[31] were obtained from Drs Loskutoff (Scripps Clinic, La Jolla, CA), and Sprengers (Gaubius Institute, Leiden, The Netherlands), respectively.

Plasmas. Blood was obtained by venipuncture from healthy volunteers in the age range of 26 to 59 years before and after ten or 20 minutes of venous occlusion induced by an arm cuff inflated midway between the systolic and diastolic pressures. Women using oral contraceptives were excluded from the study. The blood was collected on ice, anticoagulated with buffered citrate (nine parts of blood were mixed with one part of 0.1 mol/L sodium citrate/citric acid, pH 4.5), and centrifuged for 15 minutes at 1,800 g and 4°C. Plasma was collected and stored at −70°C. Platelet-rich plasma (PRP) was obtained by a ten-minute centrifugation at 200 g and 20°C; the platelet concentration was adjusted to 200 × 10^6 platelets/mL by dilution with the homologous plasma. Platelet aggregation in PRP was induced by collagen (Horm, Hormon Chemie, Munich, FRG; 5 μg/mL final concentration). After a five-minute incubation at 37°C the plasma was centrifuged (one minute, 25°C, 10,000 g) and stored at −70°C as described before.[13] Only those PRPs that exhibited normal aggregation curves in an aggregometer were used in the study. A normal plasma pool was prepared from the blood of 50 healthy blood donors.

An extract of washed platelets was made as described.[13]

Immunoradiometric assay of t-PA in plasma. t-PA antigen levels in human plasma were determined by using an immunoradiometric assay essentially as described by Rijken et al.[32] Standard curves were made by using a t-PA preparation standardized against the international reference preparation of t-PA. The latter has a specific activity of 500,000 IU/mg protein (1 IU = 2 ng).

RIA of PAI-1 in plasma. One hundred microliters of plasma, diluted fivefold with immunodilution buffer (0.05 mol/L Tris-HCl, pH 7.4, 0.2 mol/L NaCl, 0.01 mol/L EDTA, 0.1% bovine serum albumin, and 0.05% NaN_3) was mixed with 100 μL anti–PAI-1 antiserum that had been diluted such (1:1,500) that, in the absence of cold PAI-1, half-maximal binding of the ^{125}I-labeled PAI-1 to the antibodies occurred. After a two-hour incubation at 37°C, 50 μL of ^{125}I–PAI-1 (8,000 cpm) was added and incubated overnight at 4°C. One hundred microliters of a suspension of donkey antirabbit IgG antibodies coupled to cellulose (Sac-Cel) was then added and incubated for 30 minutes at room temperature. Two milliliters of 0.15 mol/L NaCl was added and the mixture centrifuged for five minutes at 200 g. The pellet was washed twice with 2 mL 0.15 mol/L NaCl and counted in a gamma counter. Radioactivities after deduction of nonspecific binding of ^{125}I–PAI-1 to Sac-Cel in the absence of added antiserum (usually less than 30 cpm) were compared in a logit-log plot with a standard curve of PAI-1.

Determination of the fibrinolytic activity of the euglobulin precipitate. After 10 minutes thawing in a 37°C waterbath, 1 vol of plasma was diluted ten times with ice-cold water and acidified by the addition of a 0.75 vol of 0.25% acetic acid (resulting in a pH of approximately 5.9). After 30 minutes at 0°C the preparation was centrifuged for 20 minutes at 1,200 g and 4°C and the pellet redissolved in a 0.5 vol of 0.1 mol/L Tris-HCl, pH 7.5. Fibrinolytic activity of the euglobulin fractions was determined on plasminogen-rich bovine fibrin plates as previously described.[33] For each sample, 30 μL of the euglobulin solution and 5 μL of 17.5 mmol/L sodium flufenamate (Aldrich Chemical Co, Steinheim, FRG) was applied on the fibrin plates.

Electrophoretic-zymographic techniques. Fibrin zymography[34] and reverse fibrin zymography[35] were performed after electrophoretic separation of plasma and platelet proteins by SDS-PAGE in a 10% gel.[30] Immunoblotting[36] was executed as follows: after SDS-PAGE the proteins were electrophoretically (16 hours, 30 V, 100 mA) transferred to nitrocellulose. The membrane was treated with Blotto[37] (5% wt/vol skimmed milk powder in 0.025 mol/L Tris, 0.5 mol/L NaCl, pH 7.5, [TBS]), incubated for three hours at room temperature in 5 mL of biotinylated anti–PAI-1 IgG (2 μg/mL in Blotto), washed three times for 15 minutes with 100 mL Blotto and twice for ten minutes with TBS, incubated one hour at room temperature with a conjugate of horseradish peroxidase with avidin (Vector Laboratories, Inc, Burlingame, CA), washed three times for 15 minutes in TBS, and developed with a peroxidase staining reagent (Bio-Rad).

PAI activity assay. PAI activity in plasma was determined by the indirect chromogenic substrate assay as described by Verheijen et al.[4]

Preparation of PAI-1–deficient plasmas or platelet extracts. Five milliliters of a normal human plasma pool was passed over a 1-mL column of immobilized total anti–PAI-1 IgG (5 to 10 mg of IgG/mL gel) and the protein containing run-through fractions (except for the first milliliter) collected and stored at −70°C. As an alternative, small-scale procedure, PAI-1 or PAI-1/t-PA complexes were removed from plasma or platelet extracts by a one-hour incubation at room temperature with immunopurified or control IgG bound to immobilized antirabbit IgG antibodies (prepared as described earlier). The immunoprecipitant then was removed by centrifugation (five minutes, 1,000 g).

RESULTS

Characterization of the antibodies directed against the PAI purified from HT 1080 cells. HT 1080 cells are able to secrete both PAI-1 and PAI-2.[38] To develop an RIA measuring PAI-1 in human plasma and in platelet extracts it was essential to determine whether the PAI purified by us from corticosteroid-stimulated HT 1080 cells is immunologically related to plasma PAI-1 and whether the antiserum raised reacts with PAI-1 in plasma and platelet extracts. To establish the specificity of the antiserum, we subjected an extract of washed platelets to SDS-PAGE followed by reverse fibrin autography as well as immunoblotting using biotinylated anti–PAI-1 IgG. A 51-kd immunoreactive band was observed in immunoblotting (Fig 1, lane 1). This band comigrated with the lysis inhibition band seen in reverse fibrin autography; the latter band could be removed by immunoprecipitation of the platelet extract with immunopurified anti–PAI-1 antibodies (Fig 1, lanes 2 and 3).

The addition of an excess of t-PA (5 U/mL, final concentration) to human plasma resulted in the formation of a 110-kDa t-PA/PAI-1 complex band; a minor amount of t-PA remained in its free form. Immunoprecipitation using immunopurified anti–PAI-1 antibodies completely removed the 110 kDa band, whereas the 67-kDa t-PA band still remained visible, thus demonstrating that the anti–PAI-1 antibodies also recognize PAI-1 complexed to t-PA (Fig 1).

Further proof of the immunologic relationship of the PAI purified by us from HT 1080 cells with PAI-1 was obtained by immunoprecipitation of radiolabeled PAI with antisera to bovine or human endothelial cell–derived PAI-1 (Fig 2). With our antiserum, half-maximal binding occurred at an antiserum dilution of 1:1,500. When using the antisera against PAI-1 from human or bovine endothelial cells, half-maximal binding occurred at lesser dilutions, but the slopes of the three curves was comparable. Preincubation of our antiserum with different concentrations of the PAI purified by us from HT 1080 cell conditioned medium or with a PAI-1 preparation that, by aminoacid sequence analysis, was identical to the endothelial cell–derived PAI-1[39] (a kind gift of Dr Andreasen) resulted in similar PAI concentration-dependent binding inhibition curves. Thus, the specificity and utility of these antigen and antisera preparations for the development of an RIA for measuring PAI-1 has been established.

Determination of optimal plasma dilutions for the assay of PAI-1. The presence of a fairly high concentration of proteins in plasma may influence the binding of an antigen to antibodies. To validly use standard curves for PAI-1 in immunodilution buffer it was therefore essential to examine

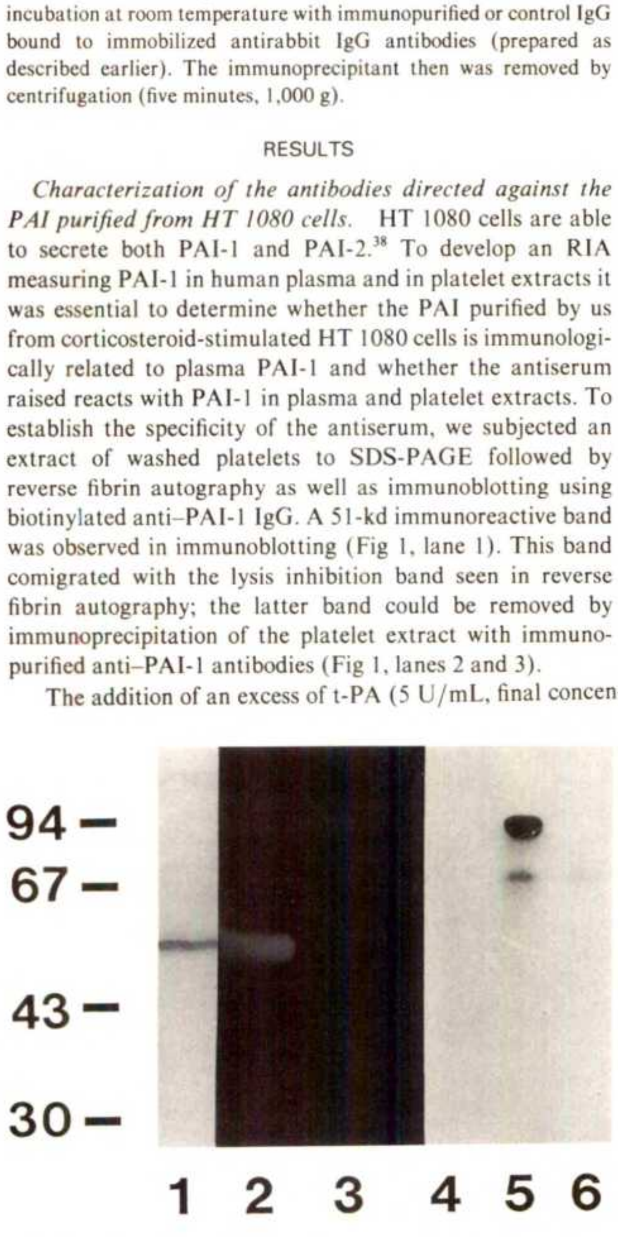

Fig 1. Analysis of the specificity of the anti–PAI-1 antiserum. Lane 1, extract of washed platelets subjected to SDS-PAGE and immunoblotting using biotinylated anti–PAI-1 IgG; lanes 2 and 3, extracts of washed platelets subjected to SDS-PAGE followed by reverse fibrin zymography; lanes 4 to 6, regular fibrin zymography of euglobulin precipitates prepared from human plasma before (lane 4) or after (lanes 5 and 6) the addition of 5 U/mL t-PA. Lane 3 and 6 show a platelet extract or plasma euglobulins, respectively, after immunodepletion with immunopurified anti–PAI-1 IgG. The positions of the molecular weight (mol wt) standard proteins phosphorylase b (94,000), bovine serum albumin (67,000), ovalbumin (43,000), and carboanhydrase (30,000) are indicated at the left.

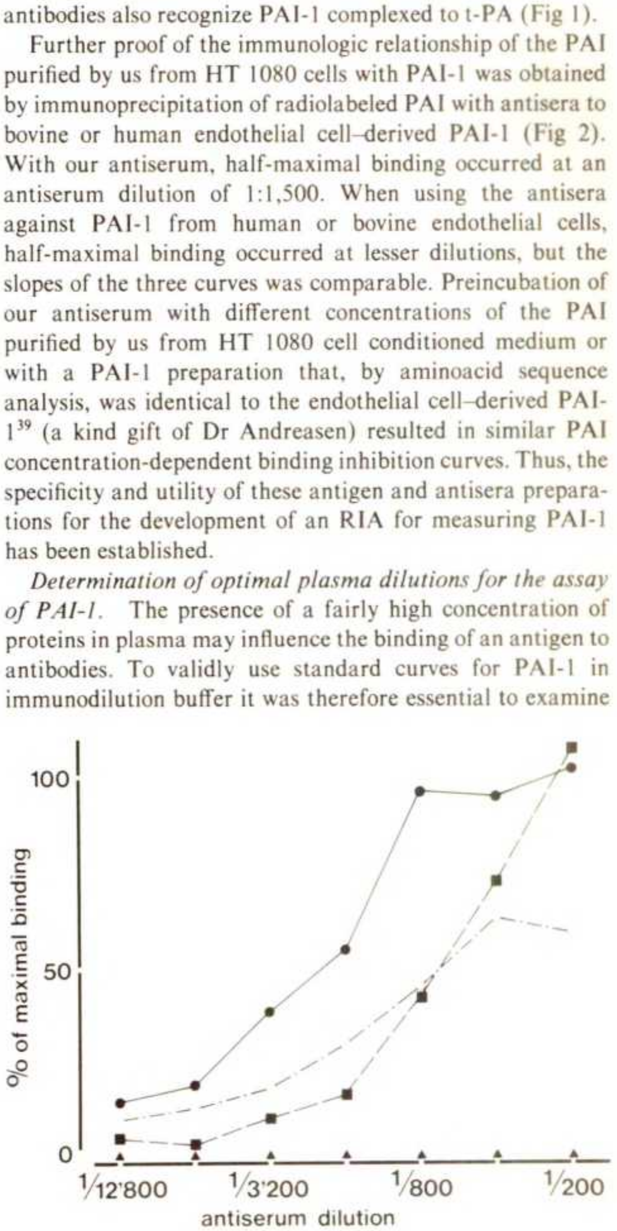

Fig 2. Binding of the PAI purified from HT 1080 cells to antibodies to human and bovine PAI-1. Radioiodinated PAI-1 (0.2 ng, 8,000 cpm) was incubated overnight with various dilutions of antiserum prepared against PAI purified from HT 1080 cells (●), PAI-1 purified from human (■) or bovine (○) endothelial cells, or with preimmune rabbit antiserum (▲). The complexes of ^{125}I-PAI with rabbit antibodies were precipitated with cellulose-bound donkey antibodies to rabbit IgG (see Materials and Methods) and, after washing the cellulose, counted in a gamma counter. The results are expressed as percentages of maximal binding, which, under the conditions of the RIA, was 30% at a 200-fold dilution of antiserum against human PAI-1. By using immunopurified IgG maximal binding was approximately 70%.

whether, at the plasma dilutions used, the binding of antigen is affected. To this end standard curves of PAI-1 in buffer and in different dilutions of PAI-1–depleted normal plasma were made by using the antiserum dilution (1:1,500) that resulted in half-maximal binding of labeled PAI-1 in the absence of added cold antigen. Standard curves of PAI-1 in plasma diluted five times or more were essentially identical to those made in immunodilution buffer (Fig 3). Furthermore, the dilution curve of pure PAI-1 added to plasma was parallel to that of plasma containing endogenous PAI-1. Henceforth, fivefold-diluted plasma was used for all PAI-1 determinations. Figure 3 shows that the range of the RIA for PAI-1 was 1.6 to 50 ng/mL. This results in a factual range in plasma of 8 to 250 ng/mL and allows a direct assay of PAI-1 antigen in over 95% of all plasma samples.

Correlation of PAI activity and PAI-1 antigen. In the plasma of 39 healthy individuals (19 males, 20 females) there was a significant correlation (Spearman's rank correlation coefficient, .613; $P < .001$) between PAI-1 antigen measured by RIA and PAI activity (Fig 4). However, a threefold discrepancy between antigen and activity was noted. A concentration of 50 ng/mL active PAI-1 corresponds to approximately 30 U/mL (based upon a specific activity of t-PA of 0.5 U/ng and the respective mol wts of t-PA and PAI-1. Instead, the average PAI activity of plasma samples containing a mean PAI-1 concentration of 50 ng/mL was only 9 U/mL.

Intraassay and interassay variability of the RIA. To establish the intraasay variability of the RIA, four sets of 18 duplicate plasma samples were randomly distributed into four assay series and the RIA performed the same day. Interassay variability was determined by testing the same plasma samples on three different days. The intraassay variability was dependent on the PAI-1 concentration. At low concentrations (between 10 and 20 ng/mL) the average intraassay variability (SD/mean value × 100%) was 15%, whereas above 20 ng/mL it was 7%. The average interassay variability was approximately 10%. Because the majority of plasmas show PAI-1 concentrations above 20 ng/mL (see the following sections), the RIA permits the measurement of PAI-1 in clinical conditions with increased PAI-1 levels with a fairly good accuracy.

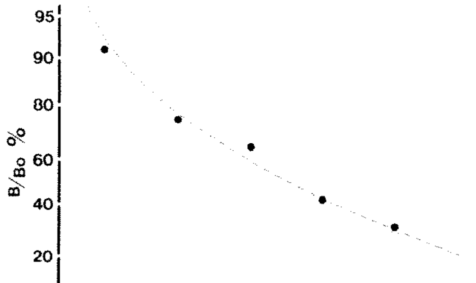

Fig 3. Comparison of standard curves of PAI-1 in fivefold-diluted, PAI-1–depleted plasma and in immunodilution buffer. Different concentrations of PAI-1 in either immunodilution buffer (O) or fivefold-diluted, PAI-1–depleted plasma (●) were incubated for two hours at 37°C with 1,500-fold-depleted antiserum to human PAI-1. Thereafter radiolabeled PAI-1 (0.2 ng, 8,000 cpm) was added and incubated overnight. Bound PAI-1 was separated from unbound by immunoprecipitation of the complexes with immobilized donkey antibodies to rabbit IgG (see Materials and Methods) and, after washing, counted in a gamma counter. The figure shows a logit-log plot of percent bound radioactivity *v* added unlabeled PAI-1.

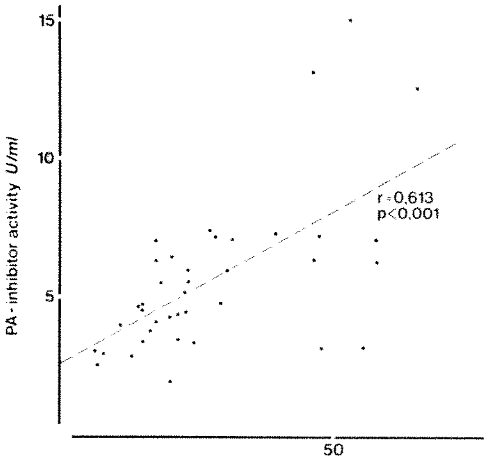

Fig 4. Correlation between PAI-1 antigen levels and PAI activity in normal human plasma. PAI-1 antigen levels and PAI activity were measured in the plasma of 39 healthy volunteers aged 22 to 58.

Effect of complexation of PAI-1 to t-PA on the measurement of PAI-1 antigen. Because PAI-1 exists in human plasma in a free and a t-PA–bound form, it was important to establish to what degree the RIA measures t-PA–complexed inhibitor. To this end PAI-1 antigen determinations were performed in ten normal plasmas before and after the addition of 10 U/mL exogenous t-PA. PAI-1 values in plasmas with or without added t-PA were not significantly different ($P > .2$; Wilcoxon signed rank test) and in general within the intraassay variability. The RIA thus effectively measures both free and t-PA–bound PAI-1.

Influence of sex and age on PAI-1 antigen levels. No significant difference was observed in plasma PAI-1 antigen levels in males (mean ± SD, 31 ± 18 ng/mL; median, 23 ng/mL; range, 6 to 65 ng/mL) and females (mean ± SD, 23 ± 12 ng/mL; median, 21 ng/mL; range, 6 to 57 ng/mL).

A significant correlation of PAI-1 antigen levels with age was observed ($r = .474$, $P < .005$). Dividing the 39 blood donors into three equal groups based upon their age indicated that PAI-1 antigen levels were twofold higher in the oldest than in the youngest group (Table 1). The difference in PAI activity was less marked: the average PAI activity was 40% higher in the oldest age group ($P > .05$). The lesser difference in PAI activity between the two age groups probably is due to the 70% higher t-PA level in the oldest group (Table 1), which leads to a proportionately lower fraction of free PAI-1 in the older individuals.

Release of PAI-1 by human platelets. Collagen stimulation of ten PRPs adjusted to 200×10^6 platelets/mL resulted

Table 1. Effect of Age on PAI-1 and t-PA Antigens and PAI Activity

Group	Age (yr)	PAI-1 (ng/mL)	t-PA (ng/mL)	PAI Activity (U/mL)
1	29 ± 3*	18 ± 6	2.9 ± 0.9	4.8 ± 1.7
2	40 ± 3	26 ± 15	3.4 ± 1.7	5.1 ± 2.7
3	53 ± 4	38 ± 18	4.8 ± 2.4	6.7 ± 3.5
P† of 1 v 3		<.002	<.02	NS

Plasma antigen concentrations of PAI-1 and t-PA as well as PAI activity was determined in the plasma of 39 healthy volunteers. The collective was divided into three groups according to age.

*Mean ± SD of 13 individuals.

†P values were determined with the Mann-Whitney rank correlation test.

NS: $P > 0.05$

in a significant increase of PAI-1 antigen levels ($P < .002$; Wilcoxon signed rank test) from 22 ± 13 ng/mL (mean ± SD, median, 21 ng/mL; range, 8 to 45 ng/mL) in platelet-poor plasma (PPP) to 79 ± 30 ng/mL (median, 78 ng/mL; range, 40 to 137) in the PRPs after platelet aggregation. From the increase in PAI-1 antigen levels after platelet aggregation (57 ng/200 × 10^6 platelets) the amount of platelet-associated PAI-1 was calculated to be 0.3 fg/platelet (or approximately 4,000 molecules of PAI-1/platelet). No correlation ($r = .05$) was observed between plasma PAI-1 levels and platelet-associated PAI-1, which indicated that platelets and plasma constitute two independent compartments for PAI-1. The mean, total platelet-associated PAI-1 calculated from the amount of PAI-1 released by 200 × 10^6 platelets and corrected for each individual platelet count was 139 ± 55 ng/mL, a value sixfold higher than that of PPP.

PAI-1 and t-PA antigen concentrations before and after venous occlusion. During venous occlusion plasma antigen concentrations of both PAI-1 and t-PA antigen augmented. PAI-1 antigen levels increased from 27 ± 16 ng/mL (median, 22 ng/mL) to 43 ± 33 ng/mL (median, 38 ng/mL) after ten minutes and to 59 ± 53 ng/mL (median, 44 ng/mL) after 20 minutes of venous occlusion (Fig 5). Concomitantly, t-PA antigen levels increased from 3.4 ng/mL to 12 and 26 ng/mL after ten and 20 minutes, respectively, of venous occlusion (Fig 5). Several mechanisms may be responsible for the increase in PAI-1 concentrations: (*a*) hemoconcentration induced by the venous occlusion, (*b*) release of PAI-1 by partially activated platelets, and (*c*) release of PAI-1 by local sources, eg, endothelial cells. To evaluate the effect of hemoconcentration, the total protein level of each individual plasma was determined; mean plasma protein concentrations increased 27% after ten minutes and 38% ($P < .001$, Wilcoxon signed rank test; Table 2) after 20 minutes of venous occlusion. After correction of each PAI-1 value for the corresponding hemoconcentration, PAI-1 concentrations after a 20-minute venostasis still were significantly ($P < .001$) increased with respect to those before stasis. To assess the contribution of platelets to stasis-induced augmentations of PAI-1, the extent of the platelet release reaction was estimated from β-thromboglobulin (β-TG) levels. Concentrations of β-TG increased significantly from 320 to 581 ng/mL, but after correction for hemoconcentration this increase was not significant anymore. Because platelets release β-TG and PAI-1 simultaneously,[11,13] it is obvious that part of the PAI-1 in the plasma before and after venous occlusion stems from platelets. Linear regression analysis of PAI-1 and β-TG levels before venous occlusion yielded a regression coefficient of .312 (not significant). The increases in PAI-1 and β-TG levels after correction for hemoconcentration were correlated in a borderline manner ($r = .333$, $P = .04$). From the slopes of the latter regression curve, it was estimated that an increase of 100 ng/mL of β-TG corresponds to an increase of 2.2 ng/mL of PAI-1 (ratio of PAI-1/β-TG, 0.022). These values are slightly higher than those arrived at by determining β-TG and PAI-1 concentrations in PRP before and after induction of platelet aggregation (β-TG, 12 μg/mL; PAI-1, 140 ng/mL; PAI-1/β-TG ratio, 0.012; average determination for ten plasmas). To avoid underestimating the contribution of platelets to increases in PAI-1 concentrations before and after venous occlusion, we have chosen the larger of the two ratios for our calculations.

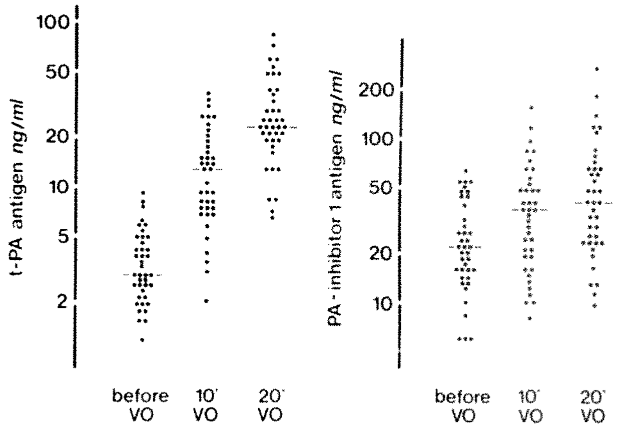

Fig 5. Effect of venous occlusion (VO) on PAI-1 and t-PA antigen levels in normal volunteers. PAI-1 and t-PA antigen levels were measured in the plasma of 39 healthy volunteers before and after ten and 20 minutes of VO.

Table 2 shows that both before and after venous occlusion approximately 25% of PAI-1 antigen was derived from platelets. After correction for the contribution of platelets and hemostasis a significant increase in PAI-1 levels still occurred after ten and 20 minutes of venous occlusion ($P < .02$ and $P < .001$, respectively, Wilcoxon signed rank test).

The effect of the increases in both t-PA and its inhibitor on the fibrinolytic activity of the euglobulins was measured on fibrin plates. It increased from an average of 0.3 U/mL before to 1.7 and 5.4 U/mL after ten and 20 minutes of venous occlusion, respectively. Before venous occlusion fibrinolytic activity was not correlated to t-PA or to PAI-1 levels (Table 3). After ten minutes of venous occlusion, fibrinolytic activity was positively correlated with t-PA levels and negatively with PAI-1 levels. After 20 minutes of venous occlusion, fibrinolytic activity was even more strongly correlated with t-PA levels but no longer with PAI-1 levels. Interesting-

Table 2. Effect of Hemoconcentration and Platelet Activation on Plasma Antigen Concentration of PAI-1

	pre-VO	10-min VO	20-min VO
Hemoconcentration	1.00	1.27 ± 0.15	1.38 ± 0.18
PAI-1	27 ± 16	43 ± 33*	59 ± 53*

	(2-22; 6)	(2-35; 7)	(2-29; 7)

Plasma concentrations of PAI-1 and β-TG are given before and after correction (C) for hemoconcentration. The contribution of platelets to PAI-1 (C) concentrations in each plasma was estimated from β-TG (C) concentrations in that plasma, by assuming a PAI-1/β-TG ratio of 0.022. All protein concentrations are given in nanograms per milliliter. *P* values are given with respect to pre-VO concentrations. Results are given as means ± SD; between parentheses are given range and median values.

Abbreviation: VO, venous occlusion.

**P* < .001.

†*P* > .05.

‡*P* < .02.

ly, before venous occlusion a striking positive correlation was observed between t-PA antigen levels and both PAI activity and PAI-1 antigen levels (Table 3).

DISCUSSION

Only recently was the key role of PAIs on fibrinolytic activity in human plasma established.[1-5] A number of assay systems have been developed that estimate PAI activity in human plasma.[1-4] These assay systems were based on the inhibition of t-PA and measure PAI levels only indirectly. They are sensitive to interference by other, nonspecific inhibitors of t-PA[2] and do not distinguish between different PAIs. Furthermore, stimuli such as exercise that induce the release of t-PA reduce PAI activity. Assays can be rendered more specific for PAI-1 by using antibodies to PAI-1 in conjunction with a PAI activity determination.[40,41] To better understand the contribution of PAI-1 to overall activity of the fibrinolytic system we have developed a PAI-1 antigen assay.

Table 3. Correlation Between PAI-1 Antigen, PAI Activity, t-PA Antigen, and Fibrinolytic Activity Before and After Ten and 20 Minutes of Venous Occlusion

Correlation	Before VO	10-min VO	20-min VO
FA *v* t-PA antigen	.037	.457*	.671*
FA *v* PAI-1 antigen	−.176	−.329†	−.059
PAI activity *v* t-PA antigen	.479‡	ND	ND
PAI activity *v* PAI-1 antigen	.613*	ND	ND
t-PA antigen *v* PAI-1 antigen	.602*	ND	ND

The table gives Spearman's rank correlation coefficients.

Abbreviations: FA, fibrinolytic activity; ND, not done.

We have used cortisol-stimulated HT 1080 fibrosarcoma cells as a source of PAI-1.[7] Because these cells are able to secrete both PAI-1 and PAI-2,[38] it was essential to establish that the purified PAI indeed corresponds to PAI-1. Its immunologic relationship with PAI-1 and the specificity of the antiserum raised against this protein were established by the following criteria: (*a*) in platelet extracts one 51-kDa immunoreactive band comigrated with the platelet PAI-1 band, which was demonstrable by reverse fibrin autography[11,13,14]; the latter was immunoprecipitable with antibodies raised against the HT 1080 PAI. (*b*) The addition of t-PA to human plasma resulted in the formation of a 110-kDa complex with PAI-1.[2,5,13] The complex but not free t-PA reacted with our immunopurified antibodies. (*c*) Radiolabeled HT 1080–derived PAI was immunoprecipitated by antibodies to human or bovine endothelial cell–derived PAI-1. (*d*) A PAI-1 preparation that by criteria of amino acid sequence analysis is identical to PAI-1 (a gift of Dr Andreasen[39]) showed a concentration-dependent inhibition curve of the binding of radiolabeled PAI to our antibodies. These results thus are in agreement with those of others[7,39,42] who purified PAI-1 from HT 1080 cells by a slightly different technique.

Standard curves of PAI-1 in PAI-1–depleted plasma were identical to those in immunodilution buffer, provided the plasma had been diluted at least fivefold. At this plasma dilution, the RIA has a range of 8 to 250 ng/mL and allows, therefore, the direct determination of PAI-1 levels in resting (range, 6 to 57 ng/mL) and postocclusion plasma (10 to 275 ng/mL) (Fig 5). No difference was observed between free and t-PA–bound PAI-1. The assay thus measures the total PAI-1 concentration.

A threefold discrepancy between PAI-1 antigen and PAI activity was noted. Part of this discrepancy is due to the measurement of complexes of PAI-1 with t-PA that are obviously inactive. A further explanation for the lower PAI activity levels may be ascribed to the presence, in plasma, of an inactive, "latent" form of PAI-1 that can be (re-)activated by chaotropic agents.[31,43] In endothelial cell conditioned medium, the active form is converted into the latent form with a half-life of a few hours,[44] and after four hours of culture the ratio of latent to active PAI-1 was more than 12. In human serum a ratio of over 3 was observed.[45] Because in these studies the completeness of activation of the latent form of PAI-1 was not established, actual ratios of latent to active PAI-1 may even have been higher.

As has been observed before for PAI activity in plasma,[1-4] PAI-1 antigen levels likewise were extremely variable: in normal individuals there was a more than tenfold difference between the lowest and highest values. PAI-1 antigen levels were the same in males and females but increased with age. Average PAI-1 antigen levels were twofold higher in the oldest group of volunteers, aged 53 ± 4 years, as compared with the youngest group, aged 29 ± 3 years. This twofold increase did not match entirely a nonsignificant 40% increase in PAI activity. The lesser increase in PAI activity than t-PA antigen concentration may be due, at least in part, to an increased t-PA level in the higher age groups. Our results are in accordance with those of Aillaud et al[46] who recently found that PAI activity and t-PA antigen levels were 60% and 120% higher, respectively, in a group of elderly individuals (average age of 80 years) as compared with a young control group. Whether the increases in PAI-1 and t-PA levels are truly an age-related phenomen or merely reflect an increased occurrence of subclinical pathologies at a higher age remains to be established.

During venous occlusion, antigen levels of both t-PA and PAI-1 increased linearly with time. After 20 minutes of venous occlusion PAI-1 levels had increased twofold and t-PA levels eightfold. Correction for hemoconcentration according to total plasma protein concentrations indicated that half of the increase in PAI-1 levels was due to hemoconcentration. Measurement of β-TG in these plasmas suggested that both before and after venous occlusion approximately one quarter of PAI-1 was derived from platelets that had been partially activated. After correction for platelet-derived PAI-1, a significant increase in PAI-1 was still observed after 20 minutes of venous occlusion. This suggests that the local vascular bed contributes to PAI-1 levels, most likely by release of PAI-1 from endothelial cells.[6,31,43] The corrected increases in t-PA levels (fivefold) are much greater than those of PAI-1 (50%), thereby resulting in general in a net increase in fibrinolytic activity.

In resting plasma no correlation was observed between t-PA or PAI-1 levels and fibrinolytic activity as measured in twofold-concentrated euglobulins. Apparently, in resting plasma the larger part of t-PA exists in an inactive form, and "resting" fibrinolytic activity is little influenced by PAI-1. After ten minutes of occlusion, the average PAI-1 levels were 43 ng/mL, and average t-PA levels were 12 ng/mL. Assuming that only one third of PAI-1 is in an active form, the average concentrations of active PAI-1 and t-PA are roughly equimolar. As expected in such a situation, a positive correlation of fibrinolytic activity with t-PA levels and a negative one with PAI-1 levels was observed. This suggests that, after ten minutes of venous occlusion, fibrinolytic activity reflects a balance between activator and inhibitor and implies that a deficient fibrinolytic activity may be due to a high concentration of PAI-1 or a deficient release of t-PA. At longer occlusion times (20 minutes), the amount of t-PA secreted is in such an excess over active PAI-1 that fluctuations of PAI-1 contribute much less to fluctuations of fibrinolytic activity.

In the resting plasma of healthy individuals a striking correlation was observed between t-PA antigen concentrations on the one hand and PAI-1 antigen levels and PAI activity on the other. This correlation could be explained if the t-PA/PAI-1 complexes had a longer in vivo half-life than free PAI-1 or t-PA or if there was a coordinate regulation of the release and/or clearance of PAI-1 and t-PA. In rabbits, the half-life of complexes of t-PA with PAI-1 and of free t-PA was only a few minutes[47] and shorter than that those of PAI activity (seven minutes).[22] It therefore seems more likely that a common mechanism regulates plasma levels of PAI-1 and t-PA.

Direct measurement of PAI-1 antigen levels before and after platelet aggregation confirms previous results of activity assays and immunologic studies that platelets release PAI-1.[11,13,14] The amount of PAI-1 per platelet (0.3 fg or 4,000 molecules) is quite small. Nevertheless, quantitation of PAI-1 released by platelets suggest that in human blood the larger part of PAI-1 (approximately 85%) is associated with platelets, as has been estimated previously from PAI activity assays.[13,14] In the present study in which plasma was prepared as recommended for fibrinolytic tests, approximately one quarter of PAI-1 was derived from platelets. The lack of correlation, however, between plasma and platelet-associated PAI-1 concentrations and the poor correlation between β-TG and PAI-1 levels in resting and poststasis plasma confirms previous suggestions that plasma and platelets constitute two independent compartments of PAI-1.[13,14] However, the presence of β-TG in the citrated plasmas indicated that approximately 25% of PAI-1 in plasma actually was derived from platelets. By collecting the blood on anticoagulants that prevent platelet release, eg, those recommended for measuring β-TG in plasma, a more precise determination of the plasma concentration of PAI-1 could be achieved.

The development of a specific RIA for PAI-1 now permits studies on the fluctuations of PAI-1 antigen in health and disease. As exemplified by the modifications of PAI-1 antigen and PAI activity with age, antigen measurements may be more sensitive in detecting increases in PAI-1 levels than are activity assays.

ACKNOWLEDGMENT

The excellent technical assistance of M. Maillard is gratefully acknowledged. Dr R. Medcalf is thanked for his critical reading of the manuscript.

Reciprocal Translocation Involving the Short Arms of Chromosomes 7 and 11, t(7p-;11p+), Associated With Myeloid Leukemia With Maturation

By Yuko Sato, Syuiti Abe, Keiji Mise, Motomichi Sasaki, Nanao Kamada, Kyuuhei Kouda,
Manabu Musashi, Yoshio Saburi, Akira Horikoshi, Yuusaku Minami, Tsuyoshi Miyakuni,
Yasunobu Yokoyama, Yoshimori Ishihara, and Yasusada Miura

A reciprocal translocation involving the short arms of chromosomes 7 and 11, t(7;11)(p15;p15), was found in nine patients including eight with acute myelogenous leukemia (AML) and one with Philadelphia (Ph^1) chromosome-positive chronic myelogenous leukemia (CML) in blastic crisis. Although a similar chromosome rearrangement has previously been reported in five patients, including three with AML and two with CML, the 7p breakpoint in some of these cases was slightly different from that detected in our patients. Notable cytogenetic and clinicohematologic findings in our patients and those reported in the literature were as follows: (*a*) t(7;11) occurred in myeloid leukemia, predominantly AML with subtype M2, and occasionally in other AML subtypes and in CML with or without Ph^1 chromosome; (*b*) t(7;11) frequently occurred as the sole chromosome abnormality; (*c*) most patients showed a low neutrophil alkaline phosphatase score; and (*d*) Auer rods were present in leukemic cells of most cases including Ph^1-positive CML. Our findings suggest that a t(7;11)-associated leukemia constitutes a subgroup of myeloid malignancy involving maturing leukemic cells.

© 1987 by Grune & Stratton, Inc.

IT IS NOW WELL ESTABLISHED that specific chromosome abnormalities correlate with a particular type of leukemia showing characteristic morphological and clinical features. The best known examples are Philadelphia (Ph^1) translocation, t(9;22), in chronic myelogenous leukemia (CML)[1] and t(8;21), t(15;17), and inv(16) in acute myelogenous leukemia (AML) with subtypes M2, M3, and M4 with abnormal eosinophils, respectively.[2-7] These specific chromosome abnormalities have a diaganostic and sometimes a prognostic significance. Recently, a reciprocal translocation involving the short arms of chromosomes 7 and 11, t(7p−;11p+), was reported in several Japanese patients with leukemia.[8-12] Although a possible association of t(7;11) with Ph^1-negative CML has been hypothesized,[11] the clinicohematologic findings thus far obtained from the patients with this abnormality seem to be insufficient to warrant this association.

In the present investigation, we studied nine patients with t(7;11), including eight with AML and one with Ph^1-positive CML, and paid particular attention to their clinicohematologic characteristics.

MATERIALS AND METHODS

Patients. Nine patients including eight with AML and one with Ph^1-positive CML in blastic crisis were evaluated and treated at the following Japanese institutes; Asahikawa Red Cross Hospital, Hokkaido University Hospital, Jichi Medical School Hospital, Nihon University Itabashi Hospital, Kinki Central Hospital, Hiroshima University Hospital, Medical College of Oita Hospital, and Naha Prefectural Hospital. Informed consent for chemotherapeutic procedures and necessary studies was obtained from all the patients. Diagnosis and classification of leukemias were based on morphological and cytochemical examinations of peripheral blood smears and bone marrow aspirates on admission. The eight AML patients included seven with subtype M2 and one with M5b according to classification by the French-American-British Cooperative Group criteria.[13] Neutrophil alkaline phosphatase (NAP) score was counted according to the method described by Tomonaga et al.[14] All eight AML patients were given intensive combination chemotherapy with cytosine arabinoside (Ara-C) or N^4-behenoyl-1-β-D-arabinofuranosylcytosine (BH-AC; Asahi Chemical Industry, Osaka, Japan), daunorubicin (DNR) or aclarubicin hydrochloride (ACM; Aclacinomycin A, Yamanouchi Pharmaceutical Co, Ltd, Tokyo), 6-mercaptopurine (6-MP), and prednisolone (PSL). In some cases, either interferon-α (INF-α) or vincristine (VCR) was added as initial induction chemotherapy. The CML patient (patient no. 9) was treated with busulfan in the chronic phase and with intensive combination chemotherapy with BH-AC, DNR, VCR, and PSL in the blastic phase.

Cytogenetic study. Chromosome analysis with Q- or G-banding techniques was performed on bone marrow and peripheral blood cells obtained from each patient at the time of diagnosis. Patient nos. 1 and 5 were examined two or three times during the clinical course. One Ph^1-positive CML patient (patient no. 9) was examined both in the chronic and blastic phases. Karyotypes were described according to the International System for Human Cytogenetic Nomenclature.[15]

RESULTS

Hematologic and clinical findings. The hematologic and clinical findings in the nine patients examined at the time of diagnosis or at the onset of blastic crisis are summarized in Table 1. The ages of these patients, who included five males and four females, ranged from 16 to 59 years old (median, 40). None of the patients except for the CML

*Tomonaga's method; normal value, 177 to 350.

†The number in parenthesis shows the survival time from blastic crisis.

‡In this patient, the percentage of monocytoid elements was 48.7%. See the text for the detail.

patient (patient no. 9) had a previous history of chemotherapy or mutagen exposure. Organomegaly was found in three patients, one (patient no. 6) with hepatosplenomegaly and two (patient nos. 3 and 9) with hepatomegaly.

In peripheral blood, the WBC count ranged from 2.4 to 69.7 × 10^9/L (median, 35.2 × 10^9/L), the hemoglobin level from 5.9 to 11.7 g/dL (median 9.3 g/dL), and the platelet count from 2.9 to 54.4 × 10^9/L (median, 7.2 × 10^9/L). The blast count ranged from 3% to 91% (median, 13%). Bone marrow aspirates showed a various number of myeloblasts, promyelocytes, and maturing granulocytic elements (Fig 1A). The proportion of myeloblasts in patient nos. 1 to 7 ranged from 37.0% to 78.4%. In patient no. 8, the proportion of myeloblasts was 13.6%, but that of monocytoid elements showing α-naphthyl butyrate esterase activity with NaF inhibition was 48.7%. In all patients, the myeloblasts exhibited peroxidase activity (Fig 1B), and in two, a fraction of myeloblasts showed naphthol-AS-D-chloroacetate esterase activity (patient nos. 3 and 9). No eosinophilia was observed in the bone marrow (below 2.8%) or the peripheral blood (below 1.0%) of all patients, although abnormal eosinophils with basophilic granules were found in two patient (patient nos. 1 and 2). Large myelocytes and metamyelocytes, and giant mature polymorphs were found in some patients (patient nos. 1 to 4). Auer rods were found in the cytoplasm of a fraction of the blasts from all patients including the patient with Ph^1-positive CML (patient no. 9); they were usually single and occasionally two or three in a leukemic blast (Fig 1C), but were not in mature polymorphs of any patient. NAP score (normal value, 177 to 350) was decreased in seven of the patients, including the CML patient in blastic crisis. Patient no. 6 was diagnosed as having M2 when first admitted, but at relapse 13 months later, his leukemic blasts exhibited myelomonocytoid features. The details of this case will be published elsewhere.[16]

Complete remission was achieved in seven of the eight AML patients, among whom patient no. 6 was still alive in the third remission at the time of the latest follow up (March 1987). Their survival times ranged from 5 to 31 months, with a median of 12.8 months. Patient no. 9 did not achieve

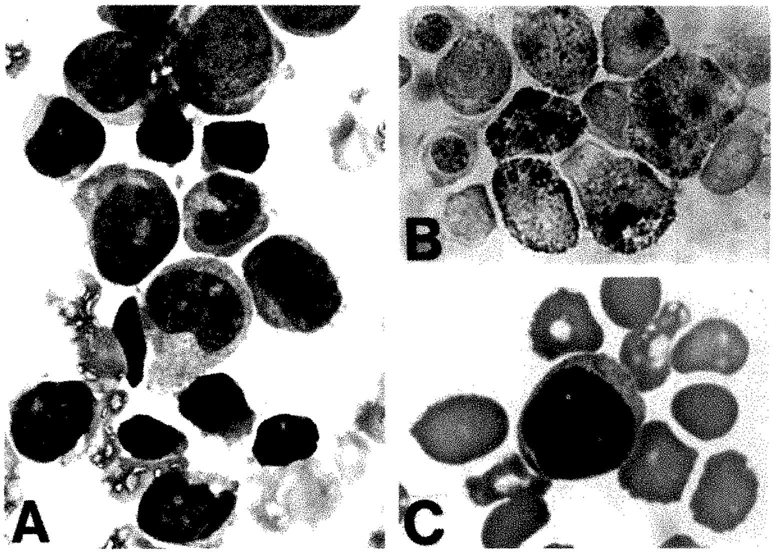

Fig 1. (A) Bone marrow aspirate from patient no. 4 showing myeloblasts and maturing granulocytic elements. (B) Myeloblasts from patient no. 4 showing peroxidase activity. (C) A myeloblast from patient no. 9 containing a single Auer rod in the cytoplasm.

remission and died 4 months after the onset of blastic crisis; her total survival time from initial diagnosis was 56 months.

Cytogenetic findings. The results of the chromosome analyses of the nine patients are summarized in Table 2. The t(7;11) translocation was detected in all of the patients. The breakpoints on chromosomes 7 and 11 were common to all patients and occurred at 7p15 and 11p15, respectively (Fig 2). At the time of diagnosis, five of the eight AML patients exhibited the t(7;11) as the sole chromosome abnormality. Patient nos. 7 and 8 showed others in addition to t(7;11), the former showing 6q − and the latter showing 7q −. Karyotypically normal cells were observed in four of the eight AML patients, including patient no. 1 who exhibited complex additional abnormalities during the later clinical course. Patient no. 9 showed t(7;11) together with trisomy 8 and an extra Ph^1 chromosome in blastic crisis in addition to the Ph^1 translocation, which was the only chromosomal abnormality observed in the chronic phase.

DISCUSSION

Since the first description of the t(7p −;11p +) translocation in the blastic crisis of a patient with Ph^1-positive CML,[7] five patients with this abnormality have been reported[8-12] (Table 3). A review of 14 cases including the present nine indicates that this abnormality frequently occurs in AML patients (11/14 cases), particularly those with subtype M2 (7/14) and occasionally in M4 and M5, rather than in CML patients with or without the Ph^1 translocation (3/14). These findings contradict the previous report that suggested an association of t(7;11) with Ph^1-negative CML.[11] The occurrence of t(7;11) may be analogous to that of the t(8;21) abnormality because the latter has been reported to occur predominantly in subtype M2 and occasionally in M1 and M4.[17,18]

Our patients commonly showed decreased NAP levels, peroxidase-positive leukemic blasts, and Auer rods in a fraction of leukemic blasts (Table 1). These features are usually observed in patients with t(8;21).[18-20] Although large myelocytes and metamyelocytes, giant mature granulocytes, and abnormal eosinophils with basophilic granules were found in some of our patients, marrow eosinophilia was not observed in our patients. The presence of these abnormal bone marrow cells and marrow eosinophilia is another morphological features of an M2 patient with t(8;21).[18-20] Auer rods, occurring in about 30% of AML patients,[21] are thought to be a distinctive feature of myeloid malignancies, although they are quite rare in myeloblastic crisis of CML. In this context, special attention should be paid to patient no. 9 who showed Auer rods in a small fraction of blasts and low NAP

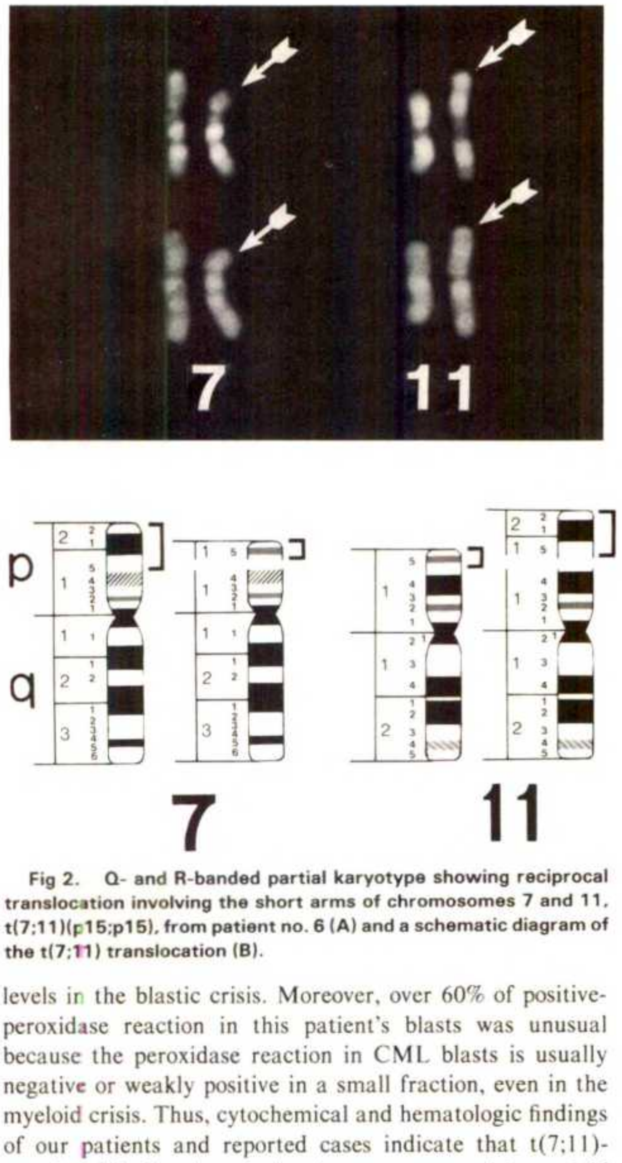

Fig 2. Q- and R-banded partial karyotype showing reciprocal translocation involving the short arms of chromosomes 7 and 11, t(7;11)(p15;p15), from patient no. 6 (A) and a schematic diagram of the t(7;11) translocation (B).

levels in the blastic crisis. Moreover, over 60% of positive-peroxidase reaction in this patient's blasts was unusual because the peroxidase reaction in CML blasts is usually negative or weakly positive in a small fraction, even in the myeloid crisis. Thus, cytochemical and hematologic findings of our patients and reported cases indicate that t(7;11)-associated leukemia may involve precursors with myeloid maturation, although other morphological features that distinguish this type of luekemia from others were not observed.

In the present study, AML patients exhibited a fairly good response to chemotherapy, although the CML patient failed to enter remission, as did two other CML patients reported in the literature (Table 3). However, the remission rate in our AML patients (7/8 cases, 87.5%) as well as the overall rate obtained when those reported in the literature were included (10/11 caess, 90.9%) is not significantly higher than that of M2 patients without t(7;11) at our institutes.

As shown in Tables 2 and 3, the t(7;11) translocation mostly occurred as the sole chromosome abnormality in the patients concerned herein. In the previously reported five patients with t(7;11), the breakpoint of chromosome 11, 11p15, concurred with that observed in our nine patients, whereas somewhat variable breakpoints (p13 to p15) were observed for chromsome 7. Recently, we have corrected the breakpoint of 7p14 to 7p15 in a previously reported CML case (patient no. 14) (Tomiyasu et al, unpublished). In addition, the 7p13 breakpoint in another reported case (patient no. 12), was revised to 7p15 (Ishihara et al, unpublished). Thus, 13 of the 14 patients thus far reported show the same 7p and 11p breakpoints in the t(7;11) translocation. A complex translocation involving chromsomes 7 and 11 at these breakpoints has recently been reported as the sole abnormality in chronic phase of a Ph^1-negative CML patient[22] in whom a low NAP level and peroxidase positivity were also observed. This patient may therefore bear a variant type of the standard t(7;11) translocation.

Because the band 11p15 includes the c-Ha-*ras*-1 oncogene locus,[23] it will be interesting to assess the involvement of this oncogene in the t(7;11) translocation. Our preliminary results from the in situ chromosome hybridization study showed a different localization for the c-Ha-*ras*-1 gene in the t(7;11) between one AML patient (patient no. 6) and one CML patient (patient no. 9) of the current series[24]; the translocation of c-Ha-*ras*-1 was demonstrated in patient no. 6 but not in patient no. 9. This may indicate a difference in the breakpoint within 11p15 at a molecular level between these two cases, as has been shown recently for the molecular breakpoints of 22q11 in Ph^1 translocation between CML and acute lymphocytic leukemia cases.[25] Further studies should be performed on more patients with t(7;11) to determine both its c-Ha-*ras*-1 localization and the involvement of this oncogene in the leukemic process.

*The number in the parenthesis shows the survival time from blastic crisis.

†The 7p breakpoint in these cases recently has been revised to be 7p15 (see the text).

In conclusion, the present study indicates that a t(7;11)-associated leukemia represents a subtype of myeloid malignancy showing characteristic clinicohematologic features as described earlier. Considering that all of the 14 patients with t(7;11) thus far reported are Japanese, its occurrence might show an uneven geographic distribution, as has already been found for the t(8;21) and t(15;17) translocations, both of which showed a much higher incidence in Japan than in other countries.[6,7,26] Nevertheless, careful observation may help to detect leukemia patients with t(7;11) in other countries, particularly because two non-Japanese patients with myeloid malignancy have recently been reported to have the t(7;11) abnormality.[27]

ACKNOWLEDGMENT

We would like to thank Messrs M. Murai, M. Sonoyama, and M. Todoroki for their excellent technical assistance. We are grateful to Drs O. Nakazawa, Asahikawa Red Cross Hospital; R. Mizutani, Second Department of Internal Medicine, Medical College of Oita; T. Ohshima, First Department of Internal Medicine, Nihon University; and A. Kuromoto, Department of Hematology, Research Institute for Nuclear Medicine and Biology, Hiroshima University, for providing the clinical data of some patients studied.

Philadelphia-Positive Chronic Myeloid Leukemia With a Chromosome 22 Breakpoint Outside the Breakpoint Cluster Region

By Licia Selleri, Franco Narni, Giovanni Emilia, Alessandro Colò, Patrizia Zucchini, Donatella Venturelli,
Amedea Donelli, Umberto Torelli, and Giuseppe Torelli

In chronic myelogenous leukemia (CML) the reciprocal translocation resulting in the Philadelphia chromosome (Ph^1) leads to the formation of a chimeric transcriptional unit carrying both c-*abl* and *bcr* genetic information whose transcript is a new fused mRNA of 8.5-kilobases (kb) and whose translational product is a 210-kD phosphoprotein with tyrosine kinase activity implicated in the pathogenesis of CML. Twenty patients affected by Ph^1-positive CML were studied by Southern blot analysis with *bcr*. Unexpectedly, in three Ph^1-positive patients, the breakpoint of chromsome 22 was located neither inside the *bcr* region nor 5′ to it. Northern blot analysis of the RNAs of two of these patients showed the absence of a detectable 8.5-kb chimeric mRNA. In the third patient a chimeric mRNA was detected by a c-*abl* cDNA probe but failed to hybridize with a *bcr* cDNA probe and showed very low hybridization levels with further 5′ *bcr* cDNA probes. The possibility is raised that in CML a breakpoint outside *bcr* might either still allow the formation of a chimeric mRNA, possibly through alternative splicing mechanisms, or might prevent the transcription of the chimera. In the latter case different molecular events resulting in the formation of a Ph^1 chromosome may underlie the same myeloid neoplastic phenotype.

© *1987 by Grune & Stratton, Inc.*

THE HALLMARK OF CHRONIC myeloid leukemia (CML) is the presence of a shortened chromosome 22, the Philadelphia (Ph^1) chromosome, in more than 90% of cases.[1] The Ph^1 chromosome, which can be considered the first karyotypic marker consistently present in a human neoplasia, is the result of a reciprocal translocation between chromosomes 9 and 22, t(9;22) (q34;q11).[2] This translocation moves the c-*abl* protooncogene from chromosome 9 to chromosome 22[3] and the c-*sis* protooncogene from 22 to 9.[4]

The breakpoint of chromosome 9 has been found to occur at variable sites in a region of up to 100 kilobases (kb) 5′ upstream from the first v-*abl*-related human c-*abl* sequence.[5] On the other hand, the breakpoint of chromosome 22 has been shown to be clustered within a limited region of about 5.8 kb, the breakpoint cluster region (*bcr*),[6] which is the middle portion of a transcribed gene of unknown function.[7]

The reciprocal translocation therefore brings the 5′ end of the c-*abl* oncogene into head-to-tail juxtaposition with the truncated 3′ portion of *bcr* on chromosome 22. This mechanism leads to the formation of a new chimeric transcriptional unit containing genetic information from both c-*abl* and *bcr* genes[7] whose resulting transcript is a new fused mRNA of about 8.5 kb.[8]

The translational product of this hybrid mRNA is a 210-kD phosphoprotein with tyrosine kinase activity. This protein is larger than the normal p145 kD c-*abl* protein because of a replacement of aminoterminal c-*abl* sequences by *bcr* sequences.[9] Interestingly, the aminoterminal alteration is in fact responsible for the transforming activity of v-*abl* in Abelson murine leukemia virus.[10] This seems to raise the question whether the altererd *abl* protein may play a role as a transforming protein in the pathogenesis of CML.

Therefore the most important genomic event in CML seems to be the juxtaposition of c-*abl* with the broken *bcr* gene. Although the breakpoint on chromosome 9 is quite variable and therefore the length of the hybrid *bcr*/*abl* gene also varies, the fused mRNA is consistent from patient to patient as a result of primary transcript splicing.[8]

It is now well established that in Ph^1-positive acute lymphocytic leukemia (ALL) the breakpoint of chromosome 22 can take place outside the *bcr* region.[11] In such cases a novel 6.5-kb chimeric mRNA[12] and a novel 190-kD chimeric protein[12-14] were observed. On the other hand, some observations seemed to suggest that perhaps in CML too the breakpoints on chromosome 22 are more heterogeneous than previously recognized.[6,15] This focused our attention on the importance of analyzing as many as possible Ph^1-positive CML patients to examine, by Southern blot analysis with a *bcr* probe, how large a variation there could be in the location of chromosome 22 breakpoints that still allows the formation of the novel chimeric mRNA.

PATIENTS AND METHODS

Patients. Twenty adult patients affected by typical Ph^1-positive CML were studied. In all cases leukapheresis procedures as well as bone marrow aspirations were performed after informed and explicit consent of the patient was obtained, as required by our institutional guidelines. Ten patients were in chronic phase, three were in accelerated phase, and 7 were in blast crisis (BC). Leukemic cells were obtained by leukapheresis.

Cytogenetic studies. Cytogenetic studies were performed on bone marrow and/or peripheral blood cells after a 24-hour incubation in tissue culture media without mitogen, and standard trypsin Giemsa chromosome preparations were made. The karyotype was expressed by using the recommendations of the International System for Human Cytogenetic Nomenclature.[16]

Southern and Northern blots. Leukocyte-enriched plasma was diluted in RPMI and centrifuged to obtain cell pellets from which nucleic acids were extracted. DNA was isolated according to the technique of Gross-Bellard et al with minor modifications[17] Control DNA was extracted from leukocytes of two normal blood donors.

Ten micrograms of each DNA was digested with the restriction endonucleases *Bam*HI, *Bgl*II, *Bam*HI together with *Bgl*II, *Eco*RI and *Hin*dIII; run in 0.7% agarose gel electrophoresis; and then transferred to a Gene Screen (NEN) membrane with a standard Southern blot technique.[18]

RNA was extracted by following the technique described by Torelli et al.[19] Total RNA was then enriched for polyadenylate-containing RNA by one cycle of purification on oligo-dT-cellulose affinity chromatography.[20] Ten micrograms of poly (A)+ RNA were size fractionated by electrophoresis on 0.8% agarose gel containing 7% formaldehyde and then transferred to nitrocellulose filters as described.[20]

Preparation of DNA probes. To study the rearrangement of *bcr* we used a subgenomic probe represented by a *Hin*dIII-*Bgl*II genomic restriction fragment of 1.2-kb (Pr-1, Oncogene Sciences, Inc, Mineola, NY) that corresponded to an intron region of the gene located in the middle of the *bcr* region[6] and two contiguous *bcr* cDNA fragments of 0.6 kb (6.13-0.6) and 0.3 kb (6.13-0.3) representing a coding portion of the gene 5′ to the *bcr* region. The cDNA fragments used to study the expression of the chimeric mRNA were represented by a 0.5-kb human *bcr* cDNA restriction fragment (Pr-2, Oncogene Sciences) isolated from cDNA V1-3[21] and by *bcr* cDNA probes (6.13 and K31) corresponding together to a coding segment of about 1.4 kb 5′ to the sequences represented by the *bcr* probe Pr-2. Furthermore, a human c-*abl* cDNA fragment of 1.7 kb (K38) corresponding to the 3′ end of the c-*abl* cDNA was used.

The probes 6.13, K31, and K38 were developed and generously provided by Dr G. Grosveld, Erasmus University, Rotterdam, The Netherlands. A c-*sis* probe corresponding to a 1.7-kb *Bam*HI subgenomic fragment cloned into pBR 322[22] was used to examine whether a possible breakpoint had occurred in the subbands q12.3 to q13.1. A C_λ probe corresponding to a 0.8-kb *Eco*RI subgenomic fragment containing the $C_{\lambda 1}$ light-chain gene[23] was used to study the presence of a possible breakpoint in the subband q11.12.

To define as precisely as possible that some of the cases pertained to the myeloid lineage, a probe for C_μ was used that corresponded to a 1.2 *Eco*RI restriction fragment containing a part of the first and all of the second and the third exon of the Ig heavy-chain μ gene.[24] A probe for T cell receptor (TCR) β was further used and corresponded to a 0.77-kb insert containing J and C regions cloned in the *Pst*I site of pBR 322.[25]

All the probes were nick-translated with α^{32}P deoxycytidine triphosphate (dCTP) to a specific activity of about 2×10^8 cpm/μg DNA.

Hybridization and autoradiography. Southern and Northern blot hybridizations were performed according to procedures already described in detail.[26] Washing of the Southern blot filters was carried out in 0.3× SSC at 65°C. Washing of the Northern blot filters was performed in 0.1× SSC at 65°C. Autoradiography was performed at −80°C with intensifier screens for two to seven days.

RESULTS

All 20 adult patients studied were affected by CML diagnosed according to French-American-British (FAB) morphological and cytochemical criteria.[27] Ten patients were in fact in chronic phase, three in accelerated phase, and seven in BC. Cytogenetic analysis of all patients showed the typical t(9;22) translocations, except in one case in which a simple variant translocation of the type t(22;22) was present. Most patients in BC showed numerical chromosomal abnormalities (hyperdiploidy) and/or Ph[1] duplication as expected.[28]

No c-*abl* rearrangement was detected in any of the cases studied,[29] which did not seem surprising because the chromosome 9 breakpoints can occur in a region very far upstream to the first c-*abl* exons. Concerning chromosome 22 breakpoints, restriction data of 17 of 20 patients together with cytogenetic data have already been discussed in detail elsewhere[29] and are consistent with the results already reported in the literature.[6,7]

In three cases rather unexpectedly (T.V., R.G., and Q.S., all in chronic phase), no rearranged bands were detectable after digestion of the DNA with the restriction endonucleases *Bam*HI, *Bgl*II, *Hin*dIII, *Eco*RI (Fig 1), and *Bam*HI together with *Bgl*II (not shown). In fact, with all the aforementioned restriction enzymes in all three cases, the hybridization with the 1.2-kb *Hin*dIII-*Bgl*II *bcr* genomic fragment showed only the normal germ line band as in the control DNA from normal leukocytes; they measured, respectively, 3.3 kb in the *Bam*HI-digested DNAs, 5.0 Kb in the *Bgl*II-digested DNAs, 4.5 kb in the *Hin*dIII-digested DNAs, 23 kb in the *Eco*RI-digested DNAs (Fig 1), and 2.1 kb in the same DNAs digested with *Bgl*II together with *Bam*HI. These experiments were performed twice for all three patients with different blood samples collected within an interval of few months. In all three cases both Ig heavy-chain and TCR β chain genes were in a germ line configuration (data not shown), which confirmed, in addition to the

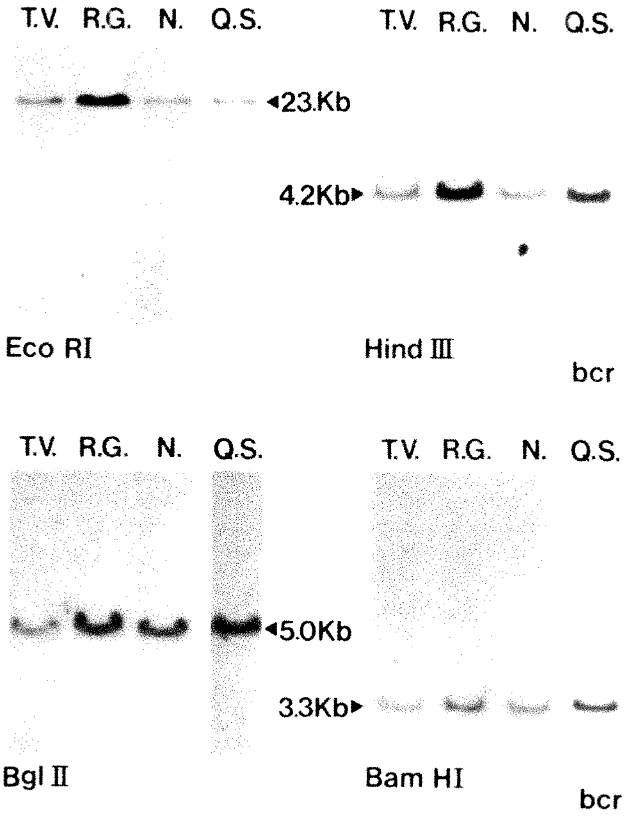

Fig 1. Southern blot analysis of the DNAs of the three patients (T.V., R.G., and Q.S.) that were digested with *Eco*RI, *Hin*dIII, *Bgl*II, and *Bam*HI and hybridized to the 1.2-kb *Hin*dIII-*Bgl*II *bcr* genomic fragment (Pr-1). No rearranged bands are present in any of the cases with all the restriction enzymes. Only the normal band, as in control DNA of normal leukocytes (N), is present with all the enzymes in all three cases.

FAB morphological and cytochemical data, that patients' leukemic cells were of the myeloid lineage.

Our findings suggested that in these three patients the breakpoint was located either 5′ or 3′ to the *bcr*, but certainly not within it despite the fact that in all three cases a t(9;22) translocation was present (Fig 2) in two successive cytogenetic analyses carried out within an interval of several months and despite the typical CML phenotype. It must be added that the peripheral cell populations studied were formed by a vast majority (>80%) of largely immature myeloid elements and that the Ph^1 translocation was observed in more than 90% of the metaphases analyzed in each case.

Because it was suggested that in Ph^1-positive ALL cases the breakpoints of chromosome 22 could be located 5′ to the *bcr* region,[11,30] we explored the possibility that a similar genomic event could have taken place in our CML patients. Therefore in Southern blot experiments we used the probes 6.13-0.6 (0.6 kb) and 6.13-0.3 (0.3 kb), which represent together 0.9 kb corresponding to the middle portion of the *bcr* cDNA sequences 5′ upstream the *bcr* region[21] (G. Grosveld, personal communication). Again the pattern obtained after digestion with *Bam*HI, *Bgl*II, and *Eco*RI was in all three cases identical to that of normal leukocyte DNA, both with the 0.6 kb probe (data not shown) and with the more 5′, 0.3-kb probe (Fig 3).

The DNAs of the three patients were then hybridized to the c-*sis* probe after digestion with *Eco*RI and *Hin*dIII and to the C_λ probe after digestion with *Eco*RI, *Bam*HI, and *Hin*dIII. No rearranged bands were found in any case, either with c-*sis* or with C_λ with all the restriction enzymes used (data not shown). With the c-*sis* probe, however, two of the three patients (T.V. and R.G.) exhibited a polymorphic pattern already described[31] after digestion with *Hin*dIII that gave bands of about 21.7 kb and 14.5 kb (not shown). Furthermore, in one of the three patients (R.G.) a polymorphic restriction pattern, already described,[31] was also observed in the *Eco*RI-digested DNA hybridized to the C_λ probe that gave an additional band of about 22 kb (not shown).

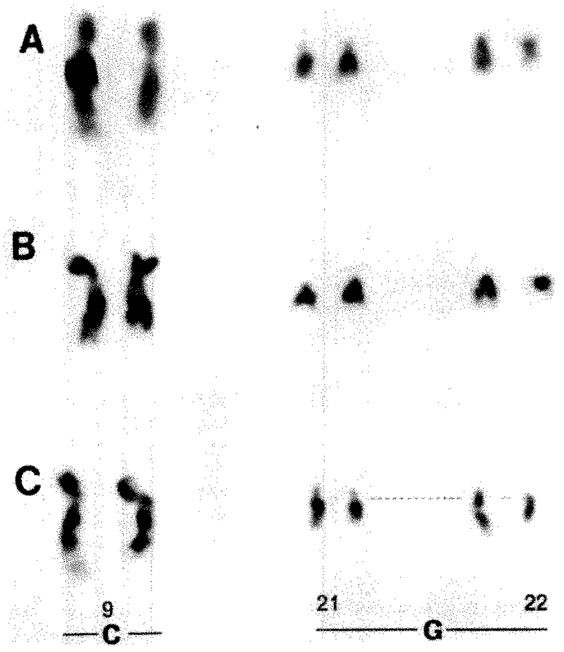

Fig 2. Partial karyotypes of the three patients showing a t(9;22) translocation in all cases. 1, the patient T.V; 2, R.G; and 3, Q.S.

As far as the expression of *bcr* is concerned, the poly (A)+ RNAs of the three described patients together with the poly (A)+ RNAs derived from two other classic Ph^1-positive CML cases were hybridized on the same filters with the *bcr* cDNA probe (Pr-2) representing exons 1 and 2 of the *bcr* region and at least two further *bcr* exons 5′ upstream to them. In all cases two faint bands representing normal *bcr* mRNA species were detected (Fig 4). A major 8.5-kb mRNA species was detectable only in the RNAs analyzed as controls and was apparently absent in the RNAs of the three patients already mentioned (Fig 4) despite the fact that the chimeric mRNA, when present, is usually more abundant than the normal *bcr* mRNA transcripts.[8]

We then submitted the same RNAs to a further Northern blot analysis using a c-*abl* c-DNA probe (K38). This experiment revealed, both in poly (A)+ and total RNA of one case (T.V.), the presence, in addition to the normal expected bands, of a faint but still detectable band of about 8.5 kb while confirming the absence of a chimeric mRNA species in the remaining two cases (Fig 5). The results obtained in patient T.V. led us to investigate whether the chimeric mRNA might be detected by *bcr* cDNA probes representing coding sequences located more 5′ to those represented by Pr-2. In fact Northern blot analysis of the poly (A)+ RNA of patient T.V., which was carried out with the *bcr* cDNA probes 6.13 and K31 and represented together about 1.4-kb sequences 5′ to the Pr-2 sequences, revealed extremely faint bands, one of which apparently corresponds to the chimeric mRNA present in a classic CML case (Fig 6). The same experiment did not show any detectable level of chimeric mRNA in patient Q.S. (Fig 6) or patient R.G. (not shown).

The densitometric analysis did not reveal relevant differences in the amount of RNA present in each lane in all experiments.

DISCUSSION

The analysis of our data led us to the conclusion that in these three patients affected by classic Ph^1-positive CML the breakpoint of chromosome 22 was certainly outside the *bcr* region. This finding seemed rather unusual, even though in the literature some evidence has already been reported of Ph^1-positive CML in which a breakpoint inside *bcr* was not found,[15] and it has been suggested that in CML the chromosome 22 breakpoints must be more heterogeneous than previously recognized.[6,15] Southern blot hybridizations with the *bcr* (Pr-1) probe suggested that in these three cases the breakpoint should be located either 5′ or 3′ to the *bcr* region.

Meanwhile, the absence of rearranged bands in the DNAs digested with different enzymes and hybridized with the probes Pr-1, 6.13-0.6, and 6.13-0.3 prevented us from localizing the breakpoint in the coding segments 5′ to the *bcr* in a region of about 13 kb flanking the 5′ site of the *bcr*.

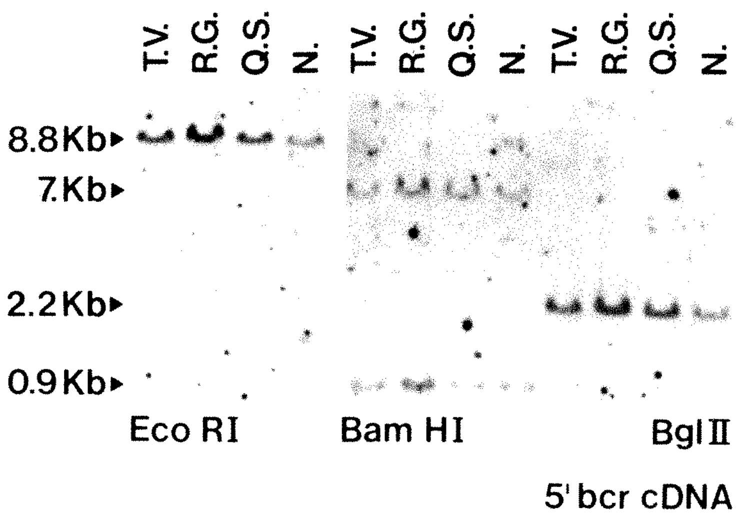

Fig 3. Southern blot analysis of the DNAs of the three patients (T.V., R.G., and Q.S.) that were digested with *Eco*RI, *Bam*HI, and *Bgl*II and hybridized to the 0.3-kb 5' *bcr* cDNA (6.13-0.3) probe. The restriction pattern with all the enzymes in all three cases is identical to that of normal leukocyte DNA (N). A faint hybridization signal of a previous hybridization of the same filter with probe 6.13-0.6 is still detectable in the region of about 8.0 kb in the DNAs digested with *Bgl*II.

Consequently, we reasoned that in these three cases the breakpoint should be located either in the far 3' extremity of the *bcr* gene or outside the gene.

The absence of rearranged bands with both C$_\lambda$ and c-*sis* probes made it clear that the breakpoint had occurred neither in the C$_\lambda$ locus located in the q11.12 subband nor in the c-*sis* locus harbored in the q12.3-13.1 subbands. At present we cannot explain the apparently high frequency of polymorphism of both these loci in these three cases.

With respect to the Northern blot hybridization data, we did not find a chimeric mRNA of 8.5 kb in two of these three Ph^1-positive CML patients. We are well aware of the uncertainties related to a quantitative evaluation of mRNA expressed at low level; nevertheless, our results indicate that in these two cases the level of transcription of the 8.5-kb mRNA, if present, must be at least much lower than in common Ph^1-positive CML. These findings seemed rather unusual because data reported in literature show the presence of this chimeric mRNA in practically all cases of Ph^1-positive CML studied thus far with rare exceptions.[32,33]

So the possibility is raised that a breakpoint of chromosome 22 outside the *bcr* region might result in a novel genomic structure that does not allow the transcription of a 8.5-kb chimeric mRNA, at least at a detectable level, while leaving unaffected the formation of the mRNA species presumed to be normally transcribed by the *bcr* and *abl* genes.[21]

A similar genomic event has been described in several patients affected by ALL with a t(9;22) translocation in which the *bcr* region was not involved in the chromosomal rearrangement.[11-14,30] By analogy with the reports in some Ph^1-positive ALL cases,[12-14] it would be worthwhile in these two cases to look for the presence of *abl*-derived kinases different from the chimeric p210 and from the normal p145 while taking in mind that the cells of these two cases are certainly not lymphoid.

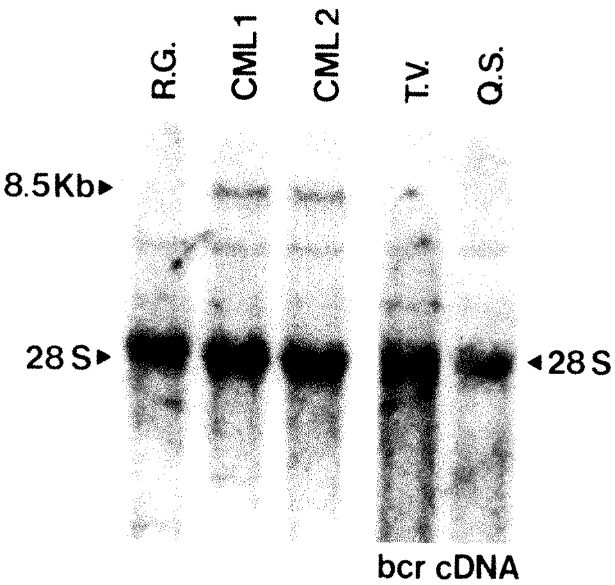

Fig 4. Northern blot analysis of the poly (A)+ RNAs of the three patients (R.G., T.V., and Q.S.) hybridized to the *bcr* cDNA probe (Pr-2). The 8.5-kb chimeric mRNA is clearly detectable only in the two CML populations used as controls (CML 1 and CML 2). The normal *bcr* mRNA species are present in all the populations.

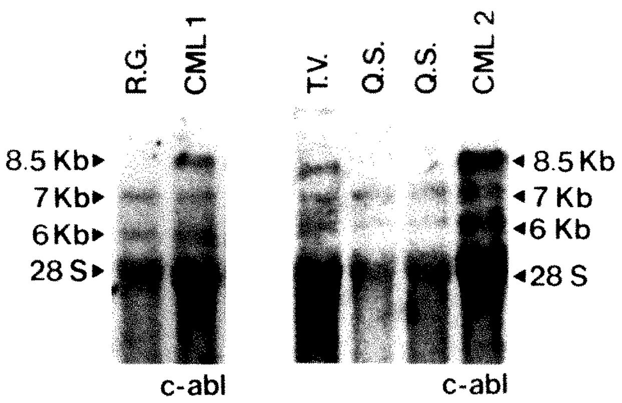

Fig 5. Northern blot analysis of the poly (A)+ RNAs of the three patients (R.G., T.V., and Q.S.) hybridized to the c-*abl* cDNA probe (K38). The 8.5-kb chimeric mRNA is clearly detectable only in the two CML populations used as controls (CML 1 and CML 2) and in one of the three patients (T.V.). The normal *abl* mRNA species of 6 and 7 kb are present in all the RNA populations.

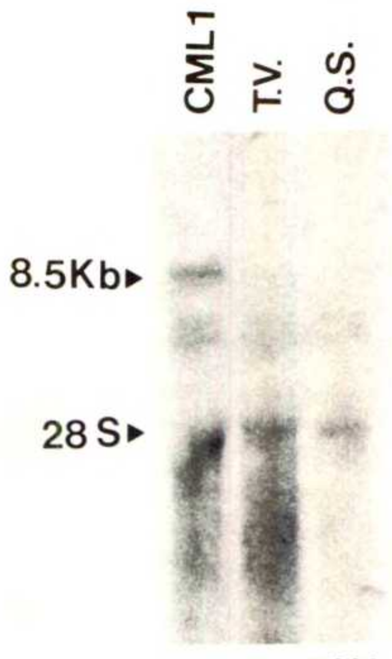

Fig 6. Northern blot analysis of the poly(A) + RNAs of patients T.V. and Q.S. that are hybridized to the 5′ *bcr* cDNA probes. The 8.5-kb chimeric mRNA is clearly detectable in the CML population used as control (CML 1). In patient T.V. an extremely faint band, apparently corresponding to the chimeric mRNA of CML 1, is detectable. In patient Q.S. no hybridization of chimeric mRNA is detectable. Normal *bcr* mRNA species are present in all the populations.

The third case (T.V.), in which the c-*abl* probe reveals the chimeric 8.5-kb mRNA, seems to suggest that unusual breakpoints sometimes may still allow the formation of a chimeric mRNA. The same mRNA species shows an extremely low level of hybridization with 5′ *bcr* cDNA sequences and apparently no hybridization at all with the 0.5-kb *bcr* probe representing only the sequences immediately flanking the breakpoint. These findings seem to suggest that the *bcr* portion of the chimera is in some way different from the classic one, possibly as a result of molecular events like deletions or alternative splicing.[34]

Because different molecular patterns underlie the same clinical features, it can be only suggested that the relationship between the genetic alteration of the Ph[1] event and the resulting neoplastic phenotype remains to be elucidated. While this manuscript was under preparation, other authors have reported identical molecular abnormalities., ie, *bcr* rearrangement as in Ph[1]-positive CML, in Ph[1]-negative CML cases with and without the classic clinical features of CML. They suggest that factors other than the *bcr-abl* rearrangement might underlie the heterogeneous clinical features of CML[35]

In view of all these results it will be necessary to carefullly define the genomic structure, the mRNA transcripts, and the presence of the related proteins in a larger number of CML patients.

ACKNOWLEDGMENT

The authors want to thank Dr Gerard Grosveld, Erasmus University, Rotterdam, for helpful suggestions, for the gift of the 6.13, K31, and k38 probes, and for kind revision of the manuscript; we would also like to acknowledge the expert technical assistance of B.M. Sala.

Establishment and Characterization of a Human Myeloid Cell Line From Philadelphia Chromosome–Negative Myeloblastic Leukemia Arising in a Patient With Myelodysplastic Syndrome

By Todd M. McCarty, S. Rajaraman, F.F.B. Elder, P. Gadson, and E. Brad Thompson

A new hematopoietic cell line derived from a patient with Philadelphia chromosome (Ph^1)-negative myeloblastic leukemia arising from a form of myelodysplastic syndrome (MDS) is described. This cell line, designated TMM, consists of immature cells with the morphological characteristics of young myeloblasts and grows in suspension culture with a doubling time of about 30 hours. By cytochemical analysis the cultured cells were positive for acid phosphatase. They were free of the Epstein-Barr virus–associated nuclear antigen as well as terminal deoxynucleotidyl transferase. Further phenotypic analysis revealed the expression of the myelomonocytic-specific antigen Leu-M1 and receptors for the Fc portion of IgG. Partial differentiation of these cells could be induced by dimethyl sulfoxide, tetradecanoyl phorbol acetate, or hypoxanthine and resulted in cells of the myeloid series expressing lysozyme and receptors for the C3b complement protein. The karyotype was 46,XY, lacked the Ph^1 chromosome, and displayed no abnormalities at the light microscopic level. No rearrangement of the *bcr-c-abl* gene complex was found. This cell line should be useful for studying an important type of the heterogeneous population constituting Ph^1-negative myeloblastic leukemia, arising in this instance from MDS, as well as for studying differentiation and proliferation of human pluripotent stem cells.

THE USE OF MODEL SYSTEMS to study human malignancies in vitro has been a productive approach in understanding the development, progression, and response to treatment of these disorders. But with the diversity of malignant disease collectively comprising the leukemias, no single model system has been satisfactory for all and in fact might be misleading for many. It is therefore important to examine various in vitro models representing the various specific categories of leukemia so as to better understand the mechanisms involved.

Dysplasias involving cells of mono/myeloid origin typify this diversity because they consist of distinct as well as ill-defined categories of disease. Although the Philadelphia chromosome (Ph^1) is found in about 90% of chronic myeloid leukemia (CML)[1] the fundamental nature of this disorder is unresolved. The remaining 10%, traditionally designated Ph^1-negative CML, is recognized as a biologically distinct subgroup.[2] More generally termed "a typical myeloproliferative disorder," this subgroup consists of a poorly understood heterogeneous population corresponding to much poorer prognoses.[2-4] In addition, a syndrome of myelodysplasia (MDS) having several subcategories has been defined in recent years, and patients with this syndrome have a high probability of developing leukemia.[5-18] Unfortunately, our ability to study this area of disease is limited, and a permanent in vitro model would be a valuable tool in understanding the nature of this disorder.

Although several Ph^1-positive CML cell lines have been established,[19-21] attempts to establish a Ph^1-negative CML cell line have been unsuccessful.[22] We are unaware of any cell lines having been established from patients with myelodysplastic syndromes (MDS).[23,24] Many myeloid cell lines originally expressing the Ph^1 chromosome have subsequently lost this marker, but lymphoblastoid cells carrying the Epstein-Barr virus resulted.[25-27] Here we describe the establishment and characterization of a Ph^1-negative CML cell line derived from a patient originally diagnosed as having Ph^1-negative CML in blast crisis. In review, the case history of the patient is consistent with an MDS progressing to a blastic phase. This cell line should prove beneficial in delineating the heterogeneity found within this category of disease, as well as in providing a new model system for studying differentiation and proliferation of human pluripotent stem cells.

MATERIALS AND METHODS

Case history. The TMM cell line was derived from the peripheral blood of a 62-year-old white male originally diagnosed as having Ph^1-negative CML in blast crisis. He was diagnosed as having chronic obstructive pulmonary disease in 1981 and treated with cephradine, vitamin K, theophylline, and terbutaline. In August 1984 he presented with a chronic buccal mucosa ulcer and was found to have thrombocytopenia (75,000/μL) and splenomegaly. His WBC was 17,100/μL with monocytosis (13%), and abnormal platelet morphology was observed. From that time until his death, the patient's blood cellularity was characterized by monocytosis (up to 59% on differential counts), frequently by eosinophilia (up to 24%), and by thrombocytopenia. In November 1984 he was diagnosed as having Ph^1-negative CML with a bone marrow karyotype of 46,XY, and a bone marrow biopsy that showed an M:E (myeloid:erythroid) of about 20:1, 5% to 10% myeloid blasts, numerous eosinophilic precursors, plus decreased and atypical megakaryocytes. Clinical discussions noted that this seemed an atypical case of CML, and in October 1985 the patient developed a marked increase in circulating blasts with progression of splenomegaly, pulmonary infiltrate, and anemia. He was treated with hydroxyurea and Depo-Testosterone. His WBC was 326,000/μL with 76% blasts, 1% banded neutrophils,

1% segmented neutrophils, 17% monocytes, and 5% lymphocytes. Leukapheresis was performed for three consecutive days, and although the WBC dropped to 100,000/μL the patient continued to deteriorate and died on October 23, 1985, of bronchopneumonia.

Cell culture. The leukapheresed blood was collected in a heparanized bag on October 17, 1985, when the patient's WBC was 223,000 with 69% blasts. Mononucleated cells were separated by Ficoll/sodium diatrizoate (Sigma Chemical Co, St Louis) density gradient centrifugation and suspended in RPMI 1640 medium (GIBCO, Chagrin Falls, OH) supplemented with 10% heat-inactivated fetal calf serum (KC Biological, Lenexa, KS). After a lag phase, cells with blast morphology began to grow. There was no massive loss of cells, and the cultured line seemed to develop from many cells rather than a few clones. Cells were grown as stationary-suspension cultures at 37°C in a humidified atmosphere of 95% air/5% CO_2. Cells were maintained in logrithmic growth by manual dilution to densities between 10^5 and 5×10^5 cells/mL as determined by a model Zf Coulter counter (Coulter Electronics, Hialeah, FL) and by manual counting using a hemocytometer. Cell viability was determined by the exclusion of trypan blue (0.5%) after a five-minute treatment.

Morphological and cytochemical analysis. Cytocentrifuge preparations were stained with Wright-Giemsa in the University of Texas Medical Branch (UTMB) Special Hematology Laboratory for morphological analysis. The slides were examined by several members of the Department of Hematology and the experienced technicians of the Special Hematology Laboratory. For cytochemical analysis the following staining reactions were performed: peroxidase, α-naphthyl butyrate esterase (α-NBE), naphthol ASD chloroacetate esterase (CAE), acid phosphatase, alkaline phosphatase, PAS, and α-naphthyl acetate esterase (Sigma), with L cells used as a positive control.

Epstein-Barr virus–associated nuclear antigen (EBNA) terminal deoxynucleotidyl transferase. Testing for the presence of Epstein-Barr virus–associated nuclear antigen (EBNA) was kindly performed by Dr Keith Ramsey of the UTMB, Department of Internal Medicine, by the method of Reedman and Klein.[28] Raji cells were used as a positive control while K-562 cells were used as a negative control. Terminal deoxynucleotidyl transferase (TdT) was assayed by indirect immunoflourescence using the BRL TdT kit. (Bethesda Research Laboratories, Bethesda, MD)

Ultrastructural analysis. Unstimulated TMM cells and TMM cells stimulated to differentiate with hypoxanthine were fixed for electron microscopy in 1.25% glutaraldehyde in Dulbecco's phosphate-buffered saline (PBS, Sigma) for 30 minutes at room temperature. Localization of endogenous peroxidase was carried out according to the procedure of Graham and Karnovsky.[29] The cells were viewed by using a Philips EM 300 transmission electron microscope (Mahwah, NJ). Electron microscopy was carried out in the UTMB Cancer Center Core Facility.

Analysis of cell marker antigens. Cytocentrifuge preparations were air-dried for one hour, fixed in cold acetone for ten minutes, and stained after reaction with various antibodies by using the avidin-biotin-peroxidase complex method. The slides were incubated with monoclonal antibodies Leu-M1, Leu-14, Leu-11B, Leu-15, Leu-9, and anti-CR1 (Becton Dickinson, Sunnyvale, CA) and monospecific polyclonal antibodies to lysozyme and α1-antichymotrypsin (Dako Laboratories, Santa Barbara, CA) for 60 minutes at room temperature in a humidified chamber. Sheep antimouse IgG $F(ab')_2$, goat antimouse IgM $F(ab')_2$ or goat antirabbit IgG $F\ (ab')_2$ (Cooper Biomedical, Westchester, PA) and streptavidin-biotin-peroxidase complex (Amersham Corp, Arlington Heights, IL) were used as the second and third reagents. The final reaction product was visualized after incubation with diaminobenzidine, 0.05% in PBS, pH 7.2, containing 0.02% H_2O_2. A single-step procedure using peroxidase-conjugated rabbit antihuman Ig (polyvalent) was carried out to detect surface Ig. The reactions were scored based on the intensity of the color reaction: (−) no reaction, (+) clearly positive, (++) strongly positive. When a positive reaction was seen, virtually all cells on the slide were positive. Controls included (*a*) omission of the primary antibody, (*b*) substitution of the primary antibody with preimmune serum of the same species, and (*c*) omission of primary and secondary antibodies.

Differentiation induction. Cells were suspended in growth medium containing various inducing agents and incubated for six days under our standard culture conditions. Dimethyl sulfoxide (DMSO) and tetradecanoyl phorbol acetate (TPA) were obtained from Sigma, St. Louis and hypoxanthine from Calbiochem-Behring Corp. (La Jolla, CA). DMSO was diluted to a concentration of 180 mmol/L in RPMI 1640, and TPA was dissolved in absolute ethanol and diluted in RPMI 1640 to a concentration of 10^{-7} mol/L. Hypoxanthine was dissolved in boiling serum-free RPMI 1640 medium at a concentration of 50 mol/L and immediately diluted for use to 5 mmol/L. The cells were suspended at a density of 10^5 cells/mL in each inducing agent and monitored throughout the six-day period. At the end of that time the cells were stained with Wright-Giemsa for morphological analysis. Cell morphology was evaluated by the experienced staff of the UTMB Special Hematology Laboratory who were unaware of the various treatments the cells had received as the slides were read. Functional analysis was determined by the expression of cell marker antigens.

Cytogenetic analysis. TMM cells were treated with Colcemid (Boehringer-Mannheim, Indianapolis) at a final concentration of 5×10^{-3} μg/mL for 40 minutes. The cells were then subjected to hypotonic treatment (0.075 mol/L KCl) for 15 minutes at 37°C, fixed, and air-dried to slides by following conventional cytogenetic methodology. Trypsin G-banding followed methods modified from Seabright.[30]

Restriction endonuclease analysis. DNA was extracted from cells, digested with endonuclease, subjected to electrophoresis in agar gels, and transferred from the gels to nitrocellulose filter paper as previously described.[31] The filters were probed with a 0.65-kilobase (kb) clone of *c-abl* or a 1.2-kb clone of *bcr* (both obtained from Oncogene Sciences, Inc, Mineola, NY) and labeled to a specific activity of $>10^8$ cpm/mg by a standard nick-translation technique.[32] Hybridization conditions were as described previously.[31]

RESULTS

Establishment of TMM cell line. The patient's leukapheresed cells were placed in culture medium at a density of 5×10^5 cells/mL and left undisturbed for 1 week. During that time about 30% of the cell population became pyknotic and nonviable. Cells that did not adhere to the growth chamber were removed and placed into fresh culture medium. Small aggregates of viable cells were evident at that time, and the first subculture was made. In the following 2 weeks about 60% of the cell population was viable, and the cell aggregates were actively proliferating. During the next 13 weeks the cells were manually diluted once a week to a density of 10^5 cells/mL and fed with fresh medium. After 16 weeks in culture medium the cells were 95% viable and had a doubling time of about 30 hours. Since that time they have been stable. The cells that have been in continuous culture for over 8 months continue to have a doubling time of about 30 hours and grow as a mix of single cells and free-floating aggregates.

Morphological analysis. The patient's cells originally received in our laboratory were of myeloblastic appearance, and the differential count of peripheral blood included some mature neutrophils and monocytes. The blasts had round or lobulated nuclei with basophilic cytoplasm and a few vacuoles (Fig 1A). The morphological appearance of TMM cells was consistently that of immature, undifferentiated blasts resembling the original leukemic cells. The cytoplasm was basophilic, devoid of granules, and contained a few vacuoles. The nuclei were spherical and contained fine chromatin strands that stained reddish purple. The nuclear-to-cytoplasmic ratio was high, and one to five nucleoli with sharply defined borders were discernible (Fig 1B).

Cytochemical analysis. Cytochemical analysis of the original leukapheresed leukemic cells resulted in 58% of the cells staining positive for peroxidase, 79% for α-NBE, and 100% for acid phosphatase. TMM cells were 100% positive for acid phosphatase, with a punctate pattern observed, but were negative for α-NBE. Both the original leukemic cells and TMM cells were negative for TdT. TMM cells were negative for EBNA (Table 1).

Ultrastructural analysis. Electron microscopy studies revealed that TMM cells contain the large, spherical nuclei typical of blasts. In the cytoplasm a few vacuoles together with other usual cytoplasmic structures such as mitchondria, rough endoplasmic reticulum, and microtubule organizing centers were seen (Fig 2A). No viral structures were found. The TMM cells treated by hypoxanthine (5 mmol/L) were smaller and had indented to segmented nuclei and more mature cytoplasm. Many spherical, homogenously electron-dense, peroxidase-positive cytoplasmic granules were present, similar in appearance to those of normal granulocytic cells (Fig 2B).

Table 1. Cytochemical Analysis of Original Leukapheresed Leukemic Cells and TMM Cells

	Original Leukapheresed Leukemic Cells (%)	TMM Cells (%)
CAE	0	0
α-NBE	79	0
Peroxidase	58	3
Acid phosphatase	100	100
Alkaline phosphatase	0	0
PAS	0	0
EBNA	NT	0
TdT	0	0

Abbreviation: NT, not tested.

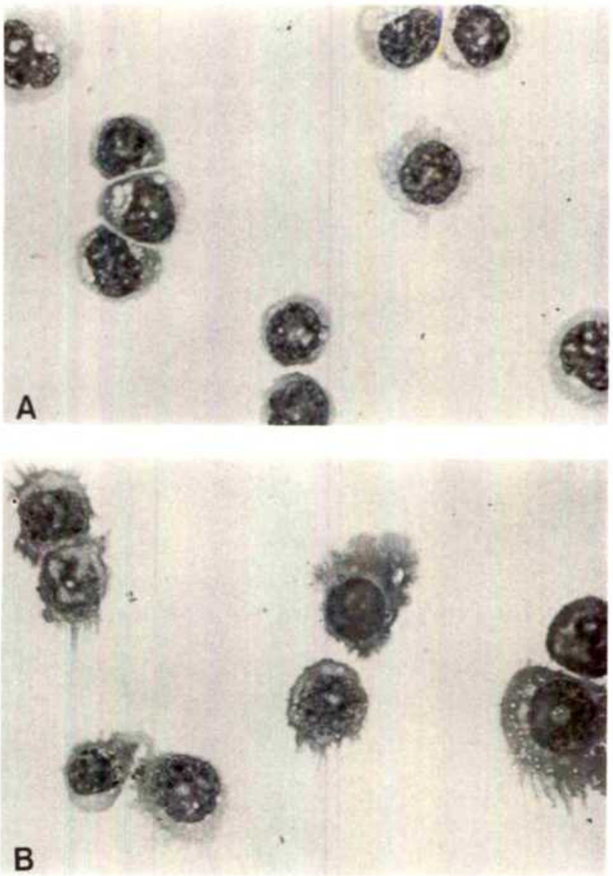

Fig 1. (A) Cytospin preparation of TMM cells stained with Wright-Giemsa (original magnification × 225; current magnification ×110). (B) Cytospin preparation of original leukapheresed leukemic cells stained with Wright-Gimesa (original magnification × 225; current magnification × 110).

Cell marker analysis. Both the original cells and TMM cells were surface Ig–negative, B-cell associated antigen (Leu-14)–negative, E rosette (Leu-9)–negative, Fc receptor (Leu-11b)–positive, myelomonocytic antigen (Leu-M1)–positive, α_1-antichymotrypsin–negative, C3b receptor (anti-CR1)–negative, and C3bi receptor (Leu-15)–negative. The original cells were positive for lysozyme, whereas TMM cells were negative (Table 2).

Differentiation induction. The uninduced TMM cells contained 2% mature myeloid cells. TPA and hypoxanthine each stimulated partial morphological maturation (42% and 68%, respectively) to cells with the appearance of early myeloid precursors while also inducing lysozyme and receptors for the C3b complement protein. TPA treatment did not stimulate increased adherence to the surface of the culture vessel but did slightly increase the tendency for cells to adhere to another. TPA did not induce α-naphthyl acetate esterase. Neither hypoxanthine nor TPA caused any of the cells to take on the appearance of monocyte/macrophage-like cells. DMSO also stimulated the cells to express lysozyme, but did not induce morphological maturation (Table 2).

Cytogenetic analysis. Cytogenetic analysis of 25 G-banded metaphase cells showed a range of 43 to 46 chromosomes. The modal number was 46 (22 of 25 cells), and the karyotype was 46,XY (Fig 3). The remaining three cells had karyotypes of 45,XY,−12, 44,XY,−7,−12; and 43,XY,−12,−21,−22, respectively. Scoring of 100 randomly selected metaphases showed 2% of the cells to be in the tetraploid range.

Lack of bcr-c-abl *complex rearrangement.* Although TMM cells lack the Ph^1 chromosome, instances are known in which euploid cells show rearrangement of the c-*abl* gene and *bcr* gene. Restriction endonuclease digestion and Southern blot analysis of DNA from TMM cells and the leukemic

patient's peripheral blood cells has not as yet shown any such rearrangement (Fig 4).

DISCUSSION

We herein described a novel cell line, designated TMM, derived from the peripheral blood of a 62-year-old male with a form of Ph^1-negative myeloblastic disease arising from what, in retrospect, was MDS. Several features of the patient's blood and marrow point to the blast crisis arising from an MDS, ie, thrombocytopenia with abnormal megakaryocytes, monocytosis with peripheral monocytes and promonocytes $>1 \times 10^9$/L, and abnormal erythrocytes with anemia. Therefore a current definition of the patient's disease might be MDS with chronic myleomonocytic leukemia (CMML).[6] No sideroblasts were seen, and disgranulopoiesis was not commented on in the patient's hematologic records. The relative eosinophilia is not typical and remains unexplained.

When compared, the similarity of its cellular characteristics to the original leukemic cells, and the lack of EBNA and TdT indicate that the line we have established is of blast cell origin. Cytochemical analysis showed positive, punctuate staining for acid phosphatase, and morphological studies revealed a majority of undifferentiated cells with large spherical nuclei and cytoplasm devoid of granules. A few (2%) promyelocytes, myelocytes, and metamyelocytes were also observed. The majority (90%) of the cells had a karyotype of 46,XY and expressed no chromosomal abnormalities at the light microscopic level. Restriction endonuclease digestion followed by Southern blotting showed no evidence for cryptic rearrangement of the *bcr*-c-*abl* loci. As shown in Table 2 the TMM cells expressed the myelomonocytic-specific antigen Leu-M1 as well as receptors for the Fc portion of IgG. Both myeloid and monocytoid differentiation involve expression of the Fc receptor, and therefore TMM cells were induced to differentiate to help determine their classification. Phorbol esters, purines and purine analogues, and polar planar compounds stimulate myeloid, erythroid, and monocytoid differentiation in a variety of leukemia cell lines,[23,24,33,34] and therefore TPA, hypoxanthine, and DMSO were tested on TMM cells. Induced differentiation of this line by TPA and hypoxanthine resulted in cells morphologically resembling somewhat more mature cells of the myeloid lineage and stimulated expression of lysozyme and receptors for the C3b complement protein. DMSO stimulated the expression of lysozyme only. Ultrastructural analysis of hypoxanthine-induced cells showed a higher degree of differentiation compared with unstimulated TMM cells. The induced cells were smaller and had indented to segmented nuclei and more mature cytoplasm containing many granules that stained positive for peroxidase. Such granules, reported to contain lysozyme, myeloperoxidase, and many acid hydrolases,[35,36] are important in the inflammatory, and, in associa-

DNA from lanes A and a, patient's leukapheresed cells; lanes B and b, TMM cultured cells; lanes C and c, normal periperal leukocytes. Lanes A, B, and C were probed with *bcr*; lanes a, b, and c, with c-*abl*.

tion with C3b receptors, the immune response of granulocytes. The characteristics of induced TMM cells were considered to be consistent with these properties. The lack of C3bi receptors and α_1-antichymotrypsin and the inability of the cells to adhere to the growth chamber suggest that these compounds do not induce characteristics of the monocyte/macrophage lineage. TPA treatment did not induce a nonspecific esterase (α-naphthyl acetate esterase). It is unusual for phobol esters to induce differentiation toward the granulocytic lineage; however morphologically at least, that seems to have occurred in this case. The action of phorbol esters is complex; certain concentrations of TPA plus colony-stimulating factor can stimulate the proliferation of leukemic cells in vitro, and TPA can increase the number of myeloid cells per colony in tests with cells from patients with chronic myelogenous leukemia.[37-39] The biochemical markers examined thus far are consistent with the TPA induction of myeloid morphology, but of course the list of markers that can be tested is long, and leukemic cells often show irregular or inconsistent marker expression[24] so that it may be that with further testing other markers will behave differently. It is also possible that monocytoid differentiation could be induced by using other compounds.

Cell lines cultured from the blast crisis phase of various leukemias have differing properties, and these have been used to advantage in many studies. In CML, although granulocytic cells usually predominate in the chronic phase, blast crisis can result in various lineages predominating in various patients, including myeloid, lymphoid, and erythroid types.[40,41] K-562 cells, derived from a patient with CML in blast crisis, express erythroid characteristics,[42] whereas MEG-01, also established from a patient with CML in blast crisis, has megakaryocytic properties.[43] Recent evidence indicates T-cell[44] as well as B-cell involvement in blast crisis, the latter reported in the CML cell line NALM-1.[45] TMM, the new line reported here, was obtained from a patient whose clinical studies fit the criteria for MDS with CMML. TMM cells have characteristics not found in these previously established lines. TMM cells therefore may prove useful in studying the process of differentiation and proliferation of human pluripotent stem cells.

Within CML, variation in prognosis has been suggested to correlate with gene rearrangements associated with the Ph^1 chromosome. Although about 10% of CML patients lack the Ph^1 chromosome, some of these still show an associated molecular aberration involving the protooncogenes c-*sis* and c-*abl*.[46-49] C-*sis* is usually not expressed in these cells, but a c-*sis* gene product and/or platelet-derived growth factor, which share homologous sequences, may play a role in myelofibrosis, which often accompanies CML.[50,51] On the other hand, c-*abl* has been found to be rearranged to show increased expression in all cases of Ph^1-positive and in some Ph^1-negative CML.[52] An aberrant 8-kb c-*abl* mRNA transcript as well as the corresponding abnormal protein has been found in many of these patients[48,53] and in the Ph^1-positive CML cell line K-562.[54,55] Morris et al[49] have recently reported that differences in the location and expression of c-*abl* correlate with the survival heterogeneity found by Canellos et al[3] and the Rosewell Park Memorial Institute study of Ph^1-negative CML patients.[2] The value of in vitro models that would enable the expansion of our knowledge in this ill-defined category of myeloid leukemia has recently been noted.[49] It appears that patients with the normal c-*abl* gene have a much shorter survival time. Nonrandom cytogentic abnormalities have been reported in MDS. Most often these have been specific deletions or translocations, including −5, 5q−, −7, +8, 20q−, t(8:21), and +/−21.[7] Because of this, because the TMM cell line reported here came from a patient originally diagnosed as having Ph^1-negative CML, and because in any case this patient had a CMML within an MDS, the cells were tested for a cryptic rearrangement of the *bcr*-c-*abl* complex. At least one report, however, has been made of chronic MDS with the Ph^1 chromosome.[56] On the basis of our findings to date, the *bcr*-c-*abl* complex is normal in TMM cells. Again, this new cell line may be useful to workers interested in this poorly understood area of disease.

ACKNOWLEDGMENT

The authors acknowledge the expert technical assistance of members of the UTMB Special Hematology Laboratory. We also thank Drs F.H. Gardner, H.S. Juneja, J.B. Alperin, and K. Ramsey of the Department of Internal Medicine, Division of Hematology, UTMB, for their helpful discussions and interpretations of the clinical and hematopathologic case data.

Thrombin-Induced Changes in Platelet Membrane Glycoproteins Ib, IX, and IIb-IIIa Complex

By Alan D. Michelson and Marc R. Barnard

Platelet membrane glycoprotein Ib (GPIb) and the GPIIb-IIIa complex have central roles in the interaction of platelets with the plasma coagulation system, damaged vessel walls, and other platelets. We investigated the effects of thrombin on these glycoproteins. Monoclonal antibodies were used to assess platelet surface glycoproteins by flow cytometry, total platelet glycoprotein content by immunoassay, and glycoproteins released from platelets, also by immunoassay. Five new observations were made with regard to thrombin-induced changes in platelet membrane glycoproteins: (*a*) The marked decrease in platelet surface binding of antibodies directed at GPIb was not confined to antibodies directed at the von Willebrand factor binding site. (*b*) There was a marked decrease in platelet surface binding of an antibody directed at GPIX, with maintenance of the 1:1 ratio of platelet surface binding of antibodies directed at GPIb and GPIX. (*c*) Changes in platelet surface binding of antibodies were not restricted to a distinct subpopulation of platelets. (*d*) There was no associated platelet release of glycocalicin (a proteolytic fragment of GPIb). (*e*) There was no associated platelet release of the GPIIb-IIIa complex. These thrombin-induced changes may be important in modulating the reactivity of platelets with the damaged vessel wall and with each other.

© 1987 by Grune & Stratton, Inc.

PLATELET MEMBRANE GLYCOPROTEIN (GP)Ib and the GPIIb-IIIa complex have central roles in the interaction of platelets with the plasma coagulation system, with damaged blood vessel walls, and with other platelets.[1] First, the glycocalicin portion of the α chain of GPIb contains a binding site(s) for thrombin.[2,3] Second, platelet adhesion to damaged blood vessel walls is mediated by the binding of the adhesive glycoprotein von Willebrand factor (vWf) to the glycocalicin portion of the α chain of platelet membrane GPIb.[1,4,5] Third, platelet aggregation is mediated by the activation-dependent binding of several adhesive glycoproteins, including fibrinogen, fibronectin, and vWf, to the platelet membrane GPIIb-IIIa complex.[1,6-8]

Thrombin-induced changes in GPIb and the GPIIb-IIIa complex may be important in modulating the reactivity of platelets with the damaged vessel wall and with other platelets. George et al[9] recently demonstrated that thrombin activation of platelets results in decreased binding of a monoclonal antibody directed at the vWf binding site on GPIb. A number of investigators have observed a thrombin-induced increase in the platelet surface expression of the GPIIb-IIIa complex.[9-12]

In unactivated platelets, platelet membrane GPIX is bound to platelet surface GPIb in a 1:1 ratio (the GPIb-IX complex).[13,14] However, the function of GPIX is unknown. In addition to their platelet surface pools, GPIb and the GPIIb-IIIa complex are present in intraplatelet pools.[10,11,15]

In the present study, a library of monoclonal antibodies was used to investigate thrombin-induced changes in GPIb, GPIX, and the GPIIb-IIIa complex. Different pools of these glycoproteins were assessed by the following techniques: (*a*) platelet surface glycoproteins by flow cytometry,[16,17] (*b*) glycoproteins released from platelets by enzyme-linked immunosorbent assay (ELISA),[5,18] and (*c*) total platelet glycoprotein content by ELISA of Triton X-100 platelet lysates.

MATERIALS AND METHODS

Antibodies. Table 1 lists the eight murine monoclonal antibodies used in this study. We used three different antibodies (6D1, WM23, and 3G6) directed against the glycocalicin portion of the α chain of platelet membrane GPIb. Antibody 6D1 is directed at or very near the vWf binding site on GPIb,[4] whereas WM23 and 3G6 are not directed against the vWf binding site (Berndt et al[13] and B. Adelman, personal communication). WM23 has been characterized as being directed against the macroglycopeptide portion of glycocalicin rather than the terminal protein portion that contains the vWf and 6D1 binding sites (M.C. Berndt, personal communication). After complete platelet solubilization with sodium dodecyl sulfate, polyacrylamide gel electrophoresis and Western blotting, both 3G6 (B. Adelman, personal communication) and WM23 (M.C. Berndt, personal communication) recognize only a single band (GPIb) in both reduced and unreduced gels. FMC25 is directed against platelet membrane GPIX.[13,19] Antibody 10E5 is directed against the platelet membrane GPIIb-IIIa complex.[20] WM18 is also directed against the platelet membrane GPIIb-IIIa complex but at a different epitope to 10E5 because WM18 has little effect on platelet aggregation (M.C. Berndt, personal communication), whereas 10E5 inhibits platelet aggregation induced by adenosine diphosphate (ADP), epinephrine, and collagen.[20] As a marker of platelet activation, we used KC4, a monoclonal antibody directed against the platelet activation–dependent granule–external membrane (PADGEM) protein.[21,22] PADGEM protein is a component of the α granule membrane of resting platelets that is expressed on the platelet plasma membrane during platelet activation.[22] PADGEM protein is distinct from the surface glycoproteins of resting platelets but identical to GMP-140, the antigen recognized by monoclonal antibody S12.[22,23] As a control in the flow cytometric assay, we used OX6, a monoclonal antibody directed against rat lymphocyte Ia antigen.[24]

Thrombin activation of washed platelets. Blood was drawn by venipuncture from healthy adult volunteers who had not ingested aspirin within the previous ten days. The blood was drawn directly into a syringe containing $1/7$ vol of acid-citrate-dextrose (85 mmol/L trisodium citrate, 71 mmol/L citric acid, 111 mmol/L dextrose, pH 4.5) and 50 ng/mL (final concentration) prostaglandin E_1 (PGE_1, Sigma Chemical Co, St Louis). After resting for one hour at 22°C, the blood was centrifuged at 150 g for 15 minutes at 22°C and the platelet-rich plasma removed. The platelets were washed twice by centrifugation at 2,000 g for ten minutes at 22°C and resuspension in Tyrode's buffer (138 mmol/L NaCl, 29 mmol/L KCl, 12 mmol/L $NaHCO_3$, 0.4 mmol/L $NaHPO_4$, 0.1% glucose, 0.35% bovine serum albumin, pH 6.5) with 50 ng/mL PGE_1. After the second wash, 5×10^5 platelets/μL were suspended in Tyrode's buffer, pH 7.3, with 50 ng/mL PGE_1 and either 5 mmol/L EDTA or 2 mmol/L $CaCl_2$. Purified human α-thrombin (generously provided by Dr John Fenton II, New York Department of Health, Albany) at concentrations between 6.4×10^{-5}, and 1.0 U/10^8 platelets was added to the sample, which was then gently inverted once. In control assays performed in parallel, buffer only (no thrombin) was added. The samples were incubated undisturbed (to prevent platelet aggregation) for ten minutes at 37°C. To stop the reaction, hirudin (Sigma), 2.0 U/10^8 platelets, was added to all samples, including those with no thrombin. After gentle inversion, the samples were incubated at 22°C for five minutes. Each sample was then divided into two separate aliquots. The first aliquot was fixed at 22°C for 30 minutes with an equal volume of 2% formaldehyde in Tyrode's buffer, pH 7.3, with either 5 mmol/L EDTA or 2 mmol/L $CaCl_2$. These samples were then washed twice in Tris-buffered saline (10 mmol/L Tris-HCl, 0.15 mol/L NaCl, pH 7.8) by centrifugation at 2,000 g for ten minutes at 22°C, resuspended at 50,000 platelets/μL in Tris-buffered saline, and assayed by flow cytometry for platelet surface glycoproteins (see the next section). The second aliquot of thrombin-activated and control platelets was centrifuged at 2,000 g for ten minutes at 22°C. The supernatants were removed for ELISA determination of platelet release of glycocalicin (a proteolytic fragment of GPIb) and the GPIIb-IIIa complex (see later). The platelet pellets were lysed in Tyrode's buffer containing 1% Triton X-100 (Sigma), 50ng/mL PGE_1, and either 5 mmol/L EDTA or 2 mmol/L $CaCl_2$. Before being assayed, the supernatants and lysates were stored at −80°C for up to seven days. Before assay by ELISA for the total platelet content of GPIb and the GPIIb-IIIa complex (see later), the lysates were thawed and, to remove any cellular debris, centrifuged at 22°C for four minutes at 8,000 g (conditions that result in only a small degree of sedimentation of actin filament–associated GPIb[25]).

Flow cytometric assessment of platelet surface glycoproteins. Fixed, washed thrombin-activated and control platelets (50,000/μL) were prepared as described earlier and incubated for 20 minutes at 22°C with a saturating concentration of one of five monoclonal antibodies (6D1, WM23, 3G6, FMC25, or 10E5) to assess platelet surface glycoproteins. In parallel experiments, aliquots of these platelet suspensions were incubated with either monoclonal antibody KC4 or monoclonal antibody OX6 to assess platelet activation and background binding, respectively. As described by George et al[9] the platelet surface GPIIb-IIIa complex was assessed on platelets activated in a Ca^{++}-containing buffer, whereas the platelet surface GPIb-IX complex was assessed on platelets activated in an EDTA-containing buffer. Thus, the platelet samples that had been prepared in the presence of 2 mmol/L $CaCl_2$ (see earlier) were incubated with either 10E5 or OX6, whereas the platelet samples that had been prepared in the presence of 5 mmol/L EDTA were incubated with either 6D1, WM23, 3G6, FMC25, or OX6. Platelet surface expression of PADGEM protein was assessed by antibody KC4 on platelets prepared in the Ca^{++}-containing buffer. All platelet samples were then washed twice in Tris-buffered saline by centrifugation at 2,000 g for ten minutes at 22°C and incubated for 20 minutes at 22°C with a saturating concentration of fluorescein isothiocyanate—labeled goat antimouse IgG antibody (Cooper Biomedical, Malvern, PA). The platelets were then washed twice, resuspended in Tris-buffered saline, and analyzed in a FACS 440 (Becton Dickinson, Mountain View, CA). For each sample, the fluorescence signal from 10,000 individual cells was measured. Forward-light scatter profiles indicated that there was neither platelet clumping nor detectable contamination by other cell types in any of the samples. Histograms were gated for platelets by their characteristic forward and orthogonal light scatter, thereby excluding any possible contribution from other cells or debris. To compare results in linear form, data obtained from fluorescence channels in a logarithmic mode were converted to their linear equivalents (relative specific fluorescence) as previously described.[17]

ELISA determination of platelet release of glycocalicin and the GPIIb-IIIa complex. Supernatants obtained from centrifugation of thrombin-activated and control platelets were assessed for their glycocalicin content by an ELISA using monoclonal antibody 6D1 as previously described.[5,18] In parallel assays, 6D1 was replaced by either monoclonal antibody 10E5 or monoclonal antibody WM18. As described earlier, the supernatants used for assays with 6D1 were EDTA-containing, whereas the supernatants used for assays with 10E5 and WM18 were Ca^{++}-containing.

ELISA determination of total platelet content of GPIb and the GPIIb-IIIa complex. Lysates obtained after Triton X-100 solubilization of thrombin-activated and control platelets were assessed in the ELISA for their ability to inhibit monoclonal antibody 6D1 binding to platelet surface GPIb. This assay measures the total number of GPIb receptors for vWf because 6D1 binds with equal avidity to GPIb and glycocalicin.[5] The assay was validated by demonstrating a comparable total number of GPIb molecules per platelet in experiments in which the monoclonal antibody to GPIb was changed from 6D1 to WM23 or 3G6 and in other experiments in which, rather than Triton X-100 platelet lysates, the aqueous phase of Triton X-114–solubilized platelets[26] was assessed (A.D. Michelson, M.R. Barnard, E. Carroll: unpublished observations). Serial dilutions of the lysates obtained after Triton X-100 solubilization of thrombin-activated and control platelets were also assessed in the ELISA for their ability to inhibit the binding of either monoclonal antibody 10E5 or monoclonal antibody WM18 to the platelet surface. As described earlier, the lysates used for assays with 6D1 were EDTA-containing, whereas the lysates used for assays with 10E5 and WM18 were Ca^{++}-containing. Control assays in which platelets were replaced by buffer only and then treated with 1% Triton X-100 resulted in the detection of no GPIb ($n = 3$) or GPIIb-IIIa complex ($n = 3$), thereby demonstrating that the dilutions of Triton used did not interfere with the ELISA.

Platelet counts. Platelet counting was performed on a Coulter Model ZBI (Coulter Electronics, Hialeah, FL).

RESULTS

A flow cytometric method was used to demonstrate the effect of thrombin on platelet surface glycoproteins. As shown in Fig 1, thrombin resulted in a marked reduction in the platelet surface binding of each of three monoclonal antibodies (6D1, WM23, and 3G6) directed against different epitopes on GPIb (Table 1). In addition, thrombin resulted in a similar reduction in the platelet surface binding of a monoclonal antibody (FMC25) directed against GPIX (Fig 1). In contrast, thrombin resulted in a marked increase in the platelet surface binding of a monoclonal antibody (10E5) directed against the GPIIb-IIIa complex (Fig 1). Parallel assays using monoclonal antibody KC4 (directed against PADGEM protein) demonstrated that the thrombin-induced changes in the platelet surface binding of monoclonal antibodies directed against GPIb, GPIX, and the GPIIb-IIIa complex were associated with platelet activation (Fig 1).

As determined by relative specific fluorescence, in unactivated platelets the ratio of platelet surface binding of 6D1:FMC25:10E5 (monoclonal antibodies directed at GPIb, GPIX, and the GPIIb-IIIa complex, respectively) was 1.0:0.9:2.0 (means of five separate experiments). These ratios are comparable to the ratio of platelet surface GPIb:GPIX:GPIIb-IIIa complex reported by other investigators using radioligand binding methods.[1,13,14] In maximally activated platelets (thrombin, 1.0 U/10^8 platelets), the ratio of platelet surface binding of 6D1:FMC25:10E5 was 1.0:0.9:29.1 (means of five separate experiments). Similarly, despite the thrombin-induced changes, there was maintenance of the approximately 1:1 ratio of the platelet surface binding of 6D1:FMC25 at all concentrations of thrombin tested (Figs 1 and 2).

The flow cytometric method of analyzing platelet surface glycoproteins is able to detect distinct subpopulations of platelets because each platelet is analyzed individually.[16,17] However, the thrombin-induced changes in binding of monoclonal antibodies to platelet surface GPIb, GPIX, and the GPIIb-IIIa complex were not restricted to a distinct subpopulation of platelets, irrespective of whether the thrombin concentration resulted in partial or complete activation of

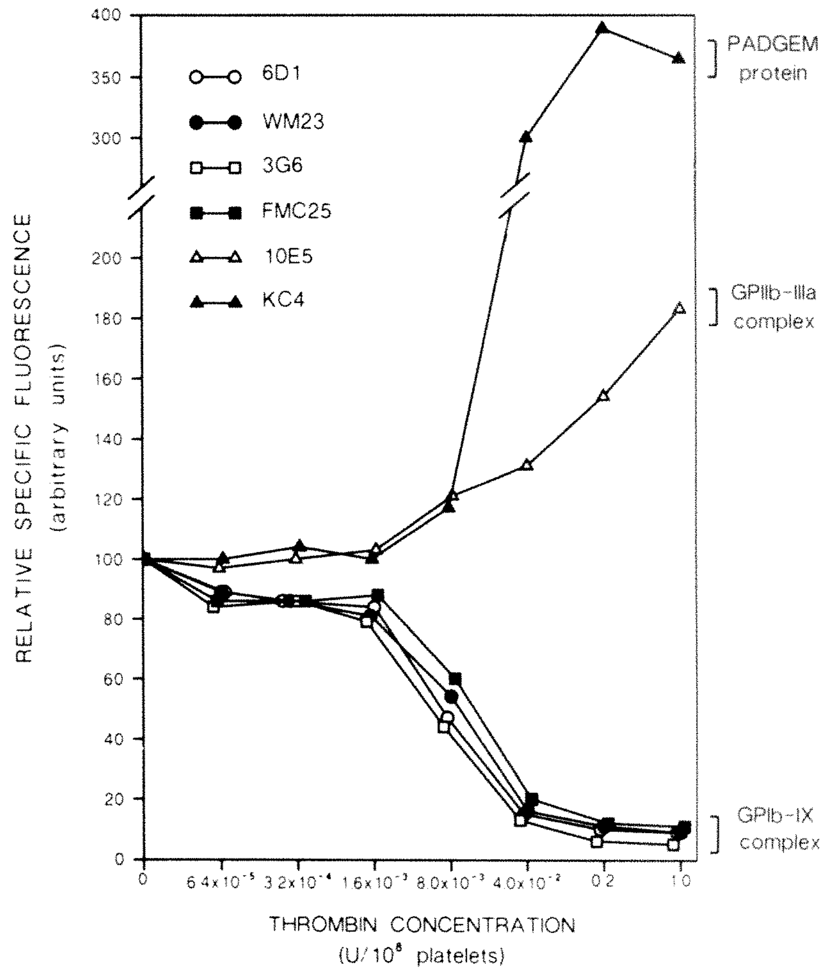

Fig 1. Effect of thrombin on the binding of monoclonal antibodies to the platelet surface as determined by flow cytometry. Platelets were incubated with monoclonal antibodies directed against either GPIb (6D1, WM23, and 3G6), GPIX (FMC25), the GPIIb-IIIa complex (10E5), or PADGEM protein (KC4). All samples were then incubated with fluoresceinated goat antimouse antibody. For each antigen, the relative specific fluorescence of control platelets was arbitrarily assigned 100 units.

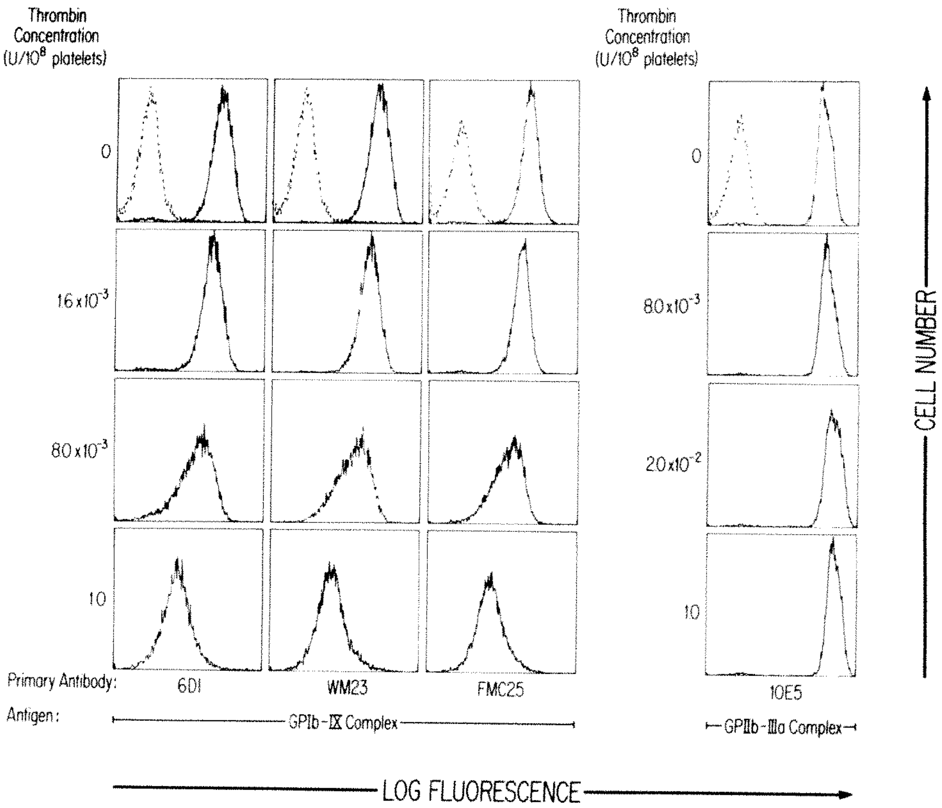

Fig 2. Effect of different concentrations of thrombin on the binding of monoclonal antibodies to the platelet surface as determined by flow cytometry. The solid lines represent platelets activated with the indicated concentrations of thrombin and then incubated with the indicated primary monoclonal antibody. The dashed lines represent platelets incubated with an irrelevant primary monoclonal antibody (background). All samples were then incubated with a fluoresceinated goat antimouse antibody. For each panel, the x-axis represents log fluorescence, and the y-axis represents cell number.

platelets (Fig 2). This is demonstrated in Fig 2 by the fact that, for all antibodies tested, increasing concentrations of thrombin resulted in a gradual shift of a single peak (to the left for the GPIb-IX complex, to the right for the GPIIb-IIIa complex).

For both control and maximally thrombin-activated platelets, the total platelet GPIb content and glycocalicin released from platelets were determined by ELISA using antibody 6D1. As shown in the upper portion of Table 2, the total platelet content of GPIb did not change significantly after activation with thrombin, 1.0 U/10^8 platelets. As shown in the lower portion of Table 2, the glycocalicin released from platelets was, as expected, very low in the control and did not rise appreciably in the thrombin-activated platelets.

For both control and maximally thrombin-activated platelets, the total platelet content and platelet release of the GPIIb-IIIa complex were determined by ELISA using antibody 10E5. As shown in Fig 3, the total platelet content of the GPIIb-IIIa complex did not change significantly after activation with thrombin, 1.0 U/10^8 platelets. Likewise, the platelet release of the GPIIb-IIIa complex was very low in the control and did not rise significantly in the thrombin-activated platelets (Fig 3). In parallel assays using antibody WM18, there was similarly no thrombin-induced change in the total platelet content of the GPIIb-IIIa complex and no release of the GPIIb-IIIa complex from platelets (data not shown).

Table 2. Effect of Thrombin (1.0 U/10^8 Platelets) on the Total Platelet GPIb Content and Release of Glycocalicin as Determined by ELISA Using Monoclonal Antibody 6D1

Parameter	Percentage of Total GPIb Content of Control Platelets (Mean ± SEM, n = 6)
Total platelet GPIb content*	
Control platelets	100.0 ± 18.4
Thrombin-activated platelets	97.4 ± 18.7
Glycocalicin released from platelets†	
Control platelets	0.3 ± 0.05
Thrombin-activated platelets	0.9 ± 0.1

*Determined from 1% Triton X-100 lysates of platelets.

†Determined from supernatants.

DISCUSSION

In this study, the effects of thrombin on platelet membrane GPIb, GPIX, and the GPIIb-IIIa complex were investigated. Five new observations were made.

First, the thrombin-induced change in the glycocalicin portion of the α chain of platelet surface GPIb was not confined to its vWf binding site. In addition to the previously reported[9] thrombin-induced marked decrease in binding of a monoclonal antibody directed at the vWf binding site on GPIb, we observed a comparable marked decrease in the binding of two other monoclonal antibodies directed at different epitopes on the glycocalicin portion of the α chain of GPIb. The thrombin-induced decrease in binding of monoclonal antibodies directed at GPIb was not due to occupation of the antibody binding site by thrombin bound to its receptor on GPIb[2,3] because (*a*) three monoclonal antibodies (6D1, WM23, and 3G6) directed against different epitopes on

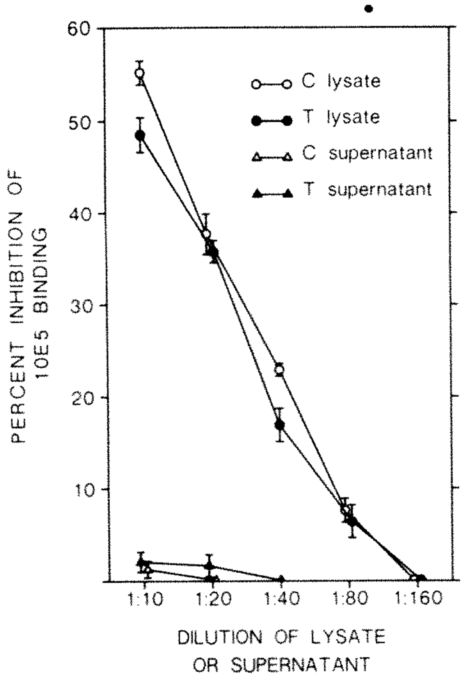

Fig 3. **Effect of thrombin (1.0 U/10^8 platelets) on the total platelet content and release of the GPIIb-IIIa complex as determined by ELISA using monoclonal antibody 10E5. The total platelet content of the GPIIb-IIIa complex was determined from 1% Triton X-100 lysates of control platelets (open circles, C lysate) and thrombin-activated platelets (closed circles, T lysate). Platelet release of the GPIIb-IIIa complex was determined from supernatants of control platelets (open triangles, C supernatant) and thrombin-activated platelets (closed triangles, T supernatant). Results are means ± SEM, n = 3.**

GPIb produced similar results and (*b*) monoclonal antibody 6D1 does not interfere with the binding of thrombin to platelets.[2]

Second, we observed a thrombin-induced marked decrease in the binding of a monoclonal antibody directed at GPIX. Although the function of GPIX is presently unknown, our data suggest the possibility that GPIX has a role in platelet activation. It has previously been demonstrated in unactivated platelets that surface GPIb is bound to GPIX in a 1:1 ratio (the GPIb-IX complex).[13,14] The present data suggest that during the thrombin-induced changes in platelet surface GPIb and GPIX there is maintenance of this 1:1 ratio.

Third, the flow cytometric method enabled us to determine that the thrombin-induced changes in the binding of monoclonal antibodies to GPIb, GPIX, and the GPIIb-IIIa complex were not restricted to a distinct subpopulation of platelets. Radioligand binding studies such as those used by George et al[9] are unable to make this distinction because the results are averaged measurements of large numbers of platelets. In contrast, because each platelet is analyzed individually, flow cytometry is able to detect distinct subpopulations of platelets, as we have recently demonstrated in children with chronic myeloid leukemia.[17]

Fourth, despite the thrombin-induced marked decrease in binding of monoclonal antibody 6D1 to platelet surface GPIb, quantitative ELISA (performed in parallel and using the same monoclonal antibody) revealed no significant thrombin-induced release of glycocalicin from the platelet and no change in the total platelet content of GPIb. In view of our previous finding that proteolytic cleavage of glycocalicin does not interfere with its measurement by our ELISA,[18] the direct measurement of released glycocalicin in the present study demonstrated that the thrombin-induced marked decrease in the platelet binding of anti-GPIb monoclonal antibodies was not the result of cleavage of platelet surface GPIb. The present study together with previous studies by other investigators[27,28] suggests that platelet surface GPIb is still present on the platelet surface after thrombin activation but its accessibility to multiple probes is greatly decreased because of either (*a*) the marked clustering of GPIb molecules that occurs on the platelet surface after thrombin activation[29]; (*b*) the marked shape change that occurs in platelets during thrombin activation (less likely because of the associated increased accessibility of surface GPIIb-IIIa complex); or (*c*) a major conformational change in the GPIb-IX complex (also less likely because such a change would not be expected to result in the same decrease in binding of four monoclonal antibodies [6D1, WM23, 3G6, and FMC25] directed at different epitopes on the GPIb-IX complex and three of these antibodies [WM23, 3G6, and FMC25] recognize their epitope on Western blots, which suggests that they are relatively insensitive to conformational changes in the antigen).

Fifth, unlike α granule constituents such as platelet factor 4 and β-thromboglobulin,[30] the GPIIb-IIIa complex was not released from platelets during thrombin activation. Although the present investigation did not directly exclude the possibility that uncomplexed GPIIb and/or GPIIIa subunits were released from platelets during thrombin activation, the lack of change in the total platelet content of the GPIIb-IIIa complex, as determined by two different complex-specific monoclonal antibodies, did not support this view.

In conclusion, given the central roles of GPIb and the GPIIb-IIIa complex in platelet adhesion and aggregation,[1] the presently described thrombin-induced changes in these glycoproteins are likely to be important in modulating the reactivity of platelets with the damaged blood vessel wall and with other platelets.

ACKNOWLEDGMENT

The authors thank Drs Burt Adelman (Medical College of Virginia, Richmond), Michael C. Berndt (University of Sydney, Australia), Barry S. Coller (State University of New York at Stony Brook), Bruce Furie (Tufts New England Medical Center, Boston), and Bruce A. Woda (University of Massachusetts Medical School, Worcester) for generously providing the antibodies listed in Table 1; Dr John Fenton II (New York Department of Health, Albany) for generously supplying purified human α-thrombin; Marcia McFadden and Julie Reitter for operating the flow cytometer; and Eddie Carroll III for excellent technical assistance. The authors also thank Drs Berndt and Peter E. Newburger for their critical review of the manuscript.

Localization of a Factor VIII Binding Domain on a 34 Kilodalton Fragment of the *N*-Terminal Portion of von Willebrand Factor

By Yukihiro Takahashi, Michel Kalafatis, Jean-Pierre Girma, Karin Sewerin, Lars-Olov Andersson, and Dominique Meyer

Factor VIII (F.VIII) was tested for its ability to bind in solid phase system to von Willebrand Factor (vWF) or fragments obtained with *Staphylococus aureus* V-8 protease, ie, SpIII (*N*-terminal), SpI (central), and SpII (C-terminal). Bound F.VIII was estimated in situ by clotting and chromogenic assays. F.VIII bound in a dose-dependent manner to immobilized vWF and SpIII but not to SpII or SpI. Binding was inhibited by 0.25 mol/L $CaCl_2$ as well as by an excess of vWF or SpIII. Accordingly, immobilized F.VIII specifically bound ^{125}I-vWF and SpIII but not SpII or SpI. Twelve monoclonal antibodies (MoAbs) directed towards SpIII, specifically blocking binding of F.VIII to vWF or SpIII, were used for the mapping of plasmic or tryptic fragments of vWF or SpIII. We thus established that a F.VIII binding domain of vWF is located on a 34 kilodalton (kd) fragment of the *N*-terminal portion of vWF, between residues 1 and 910, and that it is distinct from the GPIb and collagen binding domains.

© 1987 by Grune & Stratton, Inc.

HUMAN von Willebrand Factor (vWF) mediates adhesion of platelets to the subendothelium of the vessel wall and serves as Factor VIII (F.VIII) carrier, stabilizing its activity.[1] Results of proteolytic degration of vWF[2-13] have shown that the basic 270 kilodalton (kd)-subunit of vWF contains distinct functional domains. *Staphylococus aureus* V-8 protease (V-8 protease) hydrolyses vWF-subunit at Glu 1,365 producing two fragments, SpII, a dimer of the C-terminal portion (residues 1,366 to 2,050) containing a binding domain for GPIIb/IIIa[5] and SpIII, a dimer of the *N*-terminal portion of vWF (residues 1 to 1,365). SpIII contains binding domains for GPIb[4-6] and for heparin,[13] both being localized between residues 449 and 728 [8,13]; and two distinct domains interacting with collagen (residues 542 to 622 and 948 to 998).[9-12] The latter is in the central part of vWF-subunit fragment SpI, (residues 911 to 1,365) obtained by secondary digestion of SpIII with V-8 protease.[11,12] The localization of the domain of vWF that binds to F.VIII is unknown. Using fragments of vWF obtained with V-8 protease we demonstrate here that a F.VIII binding domain is located on a 34 kd species of the *N*-terminal part of SpIII, between amino acid residues 1 and 910 of vWF-subunit.

MATERIALS AND METHODS

Purification of human vWF and fragmentation. Human vWF was purified according to Thorell and Blomback.[14] It was digested with V-8 protease (Miles Laboratories, Inc, Naperville, IL) and proteolytic fragments SpI, SpII and SpIII were purified as reported.[4,5] Purified vWF or SpIII were digested for 24 hours in 25 mmol/L Tris-HCl, pH 8, 0.15 mol/L NaCl with Trypsin-TPCK[14] (Worthington, Freehold, NJ) at 22°C, or with plasmin[15] at 37°C. Plasmin was produced by incubating human Glu-plasminogen (gift of Dr E. Anglés-Cano, INSERM, U. 143, Paris) for one hour at 37°C with 10 IU/mL of human urokinase (gift of Dr F. Toulemonde, Institut Choay, Paris).

Purification of human F.VIII. Human F.VIII was purified from cryoprecipitate according to Andersson et al.[16] The preparation contained ~100 U/mL of F.VIII (~7,000 U/mg) and <0.001 U/mL of vWFAg.

Antibodies to vWF or to F.VIII. Among 28 monoclonal antibodies (MoAbs) to vWF reacting with SpIII, three are already known to inhibit the binding of vWF or SpIII to GPIb (MoAbs 311, 322, 328) and six, also directed to SpI, to block the binding of vWF or SpIII to collagen (MoAbs B200 to B205).[5,11,12] Among ten MoAbs to vWF directed against SpII, one (MoAb 9) is known to inhibit the binding of vWF or SpII to GPIIb/IIIa.[5] Two antibodies (Abs) to F.VIII were used: MoAb D_4H_1, with an anti-VIIIC titer of 5 Bethesda U/mg IgG and an oligoclonal IgG purified from the plasma of a hemophilia A patient with a high titer (1,500 U/mL) inhibitor.

Radiolabeling. Proteins were labeled with ^{125}I as described.[5] Specific radioactivity of vWF, SpIII, SpII, or SpI was 0.9, 2.5, 4.2, and 1.3 μCi/μg, respectively.

Binding of F.VIII to vWF or vWF proteolytic fragments. A solid phase binding assay was performed in 3 mL-polystyrene tubes, using a final volume of 0.5 mL at each step. vWF, SpIII, SpII, or SpI (4 μg/mL in 0.05 mol/L sodium carbonate, pH 9.8) were coated for three hours at 37°C. Following washing with 25 mmol/L sodium barbital-acetate buffer, pH 7.3 (Michaelis buffer) containing 0.3% BSA and 0.05% Tween 20 (washing buffer), potential traces of F.VIII were eliminated by incubating for 30 minutes at 37°C with 0.25 mol/L $CaCl_2$ in Michaelis buffer and washing. F.VIII (0 to 2 U/mL in 3% BSA-Michaelis buffer) was then incubated for one hour at 37°C. Unbound F.VIII was eliminated by washing and bound F.VIII was estimated in situ. Nonspecific binding of F.VIII was estimated using fibrinogen, fibronectin, or albumin-coated tubes. In control experiments, selected MoAbs (IgG) were previously coated to the tubes at a concentration of 20 μg/mL and vWF or fragments were immobilized as already described. In both systems, the amount of immobilized vWF or fragments was determined at various steps of the assay by either mixing ^{125}I-vWF or fragments with the unlabeled protein or by reacting for three hours at 37°C the content of the tubes with a specific ^{125}I-MoAb IgG to SpI, SpII, or SpIII in 3% BSA-Michaelis buffer, followed by washing and counting. Inhibition of F.VIII binding was tested by incubating 2 U/mL of F.VIII premixed with increasing amounts (0 to 10 μg/mL) of vWF, SpI, SpII, or SpIII as competitor. MoAbs (IgG) to vWF were used at a concentration of 20 μg/mL.

Assay of F.VIII. Bound F.VIII was estimated in situ using a one-stage activated partial thromboplastin time by adding to the tubes 100 μL of Michaelis buffer, 100 μL of F.VIII deficient plasma (Diagnostica Stago, Asnières, France), 100 μL of 5% kaolin and 100 μL of cephalin. Following three minutes at 37°C, coagulation was initiated by 100 μL of 25 mmol/L $CaCl_2$. A chromogenic assay

(Coatest factor VIII, KabiVitrum, Stockholm) was performed as described by the manufacturer except that 300 μL of Michaelis buffer were added before 100 μL of the other reagents. Results were compared with those using 0 to 10 μL of normal pool plasma (1 U/mL of F.VIII) in 100 μL of buffer for the clotting assay and in 300 μL for the chromogenic assay.

Binding of vWF or vWF degradation fragments to F.VIII. Following precoating of MoAb D4H1 (IgG) at a final concentration of 60 μg/mL, washing and incubation of F.VIII (8 U/mL) for two hours at 37°C, serial dilutions of ^{125}I-vWF, SpI, SpII, or SpIII in 3% BSA-Michaelis buffer were incubated in the tubes for one hour at 37°C and 18 hours at 4°C. Following washing, the bound material was estimated by counting. Nonspecific binding was determined in the absence of F.VIII.

Gel analysis. SDS-polyacrylamide gel electrophoresis was performed and gels were stained with coomassie blue or transferred to nitrocellulose, reacted with selected ^{125}I-antibody IgG and autoradiographed as described.[5]

RESULTS

Binding of F.VIII to immobilized vWF or vWF fragments. The amount of coated vWF or SpI, SpII, or SpIII was consistent, dose-dependent, and saturable, reaching a maximum of ~500 ng of protein bound per tube out of 2 μg applied in 500 μL. Under these conditions, purified F.VIII specifically bound to coated vWF and to SpIII in a dose-dependent and saturable manner (Fig 1) with a maximum reached at ~0.5 U/tube of F.VIII. Comparison of these results with the control curve obtained using serial dilutions of normal pool plasma in uncoated tubes (Fig 1, insets) showed that a maximum of ~0.01 U of purified F.VIII was bound per coated tube. F.VIII was unable to bind to immobilized SpII or SpI as well as to BSA, fibrinogen or fibronectin (Fig 1). Control experiments showed that bound F.VIII could be totally removed by incubating with 0.25 mol/L $CaCl_2$. Bound F. VIII was markedly inhibited by MoAb to F.VIII D4H1 at concentrations ≥ 30 μg/mL and completely neutralized by the oligoclonal Ab to F.VIII (results not shown). Measurement of vWF or fragments using ^{125}I-MoAbs 9 or B203 indicated that the amount of coated protein was constant throughout the various steps of the assay. Thus the increase of clotting times was not related to a loss of coated protein. In addition, specific binding of F.VIII to vWF or to SpIII and absence of binding to SpII or to SpI was observed when the proteins were immobilized through a MoAb to vWF coated to the tube. Specificity of F.VIII binding to vWF or to SpIII was confirmed in experiments of competitive inhibition (Fig 2). Results were similar whether the substrate was coated vWF (Fig 2A) or SpIII (Fig 2B). By contrast SpII or SpI had no significant effect on F. VIII binding even at a concentration of 10μg/mL.

Binding of ^{125}I-vWF or vWF fragments to antibody-bound

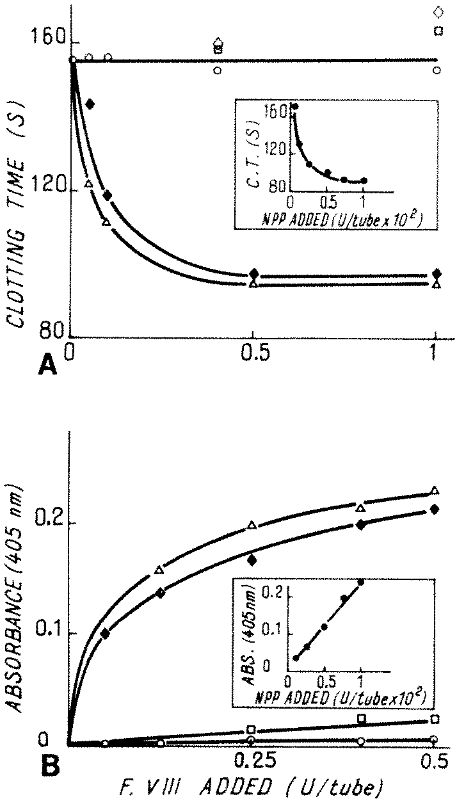

Fig 1. Binding of purified F.VIII to immobilized vWF or vWF degradation fragments. Bound F.VIII was estimated in situ using either a one-stage clotting method (A) or a chromogenic assay (B) as described in Materials and Methods. Binding of F.VIII was estimated using tubes coated with BSA (◇), SpI (□), SpII (○), SpIII (♦), or vWF (△). Insets show the control dose-response curves obtained using various amounts of normal pool plasma (NPP) in uncoated tubes.

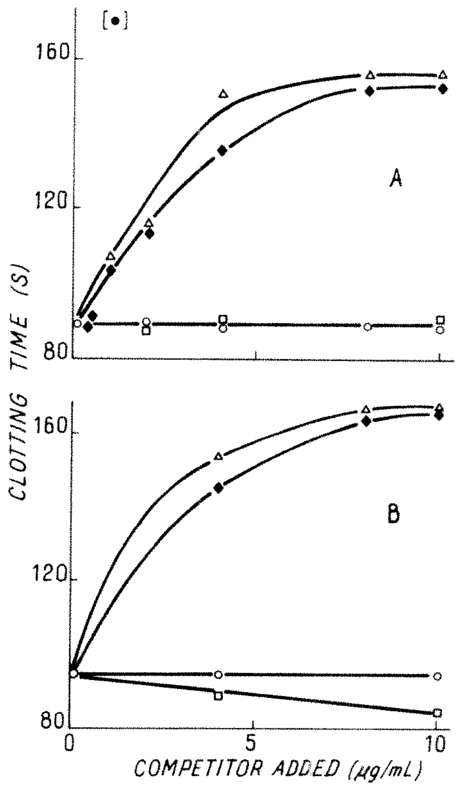

Fig 2. Competitive inhibition of F.VIII binding to vWF- (A) or SpIII-coated tubes (B) by increasing concentrations of competitor vWF (△), SpI (□), SpII (○), or SpIII (♦). Bound F.VIII was estimated by its clotting activity. [●] indicates the control clotting time when using BSA-coated tubes.

F.VIII. Using F.VIII immobilized onto antibody coated tubes, a dose-dependent binding of ^{125}I-SpIII or ^{125}I-vWF was observed, eight and 35 times higher than the control, respectively. ^{125}I-SpII or ^{125}I-SpI did not bind to F.VIII under the same conditions (not shown).

Effect of MoAbs to vWF on binding of F.VIII to coated vWF or SpIII. Among 28 MoAbs reacting with SpIII, 12 MoAbs derived from three fusions (MoAbs 418, 424, 426, 440, 456, 464, 468, 469, 470, 477, 479, 480) almost completely blocked binding of F.VIII to coated vWF or SpIII (95% to 98% inhibition). They did not bind to SpI but recognized a small number of intermediates among those produced during the limited digestion of vWF and of SpIII with trypsin or plasmin (Fig 3). Kinetic studies of the digestion established that the 34 kd fragment consistently observed (Fig 3) derived from the larger immunoreactive fragments and represented the smallest species immunodetectable (not shown). The other MoAbs to SpIII as well as MoAbs to SpII had no inhibitory effect on F. VIII binding to vWF or SpIII (not shown).

DISCUSSION

The location on vWF of the domain specific for F.VIII is unknown. In this study we estimated in a solid phase system the interaction between purified F.VIII and vWF or its fragments produced by V-8 protease (SpI, SpII, and SpIII).[4,5] Our data demonstrate that a vWF-domain interacting with F.VIII is located on the *N*-terminal part of the subunit. Our findings also strongly suggest that there is no other F.VIII binding domain on the rest of the molecule. We have thus established that F.VIII binds in a specific and dose-dependent manner to immobilized vWF and SpIII, a dimer of the *N*-terminal portion of vWF-subunit (residues 1 to 1,365). Conversely, F.VIII does not bind to SpII, a dimer of the C-terminal end of vWF-subunit (residues 1,366 to 2,050) nor to SpI, the C-terminal part of SpIII (residues 911 to 1,365). Thus, the binding domain for F.VIII on the vWF-subunit is localized in the *N*-terminal part of SpIII, between residues 1 and 910. Control experiments in which accessibility to the bound protein was modified by using fragments immobilized on previously coated MoAbs indicated that the absence of a binding site for F.VIII on SpI and SpII was not related to steric hindrance. In addition inhibition experiments of F.VIII binding to coated vWF or SpIII by vWF, SpI, SpII, or SpIII clearly confirmed that solely SpIII was able to substitute for vWF and interact with F.VIII. Similarly, when F.VIII was immobilized through a specific MoAb, significant binding of labeled vWF and SpIII was observed, contrasting with a total lack of binding of SpII.

Additional evidence for the presence of a F.VIII binding domain at the *N*-terminal part of SpIII was obtained using MoAbs to different regions of the vWF-subunit. Thus, the absence of noticeable effect on F.VIII binding to vWF or SpIII by MoAbs previously known to block the interaction of vWF with GPIb and collagen[5] strongly supports that the F.VIII binding domain is distinct from those involved in platelet adhesion to the subendothelium. In addition the complete inhibition of binding induced by a series of MoAbs to vWF also reacting with SpIII but not with SpI confirms the presence of a F.VIII binding domain on a portion extending between amino acid residues 1 and 910. We observed that these MoAbs recognize a 34 kd fragment produced in the early phase of digestion of vWF and SpIII by trypsin or plasmin. Recent data from Hamilton et al[15] demonstrated that a 34 kd fragment containing that *N*-terminal sequence of vWF-subunit was produced by early cleavage with these enzymes. We thus assume that the F.VIII binding domain of vWF is located on the previously identified 34 kd *N*-terminal fragment.

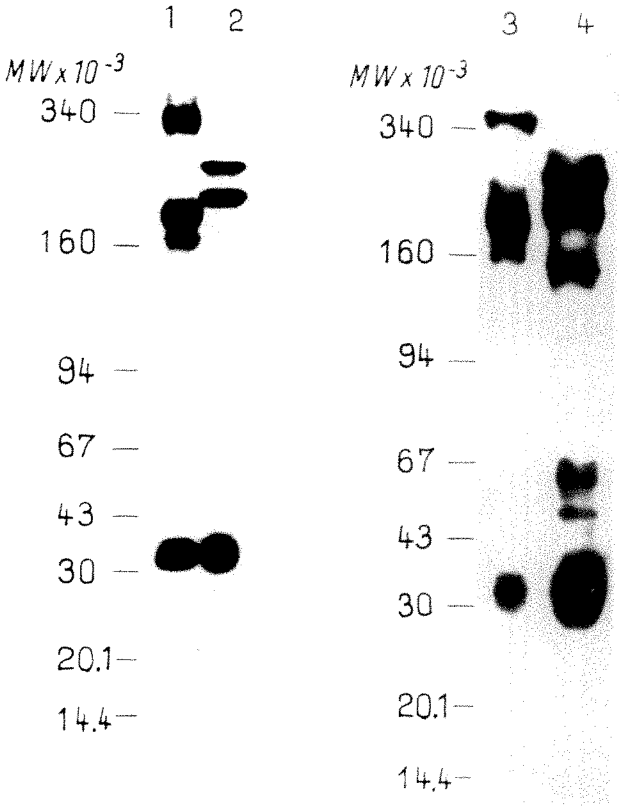

Fig 3. Immunostaining with MoAb to SpIII 418 of the intermediate products of the limited digestion of vWF or SpIII with trypsin at 22°C for 24 hours using an enzyme-substrate ratio of 1:1000 (lanes 1, 2) or with plasmin at 37°C for 24 hours using a ratio of 1:50 (lanes 3, 4). Following electrophoresis in SDS-polyacrylamide (3.5% to 20% gradient), transfer onto nitrocellulose paper and incubation with the ^{125}I-MoAb, the proteins were displayed by autoradiography. Position of the mol wt markers (fibrinogen: 340 kd; IgG: 160 kd and commercial mol wt markers) is indicated on the left.

NOTE ADDED IN PROOF

Subsequent to the submission of this manuscript to BLOOD, the paper "A Major Factor VIII Binding Domain Resides within the Amino-Terminal 272 Amino Acid Residues of von Willebrand Factor" by P.A. Foster, C.A. Fulcher, T. Marti, K. Titani, and T.S. Zimmerman appeared in the *Journal of Biological Chemistry*, 262:8443, 1987.

CONCISE REPORT

Calcium-Dependent Cysteine Protease Activity in the Sera of Patients With Thrombotic Thrombocytopenic Purpura

By William G. Murphy, Jane C. Moore, and John G. Kelton

Plasma and serum from patients with thrombotic thrombocytopenic purpura (TTP) can cause activation and aggregation of normal human platelets in vitro. It is possible that this platelet-activating factor contributes to the disease. In this report we describe studies designed to identify the platelet-activating factor in TTP. Platelet activation by sera from 15 patients with TTP was inhibited by leupeptin, iodoacetamide, and antipain but not by phenylmethylsulphonylfluoride, ε-aminocaproic acid, soybean trypsin inhibitor, aprotinin, and D-phenylanyl-1-prolyl-1-arginine chloromethyl ketone. These studies suggested that the platelet-activating factor in TTP serum was a cysteine protease. We confirmed that a calcium-dependent cysteine protease (CDP) was present in the sera of each of the 15 patients when we used an assay based on the ability of CDP to proteolyse platelet membrane glycoprotein 1b (GP1b) and hence to abolish the ability of CDP-treated normal platelets to agglutinate in the presence of ristocetin and von Willebrand factor. This proteolytic activity was inhibited by EDTA, leupeptin, antipain, iodoacetamide, and by *N*-ethylmaleamide (NEM) but not by the serine protease inhibitors. Activity was detected in 15 of 15 patients with TTP tested before therapy was begun. In contrast, no activity was detected in the serum of any of five of the TTP patients tested in remission or in any of the sera from 36 patients with thrombocytopenia and 423 nonthrombocytopenic controls. To look for in vivo CDP activity in patients with TTP, we studied platelets from two patients with acute TTP (drawn into acid-citrate-dextrose, NEM, and leupeptin). These platelets showed a loss of GP1b from the platelet surface. Both patients were also studied in remission: GP1b on the platelet surface had returned to normal. These studies provide evidence that CDP is present in the sera of patients with TTP, that it is specific to this disease, and that it is active in vivo as well as in vitro. We postulate that a disorder of CDP homeostasis plays a major role in the pathophysiology of TTP.

© 1987 by Grune & Stratton, Inc.

IT HAS BEEN SHOWN that the plasma[1] and serum[2] of patients with thrombotic thrombocytopenic purpura (TTP) contain a factor that causes activation and aggregation of normal human platelets in vitro; it is possible that this factor causes the platelet thrombi in the microvasculature that are the characteristic pathological lesions of the disease.[3] In this report we describe further studies that were designed to identify the platelet-activating factor in the serum of patients with TTP. The studies were in three parts: (*a*) Studies of the effects of enzyme inhibitors on platelet 14C-serotonin release. TTP and control sera were incubated with a panel of protease inhibitors and then added to ^{14}C-serotonin–labeled normal platelets. The release of ^{14}C-serotonin from the labeled platelets was measured. Because cysteine protease inhibitors blocked the platelet activation caused by the TTP sera, we postulated that the platelet-activating factor of TTP was a calcium-dependent cysteine protease (CDP).

(*b*) Part 2 dealt with confirmation of the presence of CDP activity in the sera of patients with TTP. To confirm that CDP was present in the sera of patients with TTP, we tested the effect of the sera on platelet membrane glycoprotein Ib (GPIb): CDP cleaves glycocalicin from GPIb.[4] The loss of GPIb results in the inability of the platelets to agglutinate in the presence of ristocetin and von Willebrand factor (vWF). After incubation of formalin-fixed normal platelets with TTP sera in the presence and absence of protease inhibitors, we studied whether the platelets could agglutinate in the presence of ristocetin and normal plasma. Sera from 15 patients with acute TTP caused normal fixed platelets to lose their ability to agglutinate in response to ristocetin. No control or remission serum had this activity.

(*c*) Evidence for in vivo activity of CDP in TTP constituted part 3 of the study. Based upon the first two series of studies, we had evidence that TTP sera contained CDP and that serum CDP activity was highly sensitive and specific for TTP. However, the observation was an in vitro one. Because CDP was capable of cleaving platelet GPIb from platelets when studied in vitro, we measured this glycoprotein in two TTP patients. Platelet GPIb levels were reduced during the acute episode of TTP but returned to normal after recovery.

MATERIALS AND METHODS

All reagents were obtained from Sigma Chemical Co, St Louis, except where stated otherwise. Platelet counts were measured on a Coulter S and platelet sizing was performed on a Coulter Channelizer (Coulter Electronics, Inc, Hialeah, FL). Fifteen patients with acute TTP were studied. All of these patients were tested at the initial presentation of their first episode of TTP before any plasma therapy had been given. Sera were available from five of these patients in remission of disease. Control sera for both the platelet release studies and ristocetin-induced agglutination inhibition studies were obtained from ten healthy volunteer donors, ten patients with idiopathic thrombocytopenic purpura, ten healthy females in

the third trimester of pregnancy, four patients with preeclampsia, eight patients with disseminated intravascular coagulation, two patients with systemic lupus erythematosus and thrombocytopenia, ten patients with thrombocytopenia after cardiopulmonary bypass, two patients with heparin-induced thrombocytopenia, one patient with a hemolytic transfusion reaction (anti-E), two patients with extensive tissue damage due to severe trauma, and eight randomly selected nonthrombocytopenic hospital controls. In addition, normal RBC were suspended in a 2% suspension in autologous normal serum and lysed by sonication and the resultant solution tested in the release assay and in the ristocetin agglutination assay. For the ristocetin-induced agglutination inhibition studies, 392 additional randomly selected hospital patients were included as controls. Sera were separated into 1-mL aliquots and stored at −70°C. Aliquots were thawed at 37°C on the day of testing.

Preparation of control CDP from platelet lysates. Fifty units of platelet concentrates were pooled, washed, and disrupted by nitrogen cavitation.[4] CDP was purified as described.[5] The proteolytic activity of the CDP preparation was determined by using a ^{14}C-caseinolytic assay.[5] The purity of the preparation was confirmed by sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS-PAGE).

Studies of the effects of enzyme inhibitors on platelet ^{14}C-serotonin release. Normal pooled platelets were loaded with ^{14}C-serotonin (Amersham Corp, Oakville, Ontario)[6] with an average specific activity of 1.67×10^{-4} μCi/10^6 platelets (n = 3). The ability of test or control serum to cause release of ^{14}C-serotonin from labeled platelets was tested in a microtiter assay.[6] The following reagents were tested for their ability to inhibit the release caused by test sera: phenylmethylsulphonylfluoride (PMSF), 1 mmol/L; D-phenylanyl-1-prolyl-1-arginine chlormethyl ketone (PPAC) Calbiochem-Behring Corp, La Jolla, CA), 1 μmol/L; soybean trypsin inhibitor, 200 μg/mL; aprotinin, 100 Kallikrein-inhibition unit (KIU)/mL; iodoacetamide (IAA), 0.5 μmol/L; leupeptin (Calbiochem-Behring), 1 μmol/L antipain, 100 μmol/L; ϵ-aminocaproic acid (EACA), 0.2 μmol/L. All concentrations given are final concentrations. In each test the inhibitor and test serum were incubated together for ten minutes at 22°C before the addition of the ^{14}C-serotonin–labeled platelets. To rule out the possibility that the platelet release induced by TTP sera was due to platelet lysis, test platelets were labeled with ^{111}In as well as ^{14}C-serotinin and tested with serum from ten of the TTP patients. The platelets were labeled with ^{111}In by using the technique of Hawker et al[7] except that they were resuspended in phosphate-buffered saline (PBS) buffer and not plasma. The ^{111}In-labeled platelets had a specific activity of 4.3×10^{-5} mCi/10^6 platelets. The CDP preparation was tested at 70 and 1.5 caseinolytic U/mL for platelet lysis and release.

Confirmation of the presence of CDP activity in the serum of patients with TTP. The rationale of these experiments is that CDP can cleave glycocalicin from platelet GPIb, a change that would result in the platelets no longer being able to agglutinate in the presence of ristocetin and vWF. Formalin-fixed normal platelets were suspended in calcium- and albumin-free Tyrode's buffer (ph 7.45) to a final count of 300×10^9 platelets/L. The platelets were incubated with TTP or control sera that had been preincubated with buffer or with enzyme inhibitors. Test serum (0.25 mL) was preincubated with 75 μL buffer or inhibitor solutions for ten minutes at 22°C in the presence of 1 mmol/L $CaCl_2$. The serum was then added to 0.5 mL of platelet suspension in the presence of 1 mmol/L $CaCl_2$ The enzyme inhibitors tested in this series of experiments were the same as before except that EDTA (5 mmol/L) and *N*-ethylmaleamide (NEM) (6 mmol/L) were included. The serum/platelet mixture was incubated at 22°C for 60 minutes. The mixture was then centrifuged (2,100 g for 20 minutes), the supernatant discarded, and the platelets resuspended in calcium- and albumin-free Tyrode's buffer (pH 7.45, 3.00×10^9 platelets/L). These pretreated platelets were then tested for their ability to agglutinate in the presence of ristocetin and vWF[8] as follows: 0.1 mL of platelet suspension, 0.1 mL normal plasma, 30 μL ristocetin (H. Lundbeck A/S, Copenhagen) (1.5 mg/mL, final concentration) were mixed in a Payton aggregometer (Payton Associates, Scarborough, Ontario) at 37°C. After ten minutes, if no aggregation had taken place, 0.1 mL of nonpretreated fixed normal platelets was added to the aggregometer cuvette. Purified CDP (70 caseinolytic U/mL and 1.5 caseinolytic U/mL[5] and plasmin (5 U/mL) (Kabi, Stockholm) were also tested in place of test serum in these experiments.

Evidence for in vivo activity of CDP in TTP. Platelets from a patient with acute TTP before plasma therapy (platelet count, 20×10^9/L) were separated from blood drawn into acid-citrate-dextrose (ACD) with NEM (6 mmol/L) and leupeptin (1 μmol/L) and resuspended in calcium- and albumin-free Tyrode's buffer (pH 7.4) at a concentration of 120×10^9 platelets/L; these platelets were tested for their ability to agglutinate in the presence of ristocetin by using standard techniques. This assay was repeated when the patient entered remission.

The same platelets were also assayed for glycocalicin content by SDS-PAGE (4% stacking gel over a 5% to 15% gradient). A quantity of 6.4×10^8 platelets were labeled with ^{3}H and solubilized in 2% SDS with NEM (6 mmol/L). Control platelets from a healthy donor were treated identically. The accuracy of the number of platelets solubilized and applied to the gel was confirmed by platelet sizing and by light and phase microscopy to rule out red cell fragment contamination.

We also assayed the platelet membrane GPIb content in a second patient with TTP by radioimmune precipitation using the monoclonal anti-GPIb antibody 6D1 (generously provided by Dr B. Colleer, State University of New York at Stony Brook) as described.[9] Platelets from acute disease (platelet count, 20×10^9/L) and remission after plasmapheresis (platelet count, 257×10^9/L) were collected from blood drawn into inhibitors as before. The platelets were frozen in dimethylsulfoxide and autologous plasma and tested together on the same day.

RESULTS

Characterization of the platelet-activating factor by the effect of enzyme inhibitors on platelet ^{14}C-serotonin release. The sera from all 15 patients with TTP had platelet-activating activity as measured by the ^{14}C-serotonin release assay (Table 1). No platelet-releasing activity was detected in any of the control sera except from one of the two patients with heparin-induced thrombocytopenia and from the patient with anti-E. Sera from five of the TTP patients in remission (after plasma therapy had been discontinued) had no platelet-activating activity. A preparation of CDP at a concentration of 1.5 caseinolytic U/mL[5] also caused platelet aggregation and release; at a concentration of 70 caseinolytic U/mL the enzyme caused platelet lysis. Lysis (measured by ^{111}In release) did not occur at the lower concentration. SDS-PAGE analysis of the CDP preparation showed a major band at 76 kilodaltons (kD). Bands were also present at 118 kD and 64 kD, with some larger molecular weight proteins also present. The preparation was free of contaminating protease activity. The platelet release caused by the sera of patients with TTP during active disease and by the CDP preparation was consistently inhibited by leupeptin, IAA, and antipain but was not inhibited by PPAC, PMSF, aprotinin, soybean trypsin inhibitor, or EACA (Table 1). Three of these patients who entered remission later relapsed. Iden-

Concentrations are given as final concentrations. Inhibitors were incubated with test sera for ten minutes at 22°C before the addition of labeled platelets. Release for PBS is expressed as a percentage of the total possible release, ie, the amount of isotope taken up by the platelets. Release for the inhibitors is expressed as a percentage of the release in PBS. All tests were done in triplicate on two or more occasions. Serum from ten TTP patients (1, 2, 3, 4, 5, 7, 8, 10, 11, 13) were incubated with platelets labeled with ^{111}In as well as ^{14}C-serotonin to determine whether there was any platelet lysis occurring. These sera caused less than 1% release of ^{111}In.

tical platelet-releasing activity recurred. TTP sera did not cause ^{111}In release at the same time as ^{14}C-serotonin was released from test platelets, which indicated that platelet lysis was not taking place. The release induced by the sera from the patient with heparin-induced thrombocytopenia and from the patient with anti-E was inhibited by monomeric IgG (2 mg/mL) but was not affected by PMSF and leupeptin. IgG did not inhibit the TTP platelet release, as previously reported.[6]

Confirmation of the presence of CDP activity in the serum of patients with TTP. Formalin-fixed normal platelets preincubated with sera from all 15 TTP patients during periods of active disease and preincubated with purified CDP lost their ability to agglutinate in the presence of ristocetin and normal plasma (Fig 1). None of the control sera or the five TTP remission sera prevented the platelets from agglutinating. Nonpretreated formalin-fixed platelets added to the mixture of nonagglutinating pretreated platelets, normal plasma, and ristocetin in the aggregometer agglutinated normally, which indicated that the inhibition of agglutination was due to an effect on the preincubated platelets. Preincubation of TTP sera with EDTA, IAA, NEM, antipain, and leupeptin resulted in a loss of the inhibition of ristocetin-induced platelet agglutination in all 15 patients. Preincubation with PMSF, PPAC, aprotinin, EACA, or soybean trypsin inhibitor had no effect (Fig 1). Plasmin, 5 U/mL, also inhibited ristocetin-induced platelet agglutination; in contrast to TTP sera and CDP, plasmin was inhibited by PMSF, EACA, aprotinin, soybean trypsin inhibitor, antipain, and leupeptin but not by IAA or NEM. No change was seen in the platelet counts or in the distribution of the platelet size of the fixed normal platelets before and after exposure to TTP sera or CDP, which indicated that fragmentation of the platelets was not occurring.

Evidence for in vivo activity of CDP in TTP. SDS-PAGE analysis of the platelets from a patient with TTP is shown in Fig 2A. The patient's platelets show a marked loss of GP1b from the membrane. Other membrane proteins have

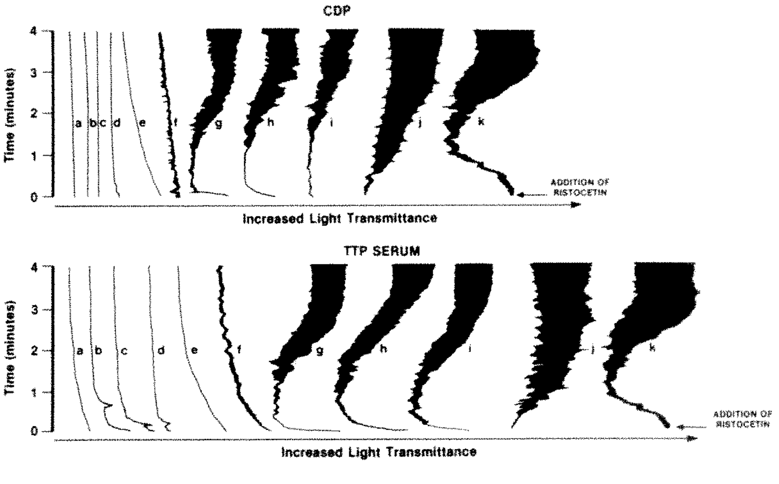

Fig 1. Effect of TTP serum and purified CDP with and without protease inhibitors on ristocetin-induced platelet agglutination. Protease inhibitors are (a) buffer, (b) PMSF, (c) PPAC, (d) EACA, (e) soybean trypsin inhibitor, (f) aprotinin, (g) IAA, (h) leupeptin, (i) NEM, (j) EDTA, and (k) a buffer control without added serum. Test sera, with and without inhibitors, were incubated with formalin-fixed normal platelets at 22°C for 60 minutes. The treated platelets were centrifuged and then resuspended in calcium- and albumin-free Tyrode's buffer (pH 7.45) at a count of 300 × 10^9 platelets/L; agglutination of the platelets in the presence of ristocetin and normal plasma was recorded in an aggregometer.

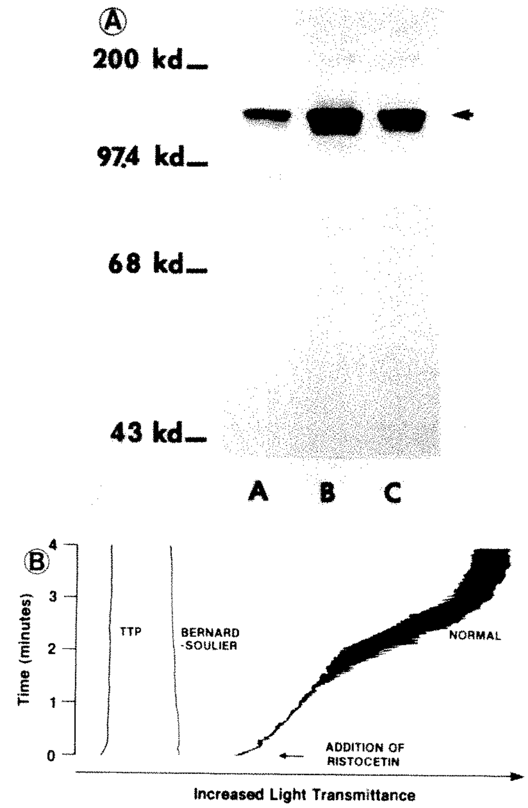

Fig 2. (A) SDS-PAGE of platelet membrane glycoproteins from a patient with TTP before treatment. Quantities of 6.4 × 10^8 platelets from the patient (lane A) and from a normal control (lane B) were labeled with ^3H and solubilized in 2% SDS. Lane C is an added control: 3.2 × 10^8 platelets from the same normal control were applied to this lane after labeling and solubilization. There is a marked loss of GP1b from the patients platelets (arrow). The electrophoretic mobility of this glycoprotein under reduced and nonreduced conditions was characteristic of GP1b.[10] Other labeled membrane proteins have also been decreased. An additional unidentified protein band is seen in the patient sample at 90 kD. (B) Ristocetin-induced agglutination of the patient's platelets. The platelets were suspended in calcium- and albumin-free Tyrode's buffer at a concentration of 120 × 10^9/L and tested for agglutination in the presence of normal plasma and ristocetin (1.5 mg/mL). Control normal platelets and platelets from a patient with Bernard-Soulier syndrome (lacking GP1b) were collected and tested identically. Blood for these analyses was drawn into ACD with leupeptin (1 μmol/L) and NEM (6 mmol/L).

also been lost from the platelets. The patient's platelets did not agglutinate in the presence of ristocetin (Fig 2B). After remission, the patient's platelets agglutinated normally.

Radioimmune precipitation analysis of platelets from a second patient studied during active disease and in remission also showed a decrease of detectable GP1b on the platelets during active disease and a return to normal levels during remission (data not shown).

DISCUSSION

TTP is characterized by disseminated platelet thrombi within the circulation; it is possible that a platelet-activating factor could participate in the pathogenesis of this disease. The studies described in this report suggest that this factor is CDP. We have demonstrated the presence of CDP in the sera of patients with TTP in several ways. First, we studied the effect of enzyme inhibitors on the platelet release reaction induced by TTP sera. Cysteine protease inhibitors but not serine protease inhibitors consistently inhibited platelet release. We then confirmed that CDP activity was present in TTP sera by demonstrating that TTP sera possessed the ability to proteolyse GP1b and that this proteolytic activity was calcium dependent and was sensitive to inhibition by cysteine protease inhibitors but not by serine protease inhibitors. The CDP activity was highly specific to TTP: we detected no activity in 459 control sera, including 36 patients with thrombocytopenia of various causes and more than 400 randomly selected hospital patients. Further, no activity was present in the sera of five of the TTP patients in remission, although it recurred in three patients upon relapse.

Platelets from two patients with TTP (from blood drawn directly into CDP inhibitors) showed a loss of GP1b from the platelet membrane during active disease. Platelets (tested in one patient) also showed a loss of the ability to agglutinate in the presence of ristocetin, comparable to that seen in Bernard-Soulier platelets. These observations are consistent with the enzyme-induced loss of glycocalicin from the platelet membrane and suggest that CDP is active in vivo in patients with TTP.

CDP is a cytosolic enzyme found normally in several tissues including platelets.[11] Its exact physiological role is uncertain, though it is known to be capable of proteolysis of a number of proteins including platelet membrane glycoproteins.[4] It has been demonstrated previously[4] and we have confirmed that the enzyme has platelet-activating activity. The pathway of aggregation is via platelet GPIIb/IIIa.[4] This is consistent with our previous observations[6] that platelet activation induced by TTP serum is inhibited by a monoclonal antibody against GPIIb/IIIa but not by anti-GP1b monoclonal antibody. It is likely, therefore, that platelet aggregation is the major in vivo effect of CDP on the platelet in TTP and that the effect on GP1b is a secondary one.

It is uncertain how our current studies showing CDP activity in TTP relate to previous observations. Several investigators have implicated vWF as an active or passive participant in TTP. Abnormally large multimers of vWF are present in the circulation of convalescent patients with recurrent TTP.[2,12,13] Because the large multimers disappear during acute episodes of the illness, it has been postulated that vWF directly participates in the intravascular platelet clumping that characterizes TTP. In addition, we have shown that the platelet-aggregating activity of TTP can be enhanced in vitro by the addition of a preparation rich in large multimers of vWF.[2] And yet, CDP has been demonstrated to cleave vWF, thereby resulting in the loss of the largest multimers.[14] Therefore, it is possible that the abnormalities of vWF in TTP patients represent an epiphenomenon and are a consequence of CDP activity. However, these issues must await further investigations for their resolution.

On the basis of the findings described in these studies, we postulate that platelet aggregation in TTP is generated through a disturbance of CDP homeostasis that leads to the presence of enzyme activity in the serum. Our studies also indicate that inhibition of ristocetin-induced platelet agglutination is a sensitive and specific assay for TTP.

CONCISE REPORT

A Novel Globin Structural Mutant, Showa-Yakushiji ($_\beta$110 Leu-Pro) Causing a β-Thalassemia Phenotype

By Yasushi Kobayashi, Yasuyuki Fukumaki, Norio Komatsu, Yuzo Ohba, Takaoki Miyaji, and Yasusada Miura

Molecular analysis of the β-globin genes from a patient with a β-thalassemia phenotype showed that a single nucleotide mutation (CTG-CCG) at codon 110 in one of the genes resulted in a leucine to proline substitution. The same mutation with a similar phenotype, was observed in her mother and sister, by Southern blotting analysis of DNAs digested with *MspI*, the recognition site of which was created by this base substitution. This indicates a close relationship between this mutation and the β-thalassemia phenotype. No anomalous peak of radioactivity was detected by reverse-phase high-performance liquid chromatography (HPLC) in the patient's reticulocytes incubated with isotopically labeled amino acid. The leucine-proline (Leu-Pro) substitution probably disrupts the G-helix and in turn interferes with globin contact points. The uncombined β-globin chain would be rapidly destroyed and the β-thalassemia phenotype would follow.

© 1987 by Grune & Stratton, Inc.

THALASSEMIA MUTATIONS are traditionally defined as those that leave the globin structure unchanged, but lead to a quantitative reduction in the synthesis of globin. In contrast, hemoglobinopathies are defined as abnormal globins with one or more structural changes, which are synthesized at a normal rate. This classification of globin gene mutations is not always apt as there are several mutations that cause not only alterations of the globin structure but also a decrease in synthesis. These are known as thalassemic hemoglobinopathies and the molecular mechanisms are activation of the splice site within the exon, loss of a normal termination or instability of the globin chains.[1] The highly unstable globin mutants causing a thalassemic phenotype are of great interest as the posttranslational defect occurs at the most distal step necessary for the functional expression of the globin genes and vital information on the effect of the amino acid substitution on the hemoglobin tetramer formation can be obtained. We report herein a β-globin gene with a novel mutation, 110 leucine-proline (Leu-Pro) that causes a β-thalassemia phenotype, through a posttranslational mechanism.

MATERIALS AND METHODS

Hematologic and hemoglobin procedures. Standard hematologic measurements were performed. Hemoglobin electrophoresis was carried out on a starch gel at pH 8.6[2] and polyacrylamide gel isoelectric focusing.[3] HbF and HbA_2 levels were determined as described.[4] Stability of hemoglobin was examined by heat denaturation[5] and by the isopropanol test.[6] Glycerol lysis time (GLT_{50} value) of erythrocytes was determined as described.[7] Incubation of blood samples with L-[4.5-^{3}H] leucine (40 to 50 Ci/mmol) for two hours and each labeled globin chain was separated by CM-cellulose chromatography eluted with 8 mol/L urea buffer to determine the globin chain synthesis ratio.[8]

DNA analysis. High-molecular-weight DNA was extracted from the peripheral leukocytes of the proband, family members, and individuals with no hematologic abnormalities, as described.[9] The β-globin genes of the proband were cloned in bacteriophage Charon 28 as 7.8 kb *HindIII* fragments. Nucleotide sequence of the β-globin genes was determined by the dideoxy chain termination method.[10] Restriction site polymorphisms within the β-globin gene cluster and creation of the new restriction site in the β-globin gene by one base substitution were determined by Southern blotting procedures, using appropriate probes.[11]

Globin chain analysis by reverse-phase HPLC. Globin chains were separated from the fresh hemolysate by reverse-phase high performance liquid chromatography (HPLC) on a TSK gel ODS-120T column in 0.1% trifluoroacetic acid (TFA) with an acetonitrile gradient of 42.2% to 48.2% in 60 minutes.[12,13] The β-globin chain prepared by a CM-cellulose column was S-alkylated with iodoacetamide and then digested with trypsin.[14] The resultant digests were also isolated by reverse-phase HPLC on a μBondapak C18 in 0.05% TFA with an acetonitrile gradient of 0% to 48% in 180 minutes.[12]

RESULTS

Hematologic data of patients. The proband is a 34-year-old Japanese woman who was admitted to the hospital because of anemia. The hematologic findings and other laboratory data of the proband, her sister, her mother, and her father are presented in Table 1. These data of the proband resembled those associated with β-thalassemia trait and were inconsistent with the presence of a significant hemolytic process due to an unstable hemoglobin. Similar hematologic findings were observed in her mother and sister but not in her father, suggesting that the mother and sister were heterozygous for the same mutation.

Structural analysis of the β-globin genes. To define the molecular lesion producing a β-thalassemia phenotype, we isolated several β-globin gene clones of the proband and chose two (clone A and clone B) that were distinguished by the polymorphism of the *AvaII* site located in position 16 of IVS2. We determined the nucleotide sequence that extends

from 372 bases 5′ of the cap site to 266 bases 3′ of the polyA site of both clones. Comparison of the nucleotide sequence with that of several human β-globin genes[15,16] revealed one notable nucleotide substitution (T-C) at the second position in codon 110 of clone A (Fig 1). Orkin *et al* reported that the β-globin gene exhibits polymorphism limited almost exclusively to common sequence types, which they designated as β-globin gene frameworks.[17] According to their definition, clone A sequence and clone B sequence were framework 3 Asian and framework 1, respectively. We analyzed the polymorphic restriction sites in the β-globin gene cluster (the *Hinc*II site 5′ to the ε-globin gene, the *Hind*III sites in the G_γ−, A_γ− globin genes, the *Hinc*II site in the ψβ-globin gene, the *Hinc*II site 3′ to the ψβ-globin gene, the *Hgi*AI, *Ava*II sites in the β-globin gene and the *Bam*HI site 3′ to the β-globin gene) to determine the haplotype of the chromosome bearing the clone A sequence. We found that the haplotype (+ − − − − − − +) was linked to this mutation allele.

Association of the mutation with the β-thalassemia phenotype. The base change at codon 110 converts the DNA sequence in the region from CTGG to CCGG, thereby creating the *Msp*I recognition site. Hence, digesting clone A DNA with both *Msp*I and *Hind*III produces a 3.9 kb fragment instead of a 4.7 kb fragment (Fig 2). To examine the association of this mutation with the β-thalassemia phenotype, we digested the genomic DNAs of family members with both *MspI* and *Hind*III and performed Southern blotting analysis of each digested DNA, using a 5′-specific β-globin gene probe (a 1.9 kb *Bam*HI fragment). This *Msp*I assay demonstrated that the proband's mother and sister but not her father were also heterozygous for this mutation (Fig 2). These results indicate a close relationship between the mutation and the thalassemia phenotype.

Analysis of globin chains using reverse-phase HPLC. To investigate features of the mutant globin chain predicted from the nucleotide sequence, peripheral blood of the proband was incubated with L-^{3}H-leucine for 15 minutes, and 120 minutes at 37°C. The labeled globin chains were analyzed with reverse-phase HPLC, under conditions that separate the unstable β-globin chain of Hb Santa Ana (β88

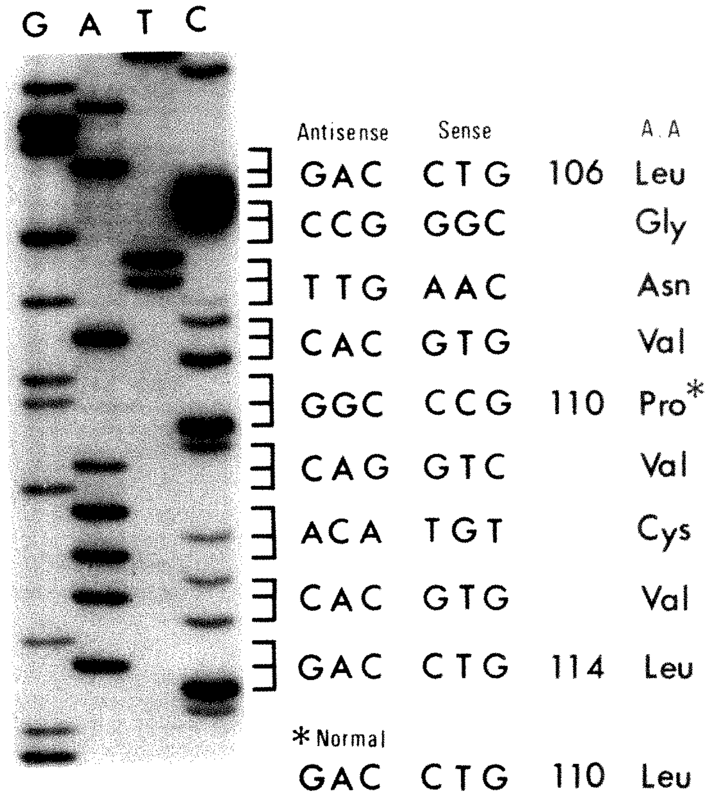

Fig 1. DNA sequence of the β-globin gene (clone A) of the proband and the autoradiogram of the gel demonstrating the sequence of the antisense strand in the vicinity of the codon 110. The T-C substitution at the second position of condon 110, that results in the substitution of proline for leucine.

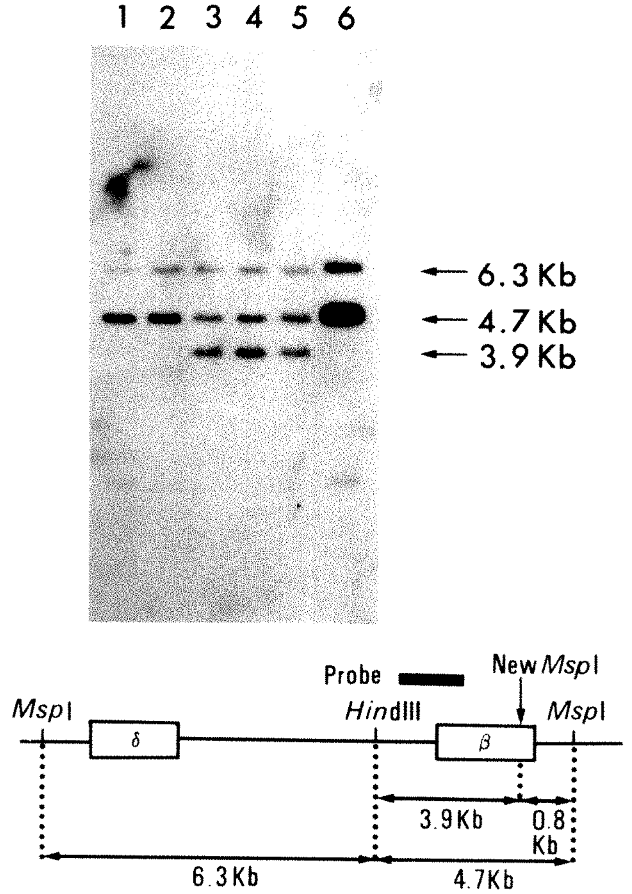

Fig 2. Identification of the mutation at codon 110 by Southern blotting. At the top is an autoradiogram of DNA fragments that hybridize with a 5′-specific β-globin gene probe after *Msp*I and *Hind*III digestion of DNAs of the proband (lane 5), her sister (lane 4), her mother (lane 3), her father (lane 2), and normal controls (lanes 1 and 6). The 4.7 kb fragment was seen in normal DNAs and the 3.9 kb fragment in patients' DNAs. The 6.3 kb band is due to cross-hybridization with the δ-globin gene sequence. At the bottom is a map of *Msp*I and *Hind*III sites in the region containing the δ- and β-globin genes. The position of the *Msp*I site created by the base substitution at codon 110 is indicated by the arrow with new *Msp*I.

Leu-Pro)[18] from the normal counterpart. We also analyzed globin chain labeled with L-^{3}H-proline, under the same conditions. Chromatographic analysis revealed no anomalous peak of radioactivity in the reticulocytes incubated for 15 minutes (data not shown) and 120 minutes (Fig 3). To confirm these results, we analyzed tryptic peptides of the β-globin chain labeled with L-^{3}H-leucine and L-^{3}H-proline, separately, by reverse-phase HPLC, as described.[12] The radioactivity was consistent with the tryptic peptides that contain leucine at amino acid 110 and there was no abnormal hyperactive peak (data not shown). These results rule out the possibility that the mutant globin comigrated electrophoretically with the normal β-globin because of the lack of charge involved in the Leu-Pro substitution. The possibility that the mutant globin chain is extremely labile is given support.

DISCUSSION

A single nucleotide change found at codon 110 causes the leucine to proline substitution in individuals with a β-thalassemia phenotype. No abnormal globin chain was detected in reticulocytes even after 15 minutes labeling with L-^{3}H-leucine, by reverse-phase HPLC under conditions that separated the Leu-Pro variant from the normal globin chain. Proline (Leu-Pro) substitutions usually exert a profound effect on stability of the hemoglobin tetramer, because proline residues are unable to form an α-helix and are at the inter-helical segments of the chain where the helix has to be broken.[19] The mutation studied here is the thirteenth reported example of a Leu-Pro substitution in globin chains.[20] All the known Hb mutants with this amino acid substitution in the α- and β-globin chains produce unstable hemoglobin and cause hemolytic anemia,[20] except for the Hb Quong Sze.[21] The unusual feature of the mutation studied here is that the Leu-Pro substitution produces β-thalassemia rather than hemolytic anemia. Four α1β1 contact points, condons 108, 112, 115, and 116, are located in the G-helix of the β-globin chain.[22] These contact points are essential for initial dimeric formation and subsequently for the hemoglobin tetramer assembly. The substitution of proline for leucine at codon 110 probably disrupts the G-helix and in turn interferes with these contact points. The uncombined β-globin chain would be rapidly catabolized by proteolysis and the β-thalassemia phenotype would appear. A similar mechanism was described for the Hb Quong Sze (α125 Leu-Pro), which produces α-thalassemia rather than hemolytic anemia.[21] However, the proline substitutions at helical position G 8 (Hb Southampton-Casper),[23] G17 (Hb Madrid),[24] and G 19 (Hb Saitama)[14] produce hemoglobin variants present at levels of 20% to 40% and do not produce the thalassemic phenotype. The phenotypic difference between these variants and the mutation studied here could be derived from the position of the amino acid substitution in the G-helix. In our patient, the substitution of proline for leucine is located at G 12, almost at the center of the G-helix, so that a profound effect on the helical formation would be expected.

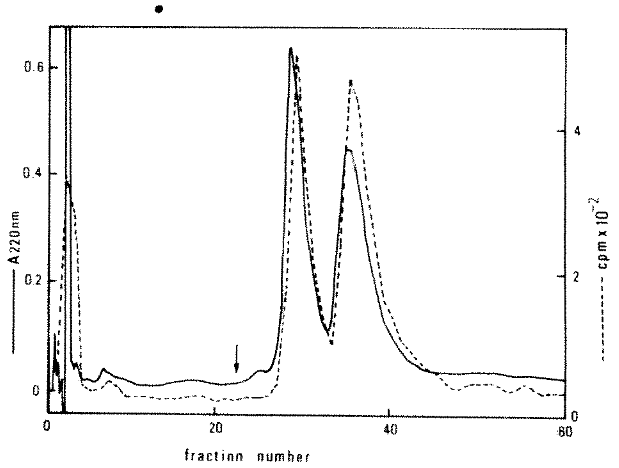

Fig 3. Chromatogram of the labeled globin chains. The peripheral blood of the proband was incubated in the presence of L-^{3}H-leucine (250 μCi/mL) for two hours at 37°C. The labeled globin chains were separated by reverse-phase HPLC on a TSK gel ODS-120T column. (——) Absorbance; (----) radioactivity. Arrow indicates the position of the abnormal β-globin chain (β88 Leu-Pro) of Hb Sant Ana.

A highly unstable β-globin mutant codon 112 (Cys-Arg), Hb Indianapolis, is also known to be associated with a β-thalassemia phenotype.[8] Heterozygotes for Hb Indianapolis have β/α-globin synthesis ratios of ~0.4. In contrast the globin chain synthesis ratios were higher than 0.7 in the cases we studied. These observations are not fully explained by the results of HPLC analysis. A condition that represses the α-globin chain production, such as in α-thalassemia, might be associated, although Southern blot analysis showed no abnormalities in the α-globin gene cluster of the proband (data not shown).

During the preparation of the manuscript, we learned from Dr Y. Naritomi et al that the same mutation has been found in an unrelated Japanese individual with a δβ-thalassemia phenotype. Therefore, we named this mutant, Showa-Yakushiji after names of the towns inhabited by each proband.

ACKNOWLEDGMENT

CONCISE REPORT

Mixed Blood Chimerism in T Cell-Depleted Bone Marrow Transplant Recipients: Evaluation Using DNA Polymorphisms

By S. Bretagne, M. Vidaud, M. Kuentz, C. Cordonnier, T. Henni, G. Vinci, M. Goossens, and J.P. Vernant

We have used DNA sequence polymorphism analysis to document engraftment after T cell-depleted bone marrow transplantation (BMT), with a selected panel of four DNA probes. In contrast to nondepleted BMT recipients, the patients who received T cell-depleted marrow exhibited a mixed blood chimerism. This mosaicism was observed before graft failure or relapse in six patients. However, in five other patients, this mixed chimerism was not followed by these complications with a follow-up of 9 to 31 months after transplantation. Our results support the hypothesis that transplanted bone marrow T cells may help to maintain engraftment by eliminating host cells that can cause graft failure.

© 1987 by Grune & Stratton, Inc.

THE ABILITY to establish the origin of cells following bone marrow transplantation (BMT) and to detect change in a patient's hematopoietic and lymphoid cell compartments from host to donor origin is clinically useful in assessing both the occurrence and completeness of engraftment. In particular, the pattern of engraftment is of interest with regard to the development of in vitro T cell depletion of the BMT. This technique, which has proved useful in the prevention of graft-*v*-host disease (GVHD),[1] dramatically increases the risk of graft failure and relapse,[2,3] a risk that is probably associated with the existence of residual host cells multiplying after transplantation. In order to explore this phenomenon, we have documented and characterized the pattern of engraftment in T cell-depleted and nondepleted BMT recipients using DNA sequence polymorphism analysis.

PATIENTS AND METHODS

Patients

Beginning in September 1984, certain patients transplanted in our unit received a T cell-depleted graft (Table 1). In this prospective study, recipients >30 years were selected for in vitro T cell depletion: 19 of these patients were analyzed for peripheral blood chimerism (12 in the depleted group and seven in the nondepleted group). In addition, three patients (patients no. 13, 14, and 15) having received a nondepleted transplant before the beginning of this study were examined retrospectively and are included in the control group.

All 22 patients received an allogeneic BMT from a HLA-identical mixed lymphocyte culture negative sibling as therapy for hematological malignant diseases (acute myeloblastic leukemia [AML], 7; acute lymphoblastic leukemia [ALL], 6; chronic myeloid leukemia [CML], 6; preleukemic state, 3). The BMT conditioning regimen consisted of chemotherapy (cyclophosphamide, 60 mg/kg × 2) and total body irradiation (TBI) (10 Gy single dose with mean dose rate 3 cGy/mn and lung shilding above 8 Gy). Six patients (no. 2, 5, 6, 10, 11, and 21) received a more ablative preparation (additive drugs or total lymphoid irradiation) (Table 1). All were given methotrexate (15 mg/m^2 on day 1, 10 mg/m^2 on days 3, 6, and 11, and weekly up to day 100) as GVHD prophylaxis. Twelve patients (no. 1 to 12) received T cell-depleted BMT either with monoclonal antibodies CD2-CD5-CD7 plus rabbit complement (patients no. 1, 2, 6, and 7) or with T101 immunotoxin (patients no. 3, 4, 5, 8, 9, 10, 11, and 12). These two techniques are equally efficient (mean depletion 99% and mean injected T cells 0.12 × 10^6/kg).[4] All patients were advised of chemotherapeutic and bone marrow procedures and their attendant risks, and gave informed consent.

DNA Analysis

In all the patients studied, engraftment was established and monitored with the use of DNA sequence polymorphism analysis as previously described[5-7] or with a Y chromosome-specific probe when donor and recipient sex were different. The genotype of the posttransplant cell fractions was compared with the pretransplant host and donor genotype.

Preparation of genomic DNA samples. Peripheral blood specimens from donors and patients before and after BMT were collected in EDTA. High molecular weight DNA was prepared by standard techniques. Ten micrograms of DNA were digested to completion with the restriction enzyme *Taq*I and 5 μg with *Hae*III in the case of sex mismatch. DNA fragments were then fractionated by electrophoresis in 1% agarose gels and transferred to nitrocellulose filters by the Southern's technique.

Hybridization with DNA probes. A panel of four probes comprising two X chromosome-specific probes (St14 and L1.28), a Y chromosome-specific sequence (HS5), and an autosomal probe (MetH) were used. The St14 probe for locus DXS52 (Xq28) is a 3.0 kg *Eco*R1 fragment that detects a multiallelic *Taq*I polymorphism.[8] Probe L1.28 detects a two alleles *Taq*I polymorphism at the locus DXS7 on the short arm of chromosome X.[9] The HS5 probe is a cloned DNA fragment that represents a major component of the human Y chromosome-specific repeated DNA family (DY21). Male DNA digested by Hae III contains 800 to 5,000 copies of a 3.4 kb DNA fragment,[10] a fragment that we never observed, in our experimental conditions, in DNA of female origin. The MetH probe detects a two allele *Taq*I polymorphism at a locus localized on the long arm of chromosome 7 (7q22-31).[11] The probes were labeled with ^{32}P deoxynucleotide triphosphates (Amersham International plc, Buckinghamshire, UK). Nitrocellulose filters were hybridized, washed, examined by autoradiography and the films were scanned with a spectrophotometer (Cellosystem, SEBIA, Issy-les-Moulineaux, France).

Fractionation of posttransplantation cells. In five patients (no. 3, 4, 8, 11, and 13) blood cells were fractionated into granulocytes, T

and B lymphocytes by Ficoll centrifugation, E-rosetting, and plastic adherence.

RESULTS

We first estimated the sensitivity of the assay by dilution experiments in which patient and donor DNAs were mixed in varying proportions. The minor cell population is still visible at levels in the order of 1% to 5% of total DNA with the use of the probes St14, L1.28, and MetH. This level of sensitivity is equivalent to that described by others using similar techniques.[5-7] In contrast, the use of probe HS5, in our experimental conditions, allows detection of 1 to 10 ng of male DNA. We evaluated that the level of sensitivity attained is as high as 0.1%, ie, a hybridization fragment was detectable in at least 0.1% of the cells from which DNA was extracted. Thus, this probe is very useful in the detection of residual male cells (residual cells of a male recipient transplanted from a female donor or cells of a male BMT in a female recipient).

The chimerism was analyzed with the HS5 probe in eight male recipients of female donor (patients no. 3, 4, 5, 9, 13, 14, 15, and 16), with St14 in ten female recipients of either male (patients no. 1 and 20) or female donor (patients no. 2, 6, 7, 8, 10, 11, 19, and 21) and with L1.28 in two male recipients of male donor (patients no. 17 and 18). In the two remaining male/male pairs (patients no. 12 and 22) these probes and MetH failed to distinguish between recipient and donor DNA.

In four recipients, the use of both St14 and HS5 probes was necessary to quantify the chimerism. In patient no. 9, male host cells exceeded 10% of total cells as demonstrated by the intensity of the hybridization signal with the Y-specific sequence, and probe St14 was used to evaluate the proportion of female donor DNA. In patients no. 10 and 11, probe St14 did not detect any DNA of male origin but the use of probe HS5 showed that engraftment of male cells persisted although clinical diagnosis of graft rejection had been made (up to 5 months after clinical diagnosis of graft rejection for patient no. 11). In patient no. 5, probe St14, in contrast to probe HS5, failed to detect residual male host cells at day 30 but could detect a male-specific allele at day 90 (Fig 1). It thus appears that the precocity with which the diagnosis of partial chimerism can be made depends on the sensitivity of the test used and on the growth rate of the residual cell population. Of the nine nondepleted BMT recipients studied (patients no. 13 to 21), eight exhibited total blood chimerism (from 2 months to 3 years post-BMT) and one (patient no. 13) (ALL) displayed a partial chimer-

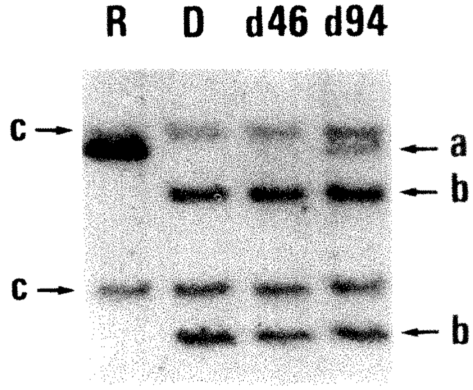

Fig 1. Expansion of residual host cells after transplantation (patient no. 5). DNA samples were obtained from the female donor (D) and from the male recipient prior to BMT (R) and after transplantation on day 46 (d46) and on day 94 (d94). Following digestion with Taq1 and hybridization with the probe St14 (DXS52) the recipient-specific allele (a) absent on day 46, was detected on day 94 post BMT (b_1 and b_2: donor specific alleles; c: constant fragments).

The Effect of Recombinant GM-CSF on the Recovery of Monkeys Transplanted With Autologous Bone Marrow

By R.L. Monroy, R.R. Skelly, T.J. MacVittie, T.A. Davis, J.J. Sauber, S.C. Clark, and R.E. Donahue

The regulatory function of recombinant human granulocyte-macrophage colony stimulating factor (rhGM-CSF) on granulocyte production in vivo was evaluated in an autologous bone marrow transplantation model using rhesus monkeys. Monkeys were exposed to 9.0 Gy total body irradiation and then transplanted with 5.0 × 10^7 low-density bone marrow cells/kg. Alzet miniosmotic pumps were subcutaneously implanted to deliver rhGM-CSF at a rate of 50,400 U/kg/d. Minipumps, containing either rhGM-CSF or saline, were implanted between zero and five days after transplantation for seven days. Kinetic recoveries of peripheral blood cells after either saline or rhGM-CSF treatment were compared. Treatment with rhGM-CSF accelerated the recovery of neutrophils. Neutrophils in rhGM-CSF-treated animals recovered to 80% (3.4 × 10^3/mm^3) pre-irradiation control levels by day 20, in comparison with only 33% (0.9 × 10^3/mm^3) recovery for saline control monkeys. In addition, the recovery of neutrophils was enhanced over that of the controls, reaching 140% v 70% on day 30. Another prominent feature of rhGM-CSF-treated monkeys was the accelerated recovery of platelets, reaching near 50% normal levels by day 24 in comparison with 20% of normal levels for controls. The infusion of rhGM-CSF was shown to be an effective regulator of early hematopoietic regeneration, leading to the accelerated recovery of both neutrophils and platelets and then providing a consistent sustained increase of neutrophils even in the absence of rhGM-CSF.

A VARIETY of glycoproteins with hormone-like stimulatory effects on hematopoietic progenitor cells have been purified and characterized. In recent articles, the molecular and biochemical properties of a specific murine and human glycoprotein, granulocyte-macrophage colony stimulating factor, were comprehensively reviewed.[1-3] Recombinant human granulocyte macrophage-colony stimulating factor (rhGM-CSF) has been shown to stimulate the proliferation of granulocyte-macrophage colonies in vitro from the bone marrow (BM) of humans[4-6] and primates.[7] Recombinant human GM-CSF was also shown to stimulate eosinophil and multipotent progenitor cells[4] and have burst-promoting activity.[4-8] Mice[9] and nonhuman primates[7,10,11] have been used to evaluate the in vivo effects of recombinant GM-CSF. In a recent report,[12] the continuous intravenous administration of rhGM-CSF, both before and after autologous bone marrow transplantation, led to an accelerated neutrophil and platelet recovery.

In this report, the regulatory function of rhGM-CSF in hematopoietic regeneration is elucidated using an autologous bone marrow transplantation model with nonhuman primates. The protocol was designed to evaluate the regulatory effects of rhGM-CSF during early hematopoietic regeneration.

MATERIALS AND METHODS

Animals. Domestic-born male rhesus monkeys, *Macaca mulatta*, mean weight 7.6 (±0.5) kg, were housed in individual stainless steel cages in conventional holding rooms in an AALAC (American Association for Accreditation of Laboratory Animal Care) accredited animal facility. Monkeys were provided ten air changes/h of 100% fresh air, conditioned to 72°F (±2°F) with a relative humidity of 50% (±20%); provided commercial primate chow and tap water *ad libitum;* and maintained on a 12-hour light/dark full spectrum light cycle with no twilight. All research was conducted according to the principles enunciated in the "Guide for the Care and Use of Laboratory Animals," prepared by the Institute of Laboratory Animal Resources, National Research Council.

Transplantation. Anesthetized monkeys had bone marrow harvested one to two hours prior to irradiation by multiple iliac crest aspirations as previously described.[13] Low-density cells, used for transplantation, were isolated from harvested marrow by isopycnic centrifugation (400 × g, 30 min) using Lymphocyte Separation Medium (specific gravity 1.077, Litton Bionetics, Gaithersburg, MD). Bone marrow cells (5.0 × 10^7/kg) were administered intravenously one to two hours after exposure. During exposure, monkeys were restrained in a plexiglass chair and exposed bilaterally, receiving a midline tissue dose of 9.0 Gy (0.4 Gy/min) ^{60}Co gamma rays. Technical manipulations of the animals were performed with the monkeys under sedation (ketamine hydrochloride, 10 mg/kg, intramuscularly (IM)). After transplantation, the animals were clinically managed, as previously described,[13] with the administration of antibiotics (gentamycin sulfate, 3 mg/kg/d, IM) and platelets. Platelets, irradiated with 30 Gy, were administered when the count was below 50,000/mm^3. Red cells were not administered. Monkeys did not experience any infections during the study period.

Pump implantation. All monkeys were initially acclimated to rhesus monkey jackets (Alice King Chatham, Los Angeles) for a period of 2 weeks prior to the implantation of the pump. The jackets were worn continuously for an additional 2 weeks after the pump was

implanted. Alzet miniosmotic pumps (2ML1, ALZA Corp, Palo Alto, CA), delivering 50,400 U/kg/d of rhGM-CSF over a period of seven days, were used in these experiments. Pumps were filled with either rhGM-CSF (n = 5) or saline (n = 2), and implanted between days 0 and 5. For surgical implantation of the pumps, monkeys were administered a general gas anesthesia: 0.5% to 5% halothane in a 65% N_2O-30% O_2 mixture. Pumps were implanted subcutaneously, along the midline of the back, caudal to the scapular crests. The skin was closed with 4/0 chromic gut placed in a continuous subcuticular suture pattern and bandaged. At the end of seven days, the pump was removed through the same surgical wound, flushed with a 50:50 hydrogen peroxide-sterile water solution and Betadine, and then packed with Betadine-soaked gauze and the animal lightly bandaged. The packing was changed on a daily basis for the next few days and was continually treated until healing was complete. All pump implantation sites healed within a week. The pump site was cultured for bacteria after pump removal and all bacterial cultures were negative.

Recombinant human GM-CSF. The rhGM-CSF used in these experiments was provided by Genetics Institute. A unit of activity for rhGM-CSF has been defined as the amount of GM-CSF needed to stimulate half of the maximal possible incorporation of ^{3}H-thymidine by CML peripheral blood myeloblasts.[7] The rhGM-CSF used in these studies had an activity of either 10^6 or 10^7 U/ml. A loading dose of 50,000 U/kg was administered intravenously on the day of pump implantation.

RESULTS

Recovery of Peripheral Blood Cells After Transplantation With or Without rhGM-CSF Infusion

The continuous subcutaneous administration of rhGM-CSF into autologous bone marrow transplanted monkeys (n = 5) led to an accelerated recovery of the peripheral blood (PB) neutrophils in comparison to control saline infused animals (n = 2) (Fig 1). Neutrophil levels recovered to 80% normal preirradiation values by day 20 in monkeys infused with rhGM-CSF, in comparison to 33% for control animals. The neutrophil recovery was also enhanced in contrast to the controls, reaching levels greater than 140% v 70% on day 31. The enhanced neutrophil production continued in the absence of rhGM-CSF. A consistent and sustained increase in neutrophil counts was observed in all treated monkeys. Treatment with rhGM-CSF led to a shortened time of neutropenia with a neutrophil count of >1,000/mm^3 on day 17 v day 20 for saline controls.

Platelet recovery in rhGM-CSF–infused monkeys was accelerated over that of controls, reaching 62% (220,000/mm^3) normal levels by day 28 v 20% (72,000/mm^3) for control monkeys on the same day. The early recovery reduced the period of thrombocytopenia and requirement for clinical platelet transfusions by at least two days.

Monocyte/macrophage recovery was enhanced but not accelerated. Monocyte levels reached 155% in rhGM-CSF–infused monkeys by day 20, in contrast to 60% recovery in control monkeys. The recovery of PB lymphocytes to normal levels was prolonged in rhGM-CSF infused animals. Lymphocyte levels in controls reached nearly 50% by day 40, while rhGM-CSF–infused monkeys were only at 12% of normal. Increased recovery of PB eosinophils was not observed in either the treated or untreated monkeys. Reticulocytes were not measured in this study; however, measured red blood cell parameters (hematocrit, RBC count, hemoglobin, and mean corpuscular volume) did not indicate any difference between the treated and untreated monkeys.

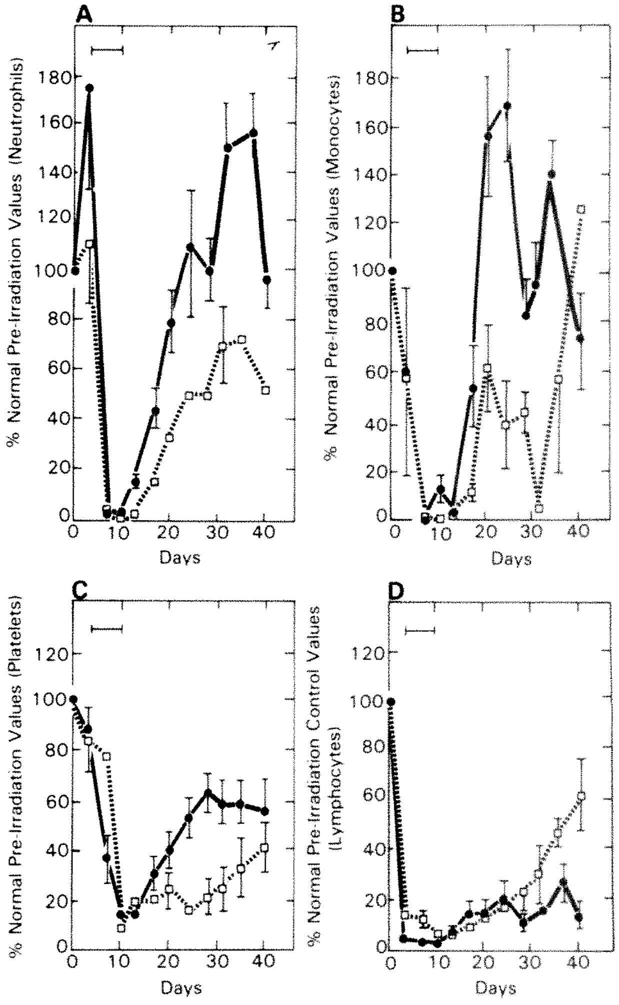

Fig 1. Peripheral blood cellular response, (A) neutrophils, (B) monocytes, (C) platelets, (D) lymphocytes, in monkeys after autologous bone marrow transplantation and then infused for seven days with rhGM-CSF (●) or Saline (□). Graphed as percent of mean normal preirradiation levels. A series of peripheral blood samples were drawn over a period of 3 to 4 weeks prior to initiating an experimental protocol to establish a hematologic baseline for each animal. Mean normal values for mature peripheral blood cells were determined from these pre-samples and identified as 100%. The mean (±SE) normal values of the monkeys used in this study are neutrophils, 4.2(±0.9) × 10^3/mm^3; platelets, 358,000 (±29,000)/mm^3; lymphocytes, 3.4(±0.4) × 10^3/mm^3; and monocytes, 0.4 ± 0.1 × 10^3/mm^3. The period of rhGM-CSF infusion is indicated with a bar.

Physiological Response of the Monkeys to the Infusion of rhGM-CSF

In comparison with controls (n = 2) and historical data (n = 10),[13] three of the monkeys infused with rhGM-CSF (n = 5) after irradiation and bone marrow (BM) transplantation experienced a severe weight loss (20% to 40%). The severity of the weight loss became apparent between 21 and 28 days, when saline control monkeys began to gain weight, and the rhGM-CSF–infused monkeys did not. The weight loss was not the result of anorexia or diarrhea since food intake and stools were comparable in both groups of monkeys. Two of the three monkeys experiencing a severe weight loss were euthanized (days 32 and 45) and necropsied. Pathology reports identified potential malabsorption associated with lymphangiectasia. The causes underlying this condition are currently under investigation. Both of these animals showed normal hematopoietic tissue.

DISCUSSION

Our objective in this study was to evaluate the regulatory properties of rhGM-CSF during early hematopoietic regeneration. The results demonstrate that a seven-day continuous subcutaneous treatment with rhGM-CSF during the early regenerative phase of hematopoiesis led to an accelerated recovery of PB neutrophils. The neutrophil response was also shown to be enhanced, attaining peak circulating counts 3 to 4 weeks after rhGM-CSF treatment. This continued neutrophil response is suggested to be the result of rhGM-CSF stimulating the regenerating BM to increase preferentially the size of the granulocyte-macrophage progenitor/stem cell pool. This increased progenitor/stem cell pool was thus responsible for the continued and elevated neutrophil output, even after rhGM-CSF was removed. Preliminary results for two of the rhGM-CSF–treated monkeys show that colony-forming unit granulocyte-macrophage (CFU-GM) activity in the BM attained peak activity (~140% of normal) on days 20 and 31. This was followed by a return to normal over the next 3 weeks. Observations using a hematopoietic suppression model also show that rhGM-CSF preferentially increases the pool of CFU-GM progenitor cells (unpublished observations).

Changes in the level of PB platelets after treatment with GM-CSF were not previously reported in either the normal murine[9] or primate models.[7] The recent report by Nienhuis and coworkers,[12] shows that GM-CSF treatment improves the recovery of platelets after transplantation. In our report, platelet recovery to a 50% level was also rapid, and reduced the time by two days that monkeys remained below a threshold for platelet transfusion. However, all treated monkeys demonstrated a consistent and sustained platelet recovery after treatment was terminated. In vitro results have suggested that megakaryocytes were stimulated by murine GM-CSF but that the stimulation required a higher dose of the factor than for CFU-GM progenitor cells.[11] The delivery dose used in these in vivo studies appeared sufficient for increased platelets in circulation. Whether rhGM-CSF has a direct effect on megakaryocyte progenitor cells or an indirect effect by increasing production of thrombopoietin or some other mechanism is uncertain.

The shortened period of neutropenia after bone marrow transplantation using GM-CSF was recently reported[12] and the results were comparable to our findings. In that study, GM-CSF was administered until the neutrophil count was at least >2,000/mm^3. However, circulating neutrophils were reduced by >50% upon termination of GM-CSF. This is in contrast to our results, which showed a sustained increase in neutrophils even after GM-CSF was removed.

We have therefore demonstrated that rhGM-CSF is an effective regulator of early hematopoietic regeneration, promoting an accelerated recovery of neutrophils and platelets even after GM-CSF was removed. The early effect of the GM-CSF was also long lasting, providing a sustained recovery of neutrophils and platelets. The potential clinical applications will include stimulation of hematopoietic regeneration following bone marrow aplasia, irradiation, cytotoxic therapy, or bone marrow transplantation.

ACKNOWLEDGMENT

We thank Drs Steven Stiefel and Jim Nold for their consultation on pathological findings and Thomas Lee, Karl Noldy, and Jeff Hyde for their dedicated technical support. We also thank the engineering staff and process development laboratory at Genetics Institute for recombinant human GM-CSF.

CONCISE REPORT

Tumor Necrosis Factor (TNF)-alpha but not TNF-beta Induces Secretion of Colony Stimulating Factor for Macrophages (CSF-1) by Human Monocytes

By W. Oster, A. Lindemann, S. Horn, R. Mertelsmann, and F. Herrmann

Tumor necrosis factor (TNF)-alpha has been identified as a major inducer of colony stimulating factor (CSF)-secretion by human vascular endothelial cells and fibroblasts. In the present study we assessed the capacity of TNFs to induce release of CSF-1 from highly purified peripheral blood monocyte preparations. Whereas monocytes do not accumulate CSF-1 messenger (m)RNA constitutively and consequently do not produce CSF-1 protein, CSF-1 mRNA and protein secretion became detectable, when monocytes were cultured in the presence of TNF-alpha, that was synergistically enhanced by interferon-gamma (IFN-gamma). However, under identical experimental conditions TNF-beta failed to induce monocyte CSF-1 synthesis. Cultures of monocytes in the presence of TNF-beta before addition of TNF-alpha abolished the CSF-1 inducing capacity of TNF-alpha, suggesting that TNF-beta may act as antagonist to TNF-alpha for CSF-1 production. These data point out a previously unrecognized function of TNF-alpha to modulate CSF-1 release by monocytes and demonstrate disparate biological properties of different TNF species in hematopoiesis.

©1987 by Grune & Stratton, Inc.

COLONY STIMULATING FACTOR (CSF)-1 (also referred to as M-CSF) has been genetically cloned and expressed[1] and biologically characterized.[2] CSF-1 specifically stimulates proliferation of monocyte/macrophage precursors,[2] induces selected functions of mature monocytes,[3] and is involved in the production of various biological mediators including interferon,[4] prostaglandin E,[5] interleukin 1,[6] CSF for granulocytes (G-CSF),[7] and TNF-alpha[8] by monocytes/macrophages. Recently, phorbolester-stimulated peripheral blood monocytes have been identified as a potent source of CSF-1.[9]

TNF-alpha, synthesized by activated monocyte/macrophage cells,[10] and TNF-beta, originating from stimulated T cells,[11] reveal a 36% identity and 51% homology in the overall amino acid sequence,[10] share common receptor binding domains,[12] and exert similar cytolytic and cytostatic effects on various tumor targets in vitro and in vivo.[13]

The roles of both TNF species have been described to extend to modulation of hematopoiesis, by sharing similar inhibitory effects on colony growth of granulocyte-macrophage, erythrocyte, and granulocyte-erythrocyte-megacaryocyte-macrophage precursors (CFU-GM, BFU-E, CFU-GEMM).[14-16] In addition, TNF-alpha has been shown to induce CSF secretion by human lung fibroblasts[17] and vascular endothelial cells[18] with molecular and biological characteristics of granulocyte-macrophage (GM)-CSF. So far there has been no evidence for disparate effects of TNF-alpha and TNF-beta on normal hematopoietic cells.

In the present study we assessed the capacity of both molecules to modulate CSF-1 expression and secretion by human monocytes, using Northern blot analysis and murine CFU-GM colony assays. Our data revealed that TNF-alpha but not TNF-beta transcriptionally regulates production of CSF-1 by human monocytes. TNF-alpha induced mRNA accumulation for CSF-1 is synergistically enhanced by the presence in culture of IFN-gamma and can be antagonized by TNF-beta.

MATERIALS AND METHODS

Preparation of monocytes and T cells. Peripheral blood derived mononuclear cells were isolated from leukapheresis residues of consenting healthy volunteer donors by Ficoll-Hypaque gradient (density 1.078 g/dL) centrifugation. T cells were recovered with AET (2-aminoethylisothiouronium bromide hydrobromide)-treated sheep RBCs (SRBCs) (5% vol/vol solution). Monocytes were separated by two sequential adherence steps of the SRBC-rosette negative fraction. Individual cell fractions, assessed by morphology (Wright Giemsa and alpha-naphthyl acetate esterase [ANAE] staining) and immunofluorescence analysis, using monoclonal antibodies (MoAb) to the T11, Mo2, and B1 antigens,[20] revealed preparations of >98% purity. Monocytes or T cells were plated at 10^6 cells/mL in RPMI 1640 supplemented with 5% fetal calf serum (FCS), penicillin/streptomycin, L-glutamine and sodium pyruvate in plastic petri dishes (35 mm/well; Corning, New York). Recombinant human (rh) TNF-alpha or TNF-beta (kindly provided by Genentech, San Francisco, through R. Flener, Boehringer, Vienna) was added to cultures at 50 ng/mL (specific activity 5×10^7 U/mg or 1.2×10^8 U/mg, respectively). In selected experiments cultures received IFN-gamma (0.05 ng/mL; specific activity of IFN-gamma 4×10^7 U/mg; kindly provided by Genentech). In control cultures the addition of TNF-alpha, TNF-beta, and IFN-gamma was omitted. Cell-free supernatants were collected after 48 to 72 hours of culture. To neutralize the effects of carry-over of TNF preparations on growth of hematopoietic progenitor cells, TNF-monocyte conditioned media (TNF-MCM) and TNF-T cell conditioned media (TNF-TCM) were pretreated with MoAb to TNF-alpha or TNF-beta (kindly provided by Genentech) at concentrations sufficient to neutralize threefold more TNF-alpha or TNF-beta than was originally added. For RNA analysis cultures were performed for six to 24 hours or in selected experiments for up to 96 hours.

Northern blot analysis. Total RNA was prepared using the guanidium/cesium chloride method and denatured with glyoxal and dimethylsulfoxide as described previously[21] after quantification by spectralphotometry. Aliquots of each RNA were stained in minigels

before denaturation with ethidium bromide to visualize 28 S and 18 S ribosomal RNA bands, in order to confirm quantification and integrity of the RNA samples. Identical amounts of total RNA (10 μg) were size-fractionated in 1.2% agarose gel electrophoresis, transferred to nylon base paper by capillary blot using 10 × SSC and baked for two hours at 18°C.[21] Specific c-DNA probe for M-CSF (1 kb Bgl I-PST I fragment cloned in PUC 18, kindly provided by P. Ralph, Cetus Corporation, Emeryville, CA) was radiolabeled as reported previously[22] with a specific activity of 2,5 to 3,5 × 10^8 cpm per μg DNA. Hybridization was performed in 50% formamide, 1% SDS, 5 × Denhardt's, 6 × SSPPE at 42°C for 18 hours. Filters, washed with 2 × SSC at 27°C, 0.1 × SSC, 1% SDS at 65°C and 0.1 × SSC at 27°C, were exposed to Kodak XAR5 with Dupont Cronex intensifying screens.

Murine CFU-GM colony assay. CFU-GM were assayed in a double layer agar culture system as previously described.[23] Underlayer (0.5 mL) were composed of 0.5% agar (Agar Noble, Difco, Detroit, IL) in Iscove's modified Dulbecco's minimum essential medium (IMDM) supplemented with L-glutamine, penicillin/streptomycin, 20% FCS and 5 × 10^{-5} mol/L 2-mercaptoethanol. As a potential source of CSF, media conditioned by monocytes (MCM) cultured for 48 to 72 hours in the presence or absence of TNF-alpha (50 ng/mL) and TNF-beta (50 ng/mL), respectively were added to the underlayers at 10% vol/vol final concentration. Overlayers (0.5 mL) were composed of 0.3% agar in the same medium and contained 5 × 10^4/mL murine (BDF, 1 mice) bone marrow cells (obtained from femures). CFU-GM were enumerated at day 7 and lineages of colonies were assessed by cytochemical in situ staining of whole agar cultures.[23] Naphtol-AS-D-chloroacetate esterase staining (CAE) detects granulocytic colonies, ANAE staining macrophage colonies.

RESULTS AND DISCUSSION

We have previously shown, that monocytes are a potential source of CSF-1 when induced with phorbol esters.[9] In the present study we investigated effects of TNF-alpha and TNF-beta on CSF-1 secretion by monocytes. Whereas monocytes do not transcribe CSF-1-gene constitutively (Fig 1, lane a) CSF-1 mRNA of 4.5 kb length became detectable, when monocytes were cultured in the presence of TNF-alpha for six hours (Fig 1, lane b) to 24 hours (not shown). In contrast, under identical conditions, TNF-beta failed to induce CSF-1 mRNA synthesis by monocytes (Fig 1, lane c); concentrations of TNF-beta >50 ng/mL (up to 500 ng/mL) and prolongation of incubation periods to >24 hours (up to 96 hours) did not affect CSF-1 processing (not shown). Autoradiograms exposed for as long as 14 days continued to show no signal for CSF-1 mRNA, when monocytes were incubated in the presence of TNF-beta. As in all cultures systems like the one used here, it is difficult to prove that the CSF-1 activity is actually released by monocytes and not by contaminating T cells. To determine if the effect of TNF-alpha on induction of CSF-1 release was on monocytes and not on possibly contaminating T cells, experiments were performed, in which the effects of TNFs on expression and secretion of CSF-1 by resting T cells were investigated.

Under experimental conditions that resulted in CSF-1 release by monocytes, T cells were unable to express or release CSF-1 in response to TNF-alpha (Fig 1, lane e). Since TNF-alpha and TNF-beta compete for binding to a common receptor domain[12] we investigated the possibility, whether TNF-beta acts as an antagonist to TNF-alpha for CSF-1 production by culturing monocytes sequentially in the presence of both factors. Treatment of monocytes with TNF-beta for six hours before addition of TNF-alpha abolished the potential of TNF-alpha to induce CSF-1 mRNA accumulation (Fig 2).

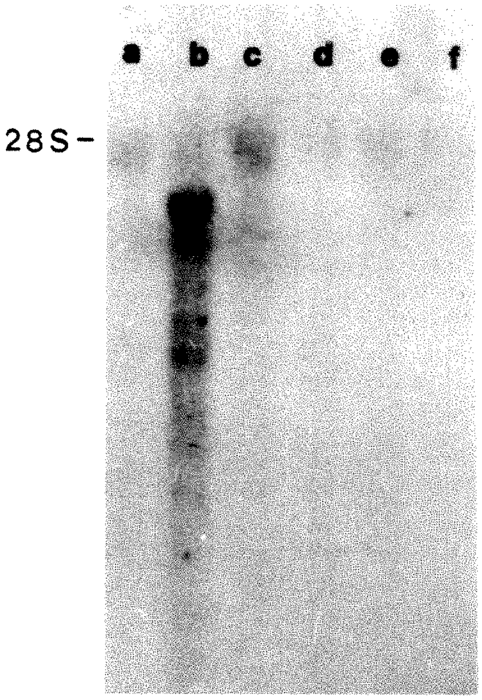

Fig 1. **Northern blot analysis probing CSF-1 cDNA. Total RNA derived from monocytes cultured for six hours in medium only (lane a), in medium containing 50 ng/mL TNF-alpha for six hours (lane b), or 50 ng/mL TNF-beta for six hours (lane c). RNA derived from T cells cultured for six hours in medium only (lane d), in the presence of 50 ng/mL TNF-alpha for six hours (lane e), or 50 ng/mL TNF-beta for six hours (lane f).**

Since IFN-gamma synergizes with TNFs in a variety of systems,[14-16] effects of IFN-gamma on TNF-alpha inducible CSF-1 mRNA accumulation was investigated. To this end, RNA of monocytes was probed with a CSF-1 c-DNA that

Cell-free media were used as potential stimuli for murine CFU-GM at final concentrations of 10% vol/vol: Monocyte conditioned medium (MCM), in the presence of TNF-alpha (TNF-alpha MCM) or TNF-beta (RNF-beta MCM), T-cell conditioned medium (TCM) in the presence of TNF-alpha (TNF-alpha TCM) or TNF-beta (TNF-beta TCM).

[†] Colony numbers are means of triplicate CFU-GM assays (±SD).

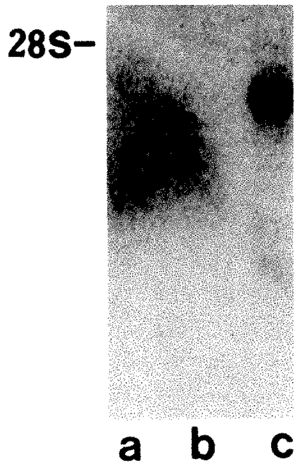

Fig 3. Northern blot analysis probing CSF-1 cDNA. Total RNA derived from monocytes cultured for 12 hours in medium containing 0.01 ng/mL TNF-alpha (lane a), 0.05 ng/mL IFN-gamma (lane b), or 0.01 ng/mL TNF-alpha plus 0.05 ng/mL IFN-gamma (lane c).

were cultured for 12 hours in the presence or absence of IFN-gamma and TNF-alpha in concentrations that had no effect on CSF-1 mRNA synthesis by their own. However, when cultures were performed in the presence of both factors, CSF-1 mRNA became detectable (Fig 3). To investigate whether increased levels of CSF-1 mRNA detected in TNF-alpha treated monocytes were accompanied by secretion of the biologically active protein, cell-free supernatants of monocytes, cultured in the presence of TNF-alpha (50 ng/mL) for 48 to 72 hours, were assayed in murine CFU-GM colony assays. Rh CSF-1 is known to stimulate only very small clusters of monocytes in agar culture of light density human marrow cells[2] but has the ability to induce the appearance of larger macrophage colonies on day 7 in a murine system. Rh GM-CSF is known to lack proliferative effects on adult or fetal murine hematopoietic cells[23] and rh G-CSF stimulates growth of murine granulocytic colonies only.[24] Thus, stimulation of murine macrophage colony growth distinguishes human CSF-1 from G- and GM-CSF activity. Murine colonies grown in double layer agar cultures were enumerated on day 7. Supernatants collected from unstimulated monocytes cultured for 48 to 72 hours contained negligible CSF-1 and G-CSF activity. Treatment of monocytes with TNF-alpha (50 ng/mL), but not TNF-beta, induced release of CSF-1 activity (Table 1). Our results point out a previously unrecognized function of TNF-alpha in modulating CSF-1 release by monocytes. Since monocytes lack CSF-1 mRNA constitutively, the level at which the upregulatory effects of TNF-alpha induced CSF-1 production take place is transcription.

In the context of the recent observation of induction of monocyte-TNF-alpha secretion by CSF-1[8] our present finding of a reversed induction sequence (ie, induction of CSF-1 secretion by TNF-alpha) suggests autocrine regulatory functions of both molecules. TNF-alpha induced CSF-1 release may stimulate proliferation of monocyte/macrophage precursor cells and augment the functional repertoire of mature monocytes in an autostimulatory manner.

In two of three experiments TNF-alpha MCM and TNF-beta MCM supported growth of granulocytic colonies as well (Table 1) suggesting the possibility that TNF-alpha not only induces secretion by monocytes of CSF-1 but also of G-CSF and that the inductive potential of TNF-beta for CSF-secretion is restricted to G-CSF.

ANNOUNCEMENTS

HEMATOLOGY
NEONATAL, PEDIATRIC, AND AIDS-RELATED ISSUES

March 18-19, 1988
Berkeley Marina, San Francisco Bay, California

This seminar, sponsored by Children's Hospital Oakland, is approved for 11 hours Category I credit. The program will address the health care provider's role in assessing and managing hematologic disorders in the neonatal and pediatric patient. Topics to be presented include inherited bleeding disorders, hyperbilirubinemia, anemia, polycythemia, DIC, management of life-threatening complications in hematology-oncology, the New York AIDS experience, neonatal and pediatric AIDS, infectious disease complications in pediatric AIDS, primary care for AIDS patients, blood products and transfusion risks, and new drug therapy in the prevention and treatment of AIDS.

For further information, contact: Kim Leadon, Children's Hospital Oakland, 747 52nd Street, Oakland, CA 94609. Phone: (415) 428-3021.

WILMOT CANCER RESEARCH FELLOWSHIPS

The University of Rochester School of Medicine offers research training to physicians who have completed at least 1 year of residency or research experience. Fellowships will begin July 1, 1988. Opportunities exist in any discipline relevant to the cause, diagnosis, treatment, or prevention of cancer, including endocrinology, experimental therapeutics, genetics, hematology, immunology, microbiology, molecular and cellular biology, pathology, and radiation oncology.

Beginning stipends range from $32,000 to $34,000, based on postgraduate experience. There is an annual allowance of $5,000 for related research costs. Support is provided for up to 3 years.

For further information, contact: Wilmot Cancer Research Fellowship Program, Medical Center Box 601, University of Rochester School of Medicine & Dentistry, 601 Elmwood Ave, Rochester, NY 14642.

ONCOLOGY PRACTICE 1988: A PERSPECTIVE

January 31-February 6, 1988
Snowmass, Colorado

For further information, contact: Stephen E. Jones, MD, Charles A. Sammons Cancer Center, Room 4800, Baylor University Medical Center, 3500 Gaston Ave, Dallas, TX 75246. Phone: (214) 820-2021.

AMERICAN BOARD OF INTERNAL MEDICINE
1988 SUBSPECIALTY EXAMINATIONS IN HEMATOLOGY

Registration Period:	January 1, 1988-April 1, 1988
Examination Date:	November 1, 1988

For information and application form, contact: Registration Section, American Board of Internal Medicine, 3624 Market Street, Philadelphia, PA 19104.

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

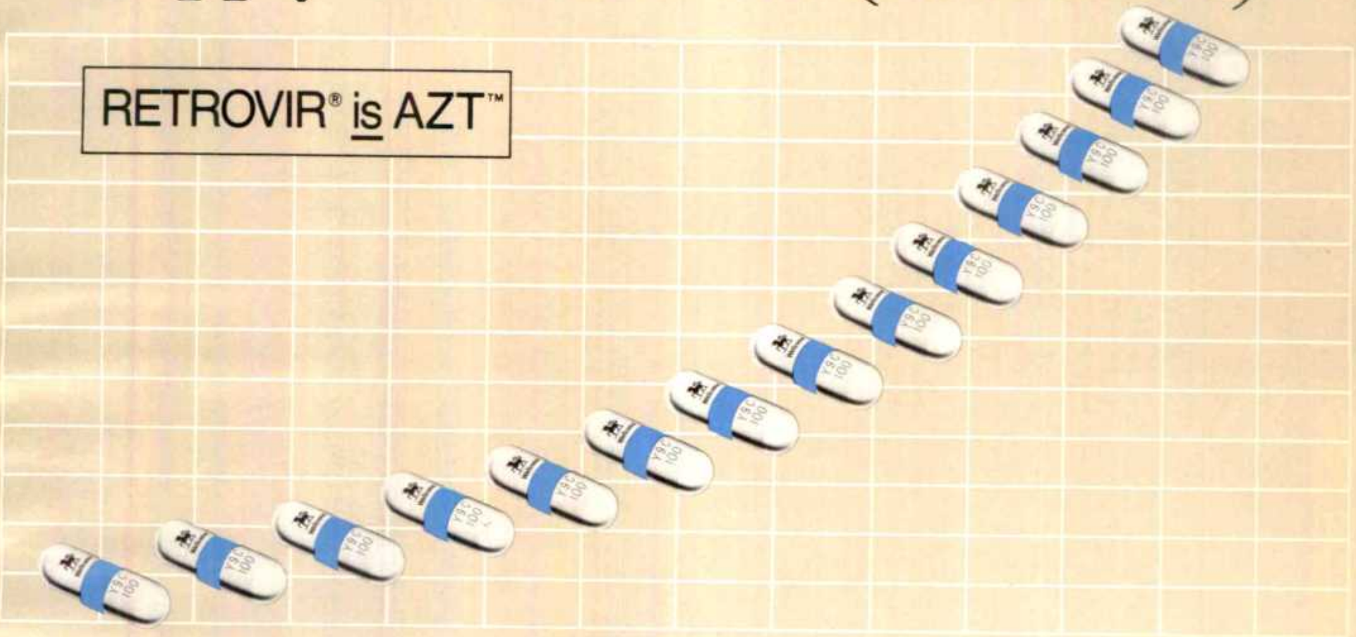
ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

NEWS ALERT NEWS ALERT NEWS ALERT NEWS ALERT

AIDS UPDATE

A significant increase in the supply of RETROVIR® (zidovudine)



All appropriate patients can now benefit from RETROVIR therapy

RETROVIR can now be prescribed just as any other medication

Since there is no longer a need for the RETROVIR enrollment program

Around-the-clock production of RETROVIR was implemented

Because of the growing number of AIDS and ARC patients in need of treatment

The supply of RETROVIR has been increased significantly

So that many more patients with AIDS and other serious HIV infections can now benefit from therapy

New clinical trials of RETROVIR are now under way

Because of our commitment to improving the treatment of HIV infections

IMPROVING LIVES THROUGH ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

Please see brief summary of prescribing information on other side of this advertisement.

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OI'S) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper inducer) lymphocyte count of less than 200/mm^3 in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 160 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss (> 15 lbs or > 10% of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 cells/mm^3 at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of < 750/mm^3. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count < 1000/mm^3 or hemoglobin < 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 µg/ml and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/TK$^{+/-}$ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 µg/ml). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 µg/ml and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 µg/ml and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 µg/ml.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in the placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudine; 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicities was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entry, and directly related to dose and duration of therapy. The frequency of granulocytopenia and anemia according to the patients' CD4 (T4) levels is shown in the following table:

	Pretreatment CD4 (T4) Levels			
	< 200/mm^3		> 200/mm^3	
Abnormality	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia (< 750/mm^3)	47%	10%	10%	3%
Anemia (Hgb < 7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudine, examining the degree of change when compared to baseline, as shown in the table below, may be more informative.

		Pretreatment CD4 (T4) Levels			
		< 200/mm^3		> 200/mm^3	
Abnormality	% Decrease from Baseline	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	> 50%	55%	19%	40%	13%
Anemia	> 25%	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasing macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseline symptoms and clinical abnormalities. The following table summarizes those reported clinical adverse events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nausea, insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4	NERVOUS		
Fever	16	12	Dizziness	6	4
Headache	42	37	Insomnia	5	1
Malaise	8	7	Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4	SKIN		
GI Pain	20	19	Rash	17	15
Nausea	46	18	SPECIAL SENSES		
Vomiting	6	3	Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are listed below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudine recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pain, lymphadenopathy.
Cardiovascular: vasodilation.
Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gums, rectal hemorrhage, mouth ulcer.
Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.
Nervous: anxiety, confusion, depression, emotional lability, nervousness, syncope, loss of mental acuity, vertigo.
Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.
Skin: acne, pruritus, urticaria.
Special senses: amblyopia, hearing loss, photophobia.
Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (two 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and duration of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serious anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur as early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of < 7.5 g/dL or reduction of > 25% of baseline) and/or significant granulocytopenia (granulocyte count of < 750/mm^3 or reduction of > 50% from baseline) may require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia or granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anemia, dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occurs following dose modification, gradual increases in dose may be appropriate depending on hematologic indices and patient tolerance.

Reviews of the first edition of
ATLAS OF BLOOD CELLS

"... it represents the first edition of a book destined to become a classic."—*Ultrastructural Pathology.*

"... this two-volume set on the morphology and pathology of the major cells of the hematopoietic system is outstanding."—*Archives of Pathology and Laboratory Medicine.*

- **ATLAS OF BLOOD CELLS: Function and Pathology, 2nd ed.** *By* D. ZUCKER-FRANKLIN, M.D., *New York University School of Medicine, New York, New York;* M.F. GREAVES, Ph.D., *Chester Beatty Laboratories, London, England;* C.F. GROSSI, M.D., *University of Alabama, Birmingham, Alabama; and* A.M. MARMONT, M.D., *San Martino Hospital, Genova, Italy.* Combining the advantages of the first edition with significant revisions and important additions, the second edition of this landmark atlas is once again presented as a two-volume set, featuring new contributors and a foreword again written by hematology's senior statesman, the late Dr. Maxwell Wintrobe. The text has been substantially revised with new material and a more clinical orientation, expanded with a new chapter, "Antigen Presenting Cells," and streamlined by joining two former chapters into one chapter. The visual element is likewise improved with the addition of new color illustrations, slides and electronmicrographs, and selective enlargement of existing illustrations. Through these careful changes, a great atlas has gotten even better ... and will continue to receive the acclaim accorded to the original edition. *About 1300 pp. (8½ x 12¼), in Two Volumes, about 1500 illus. (800 in full color), December 1987, In Prep. pre-pub price: $185.00 at-pub. price: $225.00.*

- **TEXTBOOK OF HEMATOLOGY** *By* SHIRLYN B. McKENZIE, MT(ASCP)SH, *University of Texas School of Allied Health Sciences, San Antonio, Texas.* Normal hematopoiesis is first analyzed, with attention to cell structure, cell development and hematopoietic tissue. With this introductory material as a foundation, the varied anemias, neoplastic and non-neoplastic and white blood cell disorders are examined from a pathophysiologic standpoint. The subject of hemostasis is approached in the same manner. *About 400 pp. (7¼ x 10¼), 150 illus. (4 color plates), January 1988, In Prep. About $27.50.*

- **BLOOD DISORDERS IN PREGNANCY** *Edited and with contributions by* RUSSELL K. LAROS, JR., M.D., *University of California, San Francisco, California.* Addresses hematologic problems most commonly associated with pregnancy. The initial chapters cover various anemias of pregnancy with the first chapter outlining a stepwise and logical approach to diagnosis and evaluation of anemia. Subsequent chapters detail the pathophysiology, diagnosis and treatment of the nutritional anemias, the hemoglobinopathies, varied hemolytic anemias, and aplastic anemia. *245 pp. (6⅞ x 10), 16 illus., 1986, $32.50.*

- **SCHALM'S VETERINARY HEMATOLOGY, 4th ed.** *By* NEMI C. JAIN, Ph.D., *University of California, Davis, California.* The subject is presented primarily from the point of view of its application to clinical veterinary medicine. It outlines the basic approach to examination of blood and bone marrow and details the use of essential hematologic techniques. All aspects of basic and applied hematology are thoroughly discussed, with emphasis on pathophysiologic, pathogenetic, and diagnostic implications in diseases of animals. *1221 pp. (7¼ x 10¼), 488 illus. (including 25 color plates with 202 illus.), 1986, $125.00.*

- **HEMATOLOGY, THE BLOSSOMING OF A SCIENCE: A Story of Inspiration and Effort** *By the late* MAXWELL M. WINTROBE, M.D., Ph.D. Combining autobiographical information with biographical accounts of over 500 names in the field of hematology, Dr. Wintrobe presents a comprehensive history of the contributors, and their contributions, to the science of hematology. Beginning with an overview of hematology as it evolved from antiquity to the early part of this century, the author then traces his six decades of experiences and involvement in hematology research. *564 pp. (7¼ x 10¼), 150 photographs, 1985, $60.00.*

CANADIAN RED CROSS SOCIETY
BLOOD TRANSFUSION SERVICE
OTTAWA CENTRE
DEPUTY MEDICAL DIRECTOR POSITION

The Ottawa Centre of the Canadian Red Cross Society, Blood Transfusion Service is inviting applications from physicians for the position of DEPUTY MEDICAL DIRECTOR.

The position involves major responsibility for a full service apheresis unit providing both cell support and plasma exchange services to a population of 800,000. The Deputy Medical Director participates in research and development programs and assists the Medical Director in general administration of the blood program. The Centre currently collects, tests, processes and issues approximately 65,000 units of blood annually. Applicants must be Canadian or American Board certified or equivalent.

Interested applicants should apply in confidence giving all details of experience and expected salary requirements to:

Dr. G. Rock
Medical Director

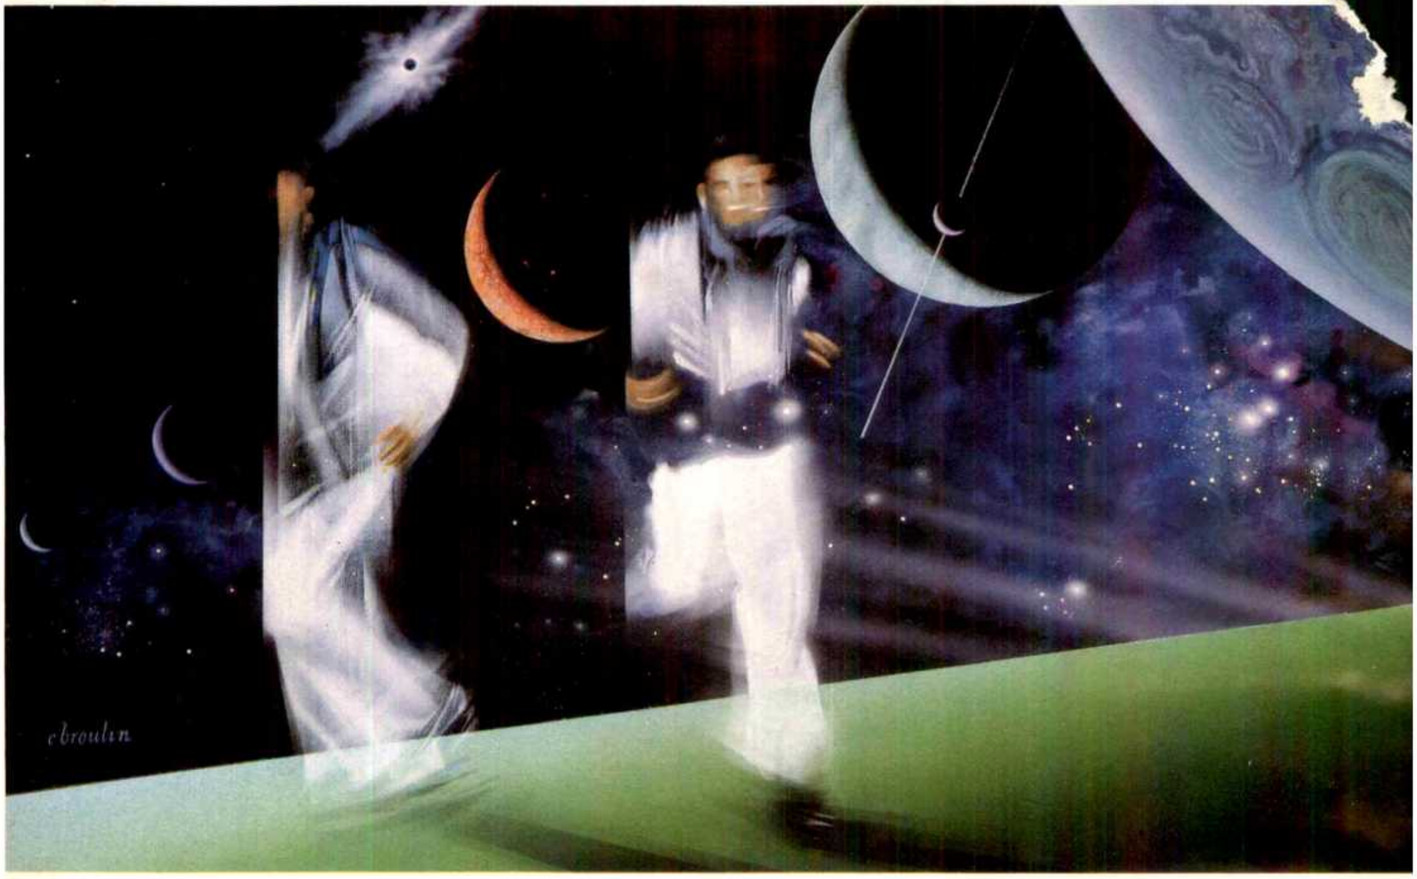
OULTER IMMUNOLOGY, A DIVISION OF COULTER CORPORATION

INTRONA: L'INTERFERON alf



FORME ET PRESENTATION :
Lyophilisat et solution pour usage parentéral : Boîte unitaire

COMPOSITION :
Lyophilisat : 23,8 mg p. flacon.
Interféron alfa-2b 3 millions U.I.
ou 5 millions U.I. ou 10 millions U.I. ou 30 millions U.I.
Excipient : Sodium (hydrogénophosphate de) anhydre,
Phosphate monosodique monohydraté, Acide amino-acétique, Albumine humaine.
Solution : Eau pour usage parentéral : (1 ml).

SORT DU MEDICAMENT :
En sous-cutanée et intramusculaire, les pics sériques sont atteints en 8 et 6 h ; les demi-vies d'absorption en 4 et 3 h et les demi-vies d'élimination en 7 et 6 h.
En intraveineuse, le pic sérique est atteint à la 30^e minute (fin de perfusion), la demi-vie d'élimination est d'environ 1 h.
Quelle que soit la voie d'administration, il n'est pas retrouvé d'interféron alfa-2b dans les urines.

PROPRIETES :
Introna, dont le principe actif est l'interféron alfa-2b (interféron alpha, sous type 2) produit par génie génétique, présente ces propriétés qui ont été mises en évidence lors des études précliniques :
1. L'ACTIVITE ANTIPROLIFERATIVE : dose-dépendante.
2. L'ACTIVITE IMMUNOMODULATRICE.
3. L'ACTIVITE ANTIVIRALE.

INDICATIONS :
- Leucémie à tricholeucocytes.
- Mélanome disséminé.
- Sarcome de Kaposi associé au syndrome d'immuno-déficit acquis (SIDA).

CONTRE-INDICATIONS :
- Sensibilité à l'interféron alfa-2b ou à l'un des excipients (albumine humaine entre autres).
- GROSSESSE : en raison de la spécificité d'espèce, les études de tératogénèse et de toxicité fœtale chez l'animal n'ont pas de valeur prévisionnelle pour l'espèce humaine ; il en résulte que l'innocuité de l'interféron alfa-2b pendant la grossesse n'a pu être établie.

MISE EN GARDE :
- Une réaction allergique sévère doit faire interrompre le traitement immédiatement.
- Une surveillance électrocardiographique doit être assurée chez les patients ayant des antécédents cardiaques (infarctus du myocarde et/ou troubles du rythme) et ceux ayant reçu des substances cardiotoxiques.
- Une hypotension peut survenir durant le traitement et jusqu'à 48 h après son arrêt.
- Tout effet secondaire sévère doit conduire à modifier voire arrêter le traitement.

PRECAUTIONS :
- Un état d'hydratation satisfaisant doit être maintenu pendant la durée du traitement.
- Les analgésiques centraux, les hypnotiques et les sédatifs administrés simultanément doivent l'être avec prudence.
- L'innocuité de l'interféron alfa-2b n'a pas été établie ni chez l'enfant ni chez l'adolescent de moins de 18 ans.
- La surveillance biologique porte sur : NFS plaquettes, fonctions hépatique et rénale.

INTERACTIONS MEDICAMENTEUSES :
Incompatibilités majeures :
Aucune substance médicamenteuse ne doit être associée à l'Introna dans la seringue ou le flacon de perfusion.
Ne pas mélanger à des solutions glucosées.

EFFETS INDESIRABLES :
D'une façon générale, les effets indésirables ont un caractère réversible en 72 h et sont dose-dépendants :

Cliniques :
Le plus fréquent est le syndrome pseudo-grippal qui peut être prévenu ou traité par l'administration de paracétamol.
Les autres principaux effets indésirables observés sont :
- Les troubles du système nerveux central.
- Les modifications cardiovasculaires.
- Les troubles gastro-intestinaux.

Biologiques :
leuconeutropénie, thrombopénie, élévation des enzymes hépatiques, troubles de l'hémostase.

MODE D'EMPLOI ET POSOLOGIE :
- La reconstitution doit être effectuée immédiatement avant l' ploi avec les précautions d'asepsie d'usage.
  Prélever la dose appropriée pour injection sous-cutanée adjonction à 50 ml de soluté isotonique de NaCL pour admi tration intraveineuse (perfusion de 30 minutes).
- Aucune substance ne doit être associée à Introna dans seringue ou le flacon de perfusion.

Les posologies recommandées sont les suivantes :
- *Leucémies à tricholeucocytes :*
  2 millions d'Unités Internationales/m²/jour par voie sous-cutar 3 fois par semaine, 1 jour sur 2.
- *Mélanome disséminé :*
  5 à 10 millions d'Unités Internationales/m²/jour par voie s cutanée, 3 fois par semaine, 1 jour sur 2.
- *Sarcome de Kaposi associé au SIDA :*
  50 millions d'Unités Internationales/m²/jour en perfusion 30 minutes, 5 jours consécutifs, 1 semaine sur 2 (intervalle 9 jours entre 2 cures).

Conservation : A conserver au réfrigérateur (de 2 à 8°C).
Après reconstitution, conserver au maximum 24 h entre 2 30 °C.

Une demande a été faite pour étendre la validité de conserva au réfrigérateur à 36 mois et à température ambiante à 18 m conformément aux résultats des études de stabilité conduites plusieurs dizaines de lots et approuvés par l'expert analyste.

SURDOSAGE :
Aucun cas de surdosage n'a été rapporté à ce jour, bien que doses de 200 millions d'Unités Internationales aient administrées.

TABLEAU A. A.M.M. :
328992.3 3 millions U.I. – 328991.7 5 millions U.I.
328990.0 10 millions U.I. – 328989.2 30 millions U.I.
Mis sur le marché en 1987.
Cette spécialité est strictement réservée à l'usage hospitalier.

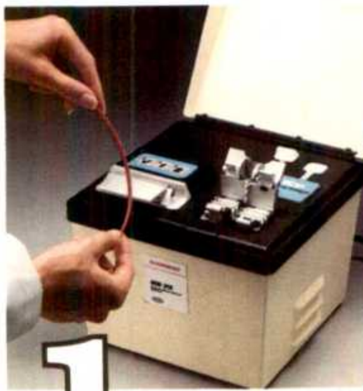
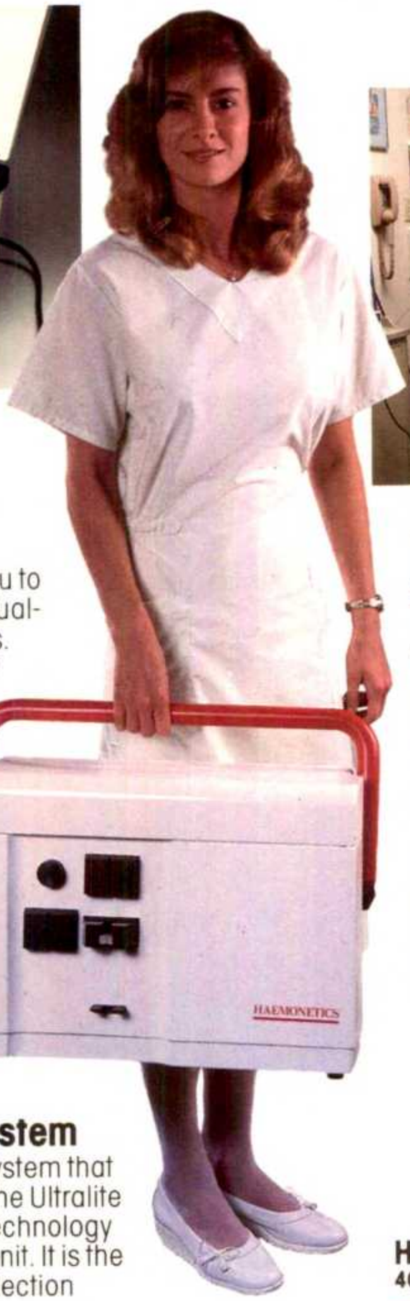
Three ways to speed the flow of blood processing.



1

The SCD™ 312 Sterile Connection Device

The only device that allows you to instantly create sterile, high quality connections between bags. This allows blood component pooling or aliquoting easily, quickly and safely.



2

The Ultralite™ Plasma Collection System

The only plasma apheresis system that goes where the donors are. The Ultralite offers proven Haemonetics technology in a compact, easy-to-carry unit. It is the smallest, lightest plasma collection system available.

3

The V50 Apheresis System

The only single venipuncture, fully automated apheresis system available for high-yield platelet collection, WBC poor and RBC free. The V50 makes blood collection and therapeutic exchange easy, convenient and safe.

Call Haemonetics today at (617) 848-7100 to learn more ways to improve blood processing, including our new five day platelet storage system, the ESP.

The First Leucovorin With Oral Convenience

Wellcovorin Tablets are dramatically improving the way patients are rescued. Often discharged from the hospital earlier, more patients are completing their therapy on an outpatient basis and returning to a more normal, comfortable lifestyle sooner.

WELLCOVORIN® TABLETS
(leucovorin calcium)

Assuring Blood Levels

For thousands of patients, Wellcovorin Tablets have provided the critical blood levels needed for life-saving rescue. The unique formulation of Wellcovorin Tablets has been shown to be completely bioavailable in a bioavailability study of 120 normal volunteers.[1]

[1] Blum, Guaspari, et al: NCI Folate Symposium, Jan. 1986.

Reducing the Cost of Rescue

Wellcovorin Tablets have reduced the cost of leucovorin rescue significantly. Before Wellcovorin Tablets, the cost of leucovorin increased rapidly and consistently every year. Now, patients pay less for Wellcovorin Tablets, and often realize considerable savings from a reduction in hospital stays and clinic visits.

Simplifying Dosing

For greater flexibility in oral dosing, Wellcovorin Tablets are available in two sizes: 5 mg (scored, bottles of 20 or 100) and 25 mg (scored, bottles of 25).

The Proven Considerate Rescue

WELLCOVORIN® TABLETS
(leucovorin calcium)

Leucovorin in convenient
5 mg and 25 mg tablets

Before prescribing WELLCOVORIN® Tablets, please consult complete prescribing information. The following is a brief summary.

INDICATIONS AND USAGE: Wellcovorin (leucovorin calcium) is indicated for the prophylaxis and treatment of undesired hematopoietic effects of folic acid antagonists (see WARNINGS).

CONTRAINDICATIONS: Leucovorin is improper therapy for pernicious anemia and other megaloblastic anemias secondary to the lack of vitamin B_{12}. A hematologic remission may occur while neurologic manifestations remain progressive.

WARNINGS: In the treatment of accidental overdosage of folic acid antagonists, leucovorin should be administered as promptly as possible. As the time interval between antifolate administration (e.g. methotrexate) and leucovorin rescue increases, leucovorin's effectiveness in counteracting hematologic toxicity diminishes.

PRECAUTIONS:

General: Following chemotherapy with folic acid antagonists, parenteral administration of leucovorin is preferable to oral dosing if there is a possibility that the patient may vomit and not absorb the leucovorin. In the presence of pernicious anemia a hematologic remission may occur while neurologic manifestations remain progressive. Leucovorin has no effect on other toxicities of methotrexate, such as the nephrotoxicity resulting from drug precipitation in the kidney.

Drug Interactions: Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin and primidone, and increase the frequency of seizures in susceptible children.

Pregnancy: ***Teratogenic Effects:*** Pregnancy Category C. Animal reproduction studies have not been conducted with Wellcovorin. It is also not known whether Wellcovorin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Wellcovorin should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Wellcovorin is administered to a nursing mother.

Pediatric Use: See "Drug Interactions".

ADVERSE REACTIONS: Allergic sensitization has been reported following both oral and parenteral administration of folic acid.

OVERDOSAGE: Excessive amounts of leucovorin may nullify the chemotherapeutic effect of folic acid antagonists.

DOSAGE AND ADMINISTRATION: Leucovorin is a specific antidote for the hematopoietic toxicity of methotrexate and other strong inhibitors of the enzyme dihydrofolate reductase. Leucovorin rescue must begin within 24 hours of antifolate administration. A conventional leucovorin rescue dosage schedule is 10 mg/m² orally or parenterally followed by 10 mg/m² orally every six hours for seventy-two hours. If, however, at 24 hours following methotrexate administration the serum creatinine is 50% or greater than the pre-methotrexate serum creatinine, the leucovorin dose should be immediately increased to 100 mg/m² every three hours until the serum methotrexate level is below 5×10^{-8}M.[1,2]

The recommended dose of leucovorin to counteract hematologic toxicity from folic acid antagonists with less affinity for mammalian dihydrofolate reductase than methotrexate (i.e. trimethoprim, pyrimethamine) is substantially less and 5 to 15 mg of leucovorin per day has been recommended by some investigators.[3,4,5]

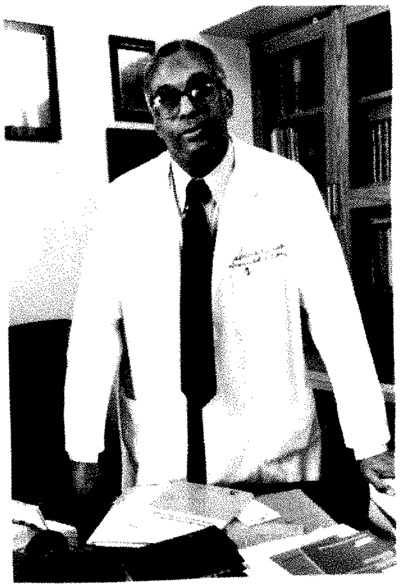
THIS SPACE CONTRIBUTED AS A PUBLIC SERVICE

You can help us raise the colorectal cancer cure rate.



"If everyone over 50 had checkups for colorectal cancer, the cure rate could be as high as 75%," says Dr. LaSalle D. Leffall, Jr., past president, American Cancer Society. "You can't cure it if you don't know you have it." But if it's detected early, the cure rate for colorectal cancer is very high. Your doctor can perform the digital and proctoscopic exams, and you take care of the simple stool blood test at home.

Since men and women are equally affected by this disease, we urge everyone over 50 to get regular checkups.

The warning signs for colorectal cancer are a change in bowel habits and blood in the stool.

People with a family history of colon or rectal cancer or ulcerative colitis are at higher risk and are urged to be doubly cautious.

Checkup Guidelines for men and women over 50 without symptoms:

- digital exam annually
- stool blood test annually
- procto exam every 3 to 5 years after 2 negative tests 1 year apart.

No one faces cancer alone.

Thrombotic and Bleeding Disorders

American Diagnostica, Inc. offers an array of innovative products for the study and diagnosis of thrombotic and bleeding disorders:

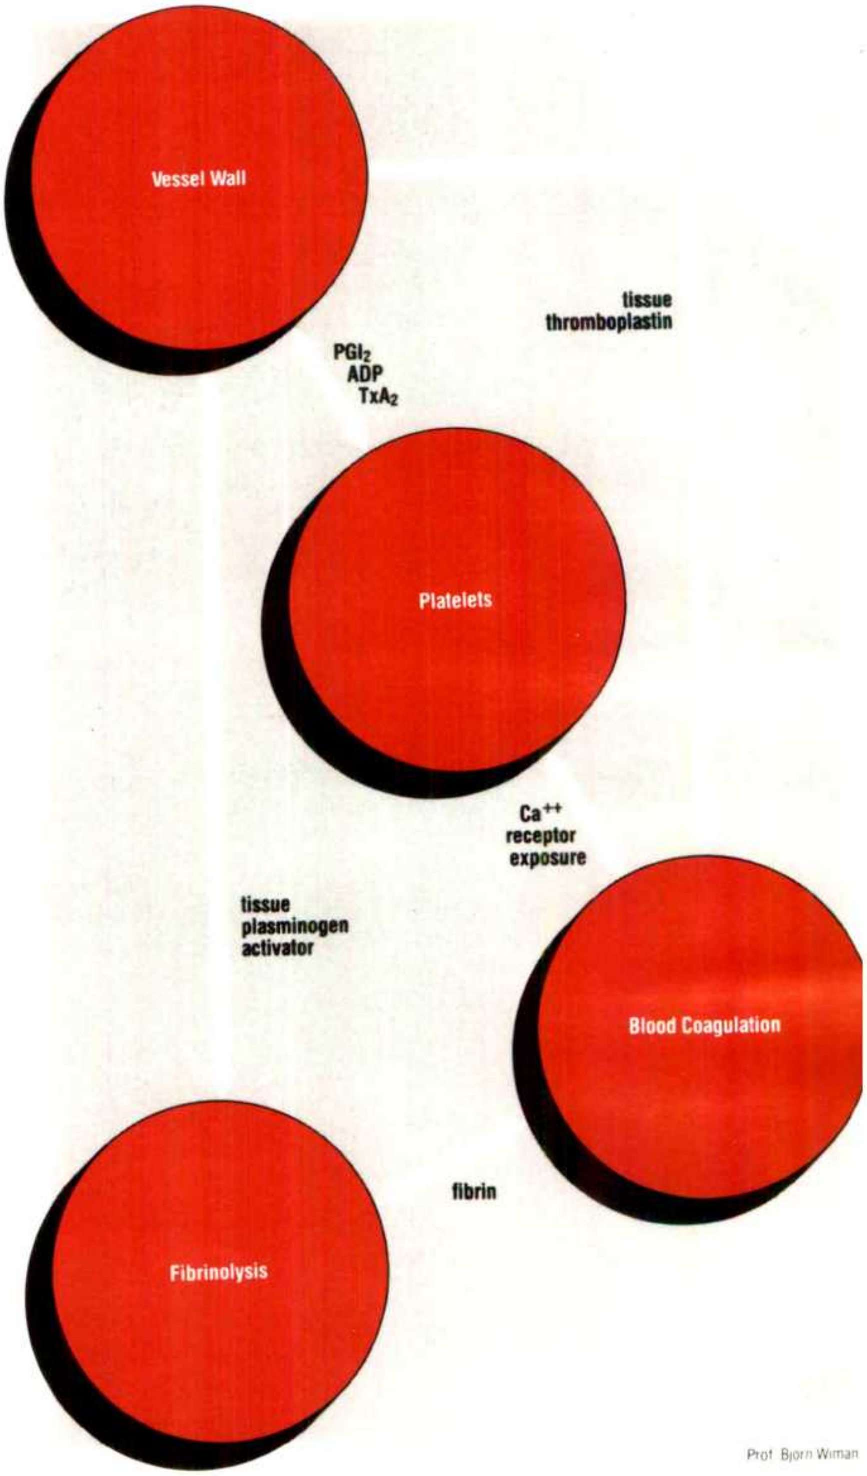
Kits and methods for Protein C antigen and functional activity assay in plasma; reagent for Protein S determination

Kits for t-PA antigen, activity and inhibitor assay in plasma

Standardized third generation chromogenic substrates for coagulation factor, heparin, Protein C, kallikrein and endotoxin assays

monoclonal antibody based kits for determination of soluble cross-linked fibrin fragments in plasma and serum

monoclonal antibody panels to hemostasis related antigens; activator and coagulation factor zymogens, enzymes and inhibitors



Prof. Bjorn Wiman

SPECIAL DEPARTMENTS

Announcements 1969

Information for Contributors .... xlvii, xlviii

Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

All manuscripts submitted for consideration for publication in BLOOD should be sent to: Arthur W. Nienhuis, M.D., Editor, BLOOD, the Journal of the American Society of Hematology, 9650 Rockville Pike, Bethesda, MD 20814. Please note that a processing fee of $50.00 must accompany each manuscript submitted for publication in BLOOD.

The American Society of Hematology certifies that the continuing medical education offering provided by *BLOOD, The Journal of The American Society of Hematology*, meets the criteria for up to 22 hours of credit in Category 5(a) for the Physician's Recognition Award of the American Medical Association.

It's been a ***GREAT*** *five years!!!*

Mycelex® Troche
(clotrimazole) 10 mg

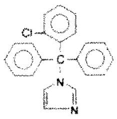
Description
Each Mycelex® Troche contains 10 mg clotrimazole [1-(o-chloro-α, α-diphenylbenzyl) imidazole], a synthetic antifungal agent, for topical use in the mouth.
Structural Formula:



Chemical Formula:
$C_{22}H_{17}ClN_2$

The troche dosage form is a large, slowly-dissolving tablet (lozenge) containing 10 mg of clotrimazole dispersed in dextrose, microcrystalline cellulose, povidone, and magnesium stearate.

Clinical Pharmacology
Clotrimazole is a broad-spectrum antifungal agent that inhibits the growth of pathogenic yeasts by altering the permeability of cell membranes. It exhibits fungicidal activity *in vitro* against *Candida albicans* and other species of the genus *Candida*. No single-step or multiple-step resistance to clotrimazole has developed during successive passages of *Candida albicans* in the laboratory.

After oral administration of a 10 mg clotrimazole troche to healthy volunteers concentrations sufficient to inhibit most species of *Candida* persist in saliva for up to three hours following the approximately 30 minutes needed for a troche to dissolve. The long term effective concentration of drug in saliva appears to be related to the slow release of clotrimazole from the oral mucosa to which the drug is apparently bound. Repetitive dosing at three hour intervals maintains effective salivary levels above the minimum inhibitory concentration of most strains of *Candida*. In another study the mean serum concentrations were 4.98 ± 3.7 and 3.23 ± 1.4 nanograms/ml at 30 and 60 minutes respectively.

Indications and Usage
Mycelex® Troches are indicated for the local treatment of oropharyngeal candidiasis. The diagnosis should be confirmed by a KOH smear and/or culture prior to treatment.

Contraindications
Mycelex® Troches are contraindicated in patients who are hypersensitive to any of its components.

Warning
Mycelex® Troches are not indicated for the treatment of systemic mycoses.

Precautions
Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials. In most cases the elevations were minimal and it was often impossible to distinguish effects of clotrimazole from those of other therapy and the underlying disease (malignancy in most cases). Periodic assessment of hepatic function is advisable particularly in patients with pre-existing hepatic impairment.

Since patients must be instructed to allow each troche to dissolve slowly in the mouth in order to achieve maximum effect of the medication, they must be of such an age and physical and/or mental condition to comprehend such instructions.

Carcinogenesis: An 18 month dosing study with clotrimazole in rats has not revealed any carcinogenic effect.

Usage in Pregnancy: Pregnancy Category C. Clotrimazole has been shown to be embryotoxic in rats and mice when given in doses 100 times the adult human dose (in mg/kg), possibly secondary to maternal toxicity. The drug was not teratogenic in mice, rabbits, and rats when given in doses up to 200, 180, and 100 times the human dose.

Clotrimazole given orally to mice from nine weeks before mating through weaning at a dose 120 times the human dose was associated with impairment of mating, decreased number of viable young, and decreased survival to weaning. No effects were observed at 60 times the human dose. When the drug was given to rats during a similar time period at 50 times the human dose, there was a slight decrease in the number of pups per litter and decreased pup viability.

There are no adequate and well controlled studies in pregnant women. Clotrimazole troches should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Pediatric Use
Safety and effectiveness of clotrimazole in children below the age of 3 years have not been established; therefore, its use in such patients is not recommended.

Adverse Reactions
Abnormal liver function tests have been reported in patients treated with clotrimazole troches; elevated SGOT levels were reported in about 15% of patients in the clinical trials (see Precautions section).
Nausea and vomiting was reported in about one in twenty patients.

Overdosage
No data available.

Drug Abuse and Dependence
No data available.

Dosage and Administration
Mycelex® Troches are administered only as a lozenge that must be slowly dissolved in the mouth. The recommended dose is one troche five times a day for fourteen consecutive days. Only limited data are available on the safety and effectiveness of the clotrimazole troche after prolonged administration; therefore, therapy should be limited to short term use, if possible.

How Supplied
Mycelex® Troches, white discoid, uncoated tablets are supplied in bottles of 70 and 140. Mycelex Troches are also available for institutional use in foil packages of 70 tablets. Each tablet will be identified with the following: Miles 095.

Store below 86°F (30°C), avoid freezing.

Twenty years ago, leukemia* killed enough people to fill the Houston Astrodome.

Twenty years ago, leukemia was a mysterious disease. Little was known about the cause. Less was known about the cure.

But since then, the Leukemia Society of America has funded 32 million dollars of medical research in an all-out effort to find a cure.

Today, more and more people with leukemia are surviving. Living normal lives. But the Leukemia Society won't be satisfied till this killer is stopped for good.

For more information, including the free booklet "What Everyone Should Know About Leukemia," write to: Leukemia Society of America, 733 Third Ave., New York, New York 10017.

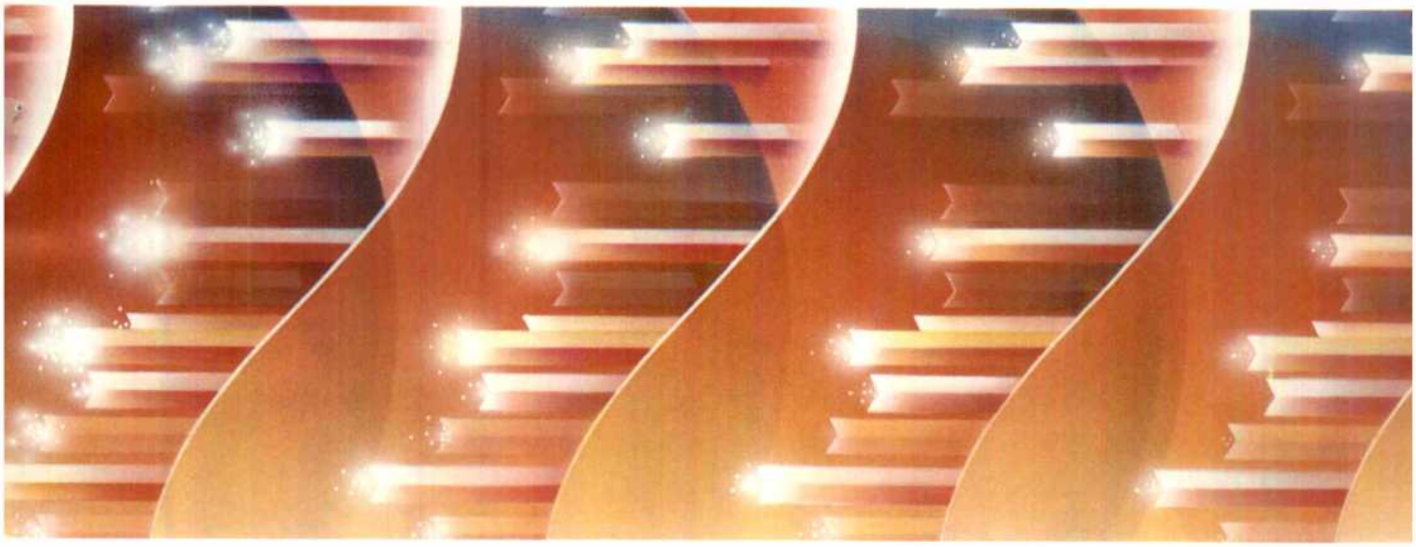
In the treatment of hemophilia A

A BREAKTHROUGH IN BIOTECHNOLOGY



NEW

MONOCLATE®

Factor VIII: C, Heat-Treated
Antihemophilic Factor
(Human)

**Now available from
Armour Pharmaceutical Company**

Please see next page for brief summary of prescribing information

ANTIHEMOPHILIC FACTOR (HUMAN)
MONOCLATE®
FACTOR VIII:C, HEAT-TREATED

BRIEF SUMMARY

DESCRIPTION: Antihemophilic Factor (Human), MONOCLATE® Factor VIII:C, Heat-Treated is a sterile, stable, lyophilized concentrate of Factor VIII:C with reduced amounts of Factor VIII:R and purified of extraneous plasma-derived protein by use of affinity chromatography. A murine monoclonal antibody to Factor VIII:R is used as an affinity ligand to first isolate the Factor VIII complex. Factor VIII:C is then dissociated from VIII:R, recovered, formulated and provided as a sterile lyophilized powder. The product as formulated contains Albumin (Human) as a stabilizer, resulting in a concentrate with specific activity between 5 and 10 units/mg of total protein. In the absence of this added Albumin (Human) stabilizer, specific activity has been determined to exceed 3000 units/mg of protein. MONOCLATE® has been prepared from pooled human plasma and is intended for use in therapy of classical hemophilia (Hemophilia A).

This product has been subjected to a heat-treatment process during its manufacture in order to reduce the risk of viral transmission, although no procedure has been shown to be totally effective in removing viral infectivity from coagulant factor products.

MONOCLATE® is a highly purified preparation of Factor VIII:C. When stored as directed, it will maintain its labeled potency for the period indicated on the container and package labels.

Upon reconstitution, a clear, colorless solution containing 50 to 150 times as much Factor VIII:C as does an equal volume of plasma is obtained.

Each vial contains the labeled amount of antihemophilic factor (AHF) activity as expressed in terms of International Units of antihemophilic activity. One unit of antihemophilic factor activity is equivalent to that quantity of AHF present in one mL of normal human plasma. When reconstituted as recommended the resulting solution contains approximately 300 to 450 millimoles of sodium ions per liter and has 2 to 3 times the tonicity of saline. It contains approximately 2-5 millimoles of calcium per liter contributed as calcium chloride, approximately 1-2% Albumin (Human), 0.8% mannitol, and 1.2 mM histidine. The pH is adjusted with hydrochloric acid and/or sodium hydroxide. MONOCLATE® also contains trace amounts (less than 50 ng per 100 AHF activity units) of mouse protein (see CLINICAL PHARMACOLOGY).

MONOCLATE® is to be administered only intravenously.

CLINICAL PHARMACOLOGY: Factor VIII:C is the coagulant portion of the Factor VIII complex circulating in plasma. It is noncovalently associated with the Factor VIII:R protein responsible for von Willebrand factor activity. These two proteins have distinct biochemical and immunological properties and are under separate genetic control. Factor VIII:C acts as a cofactor for Factor IX to activate Factor X in the intrinsic biological amplification of plasma enzymic proteins concerned with blood coagulation. Hemophilia A, an hereditary disorder of blood coagulation due to decreased levels of Factor VIII:C, results in profuse bleeding into joints, muscles or internal organs as a result of a trauma. Antihemophilic Factor (Human), MONOCLATE®, Factor VIII:C, Heat-Treated, provides an increase in plasma levels of AHF, thereby enabling temporary correction of hemophilia A bleeding.

Clinical evaluation of MONOCLATE®, Factor VIII:C heat-treated product for its half-life characteristics in hemophilic patients showed it to be comparable to other commercially available Factor VIII products. An estimated half-life of 15 hours was obtained.

Evidence of the capability of the manufacturing processes used in the production of Antihemophilic Factor (Human), MONOCLATE®, Factor VIII:C, Heat-Treated to reduce viral bioburden was obtained in inactivation studies involving the addition of known quantities of virus to cryoprecipitate. Viruses used were human immunodeficiency virus (HIV), Sindbis virus, vesicular stomatitis virus (VSV), and pseudorabies virus (PsRV).

With the assay methods used, HIV was reduced by ≧ 7.08 and ≧ 9.1 logs (in two experiments); model virus experiments demonstrated Sindbis virus reductions of ≧ 8.21 and ≧ 9.95 logs, VSV reduction of 7.51 logs, and PsRV reduction of ≧ 6.85 logs.

A total of 5 lots of MONOCLATE® were administered to a cohort of 11 patients who had not previously received any coagulation factor concentrates. The study showed no evidence of nonA, nonB hepatitis transmission as determined by bi-weekly ALT measurements over observation periods ranging from 4 months to 6 months.

Although MONOCLATE® contains trace amounts of mouse protein (less than 50 ng per 100 AHF activity units), only 1 of 18 patients treated on multiple occasions and followed for between 6 and 14 months showed evidence of antibody to mouse protein above baseline. In that patient the antibody level did not change after the second month of treatment and was not associated with any clinical adverse reaction. Pre-existing antibody to mouse protein was detected in some patients prior to MONOCLATE® administration: in the assay used, people with rheumatoid factor may test falsely positive and other proteins may also show cross-reactivity.

INDICATIONS AND USAGE: Antihemophilic Factor (Human) MONOCLATE®, Factor VIII:C, Heat-Treated is indicated for treatment of classical hemophilia (Hemophilia A). Affected individuals frequently require therapy following minor accidents. Surgery, when required in such individuals, must be preceded by temporary corrections of the clotting abnormality. Presurgical correction of severe AHF deficiency can be accomplished with a small volume of MONOCLATE®.

MONOCLATE® is not effective in controlling the bleeding of patients with von Willebrand's disease.

CONTRAINDICATIONS: Known hypersensitivity to mouse protein is a contraindication to Antihemophilic Factor (Human), MONOCLATE®, Factor VIII:C, Heat-Treated.

WARNINGS: MONOCLATE® is prepared from pooled units of human plasma which may contain the causative agents of hepatitis B, nonA, nonB hepatitis, acquired immunodeficiency syndrome (AIDS) and other viral diseases. Each unit of plasma used in the production of MONOCLATE® has been tested and found nonreactive for hepatitis B surface antigen (HBsAg) and antibody to human immunodeficiency virus (HIV) by FDA approved tests, and has been shown to have ALT levels not exceeding two times the upper limit of normal. Additional screening procedures used to eliminate high risk plasma donors, and the purification techniques and heat-treatment step used in the manufacturing process, are all designed to reduce the risk of transmitting viral infection. However, testing methods presently available are not sensitive enough to detect all units of potentially infectious plasma, and treatment methods have not been shown to be totally effective in eliminating any of the aforementioned viral diseases from this product. Accordingly, the benefits and risks of treatment with this product should be carefully assessed prior to use.

Individuals who have not received multiple infusions of blood or plasma products are likely to develop signs and/or symptoms of some viral infections, especially nonA, nonB hepatitis as shown by recent data, when treated with coagulant factor products. As indicated under CLINICAL PHARMACOLOGY, however, a group of such patients treated with MONOCLATE® did not demonstrate signs or symptoms of nonA, nonB hepatitis over observation periods ranging from 4 months to 6 months.

PRECAUTIONS: General — Most Antihemophilic Factor (Human) concentrates contain naturally occurring blood group specific antibodies. However, the processing of MONOCLATE® significantly reduces the presence of blood group specific antibodies in the final product. Nevertheless, when large or frequently repeated doses of product are needed, patients should be monitored by means of hematocrit and direct Coombs tests for signs of progressive anemia.

Formation of Antibodies to Mouse Protein — Although no hypersensitivity reactions have been observed, because MONOCLATE® contains trace amounts of mouse protein (less than 50 ng per 100 AHF activity units), the possibility exists that patients treated with MONOCLATE® may develop hypersensitivity to the mouse proteins.

Information for Patients

Patients should be informed of the early signs of hypersensitivity reactions including hives, generalized urticaria, tightness of the chest, wheezing, hypotension, and anaphylaxis, and should be advised to discontinue use of the product and contact their physician if these symptoms occur.

Pregnancy Category C — Animal reproduction studies have not been conducted with Antihemophilic Factor (Human), MONOCLATE® Factor VIII:C, Heat-Treated. It is also not known whether MONOCLATE® can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. MONOCLATE® should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS: Products of this type are known to cause allergic reactions, mild chills, nausea or stinging at the infusion site.

HOW SUPPLIED: MONOCLATE® is supplied in a single dose vial with diluent, sterile needles for reconstitution and withdrawal, winged infusion set, and alcohol swabs. I.U. activity is stated on the label of each vial.

CAUTION: Federal (U.S.A.) law prohibits dispensing without prescription.

DIRECTION INSERT

mmune Globulin Intravenous (Human)
GAMMAGARD®

ESCRIPTION

Immune Globulin Intravenous (Human), GAMMA-ARD® * is a sterile, dried, highly purified preparation f immunoglobulin which is derived from the cold ethanol actionation process and is further purified using ultrafiltration and ion exchange adsorption. When reconstituted with e appropriate volume of diluent, this preparation con-ains approximately 50 mg of protein per mL, of which t least 90% is gamma globulin. The reconstituted pro-uct contains approximately 0.15M sodium chloride and as a pH of 6.8±0.4. Stabilizing agents are present in the ollowing maximum amounts: 20 mg/mL glucose, 2 g/mL PEG, 0.3M glycine, and 3mg/mL human albumin.

The manufacturing process for Immune Globulin In-avenous (Human), GAMMAGARD, isolates gamma lobulin without additional chemical or enzymatic modifica-on and the Fc portion is maintained intact. Immune lobulin Intravenous (Human), GAMMAGARD contains all e immunoglobulin G antibody activities which are pre-ent in the donor population. On the average, the distribu-on of IgG subclasses present in this product is the same s is present in normal plasma.[1] Immune Globulin Intra-enous (Human), GAMMAGARD contains only trace mounts of IgM and IgA.

Immune Globulin Intravenous (Human), GAMMAGARD ontains no preservative.

This product has been prepared from large pools of uman plasma which was taken only from plasma units ound to have normal levels of alanine aminotransferase ALT). Each unit of plasma used in the manufacture of this roduct has been found to be nonreactive for HBsAg anti-ody by an FDA approved test.

LINICAL PHARMACOLOGY

Immune Globulin Intravenous (Human), GAMMAGARD ontains a broad spectrum of IgG antibodies against acterial and viral agents that are capable of opsonization nd neutralization of microbes and toxins.

Peak levels of IgG are reached immediately after infu-ion of Immune Globulin Intravenous (Human), GAMMA-ARD. It has been shown that IgG is distributed relatively apidly between plasma and extravascular fluid until approx-mately half of the total body pool is partitioned in the ex-ravascular space. A rapid initial drop in serum levels is, herefore, to be expected.[2]

As a class, IgG survives longer *in vivo* than other serum roteins.[2,3] Studies show that the half-life of Immune lobulin Intravenous (Human), GAMMAGARD is approx-mately 24 days. These findings are consistent with reports of a 21 to 25 day half-life for IgG.[2,3,4] The half-life of IgG an vary considerably from person to person, however. In articular, high concentrations of IgG and hyper-metabolism ssociated with fever and infection have been seen to coin-ide with a shortened half-life of IgG.[2,3,4,5]

NDICATIONS AND USAGE

mmunodeficiencies

Immune Globulin Intravenous (Human), GAMMAGARD s efficacious in the treatment of primary immunodeficient states, such as: congenital agammaglobulinemias, com-non variable immunodeficiency, Wiskott-Aldrich syndrome, and severe combined immunodeficiencies.[4,5] Immune lobulin Intravenous (Human), GAMMAGARD is especial-y useful when high levels or rapid elevation of circulating amma globulins are desired or when intramuscular in-ections are contraindicated (e.g., small muscle mass).

diopathic Thrombocytopenic Purpura (ITP)

When a rapid rise in platelet count is needed to control leeding or to allow a patient with ITP to undergo surgery, he administration of Immune Globulin Intravenous Human), GAMMAGARD should be considered. The efficacy f Immune Globulin Intravenous (Human), GAMMAGARD as been demonstrated in a clinical study involving six-een patients (twelve adults and four children) diagnosed with acute or chronic Idiopathic Thrombocytopenic Pur-ura (ITP). Each of the sixteen patients (100%) demonstrated an acute, clinically signficant rise in platelet count (platelet count greater than $40{,}000/mm^3$) following the administration of Immune Globulin Intravenous (Human), GAMMAGARD.

Ten of the sixteen patients (62%) exhibited a clinically significant rise in platelet count after only one 1 g/kg infusion; four patients (25%) exhibited this result after only two 1 g/kg infusions; and two patients exhibited this result after more than two 1 g/kg infusions. The rise in platelet count is generally rapid, occurring within 5 days. The rise, however, is transient and should not be considered curative. Platelet rises most often lasted 2 to 3 weeks, with a range of 12 days to 6 months. It should be noted that childhood ITP may resolve spontaneously without treatment.

CONTRAINDICATIONS

None known.

WARNINGS

Immune Globulin Intravenous (Human), GAMMAGARD should only be administered intravenously. Other routes of administration have not been evaluated.

Immune Globulin Intravenous (Human), GAMMAGARD contains very low quantities of IgA (not more than 10 µg/mL) and although no instances of anaphylaxis associated with the use of this product have been observed during the clinical trials, such reactions have been observed with other immunoglobulin products.[5,6] Immune Globulin Intravenous (Human), GAMMAGARD should be given with caution to patients with antibodies to IgA or selective IgA deficiencies.

PRECAUTIONS

Drug Interaction

Admixtures of Immune Globulin Intravenous (Human), GAMMAGARD with other drugs have not been evaluated. It is recommended that Immune Globulin Intravenous (Human), GAMMAGARD be administered separately from other drugs or medication which the patient may be receiving.

Pregnancy Category C

Animal reproduction studies have not been conducted with Immune Globulin Intravenous (Human), GAMMAGARD. It is also not known whether Immune Globulin Intravenous (Human), GAMMAGARD can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Immune Globulin Intravenous (Human), GAMMAGARD should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

The incidence of untoward reactions to Immune Globulin Intravenous (Human), GAMMAGARD is low, although various minor reactions, such as headache, fatigue, chills, backache, lightheadedness, fever, urticaria, flushing and nausea may occasionally occur. The incidence of these reactions directly attributable to the infusion of Immune Globulin Intravenous (Human), GAMMAGARD during the clinical trials was less than 6%. Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

During the clinical study of this product for treatment of ITP, the only side effect reported was headache which occurred in 12 of 16 patients. Oral antihistamines and analgesics alleviated the headache and were used as pre-treatment for those patients requiring additional IGIV therapy. The remaining four patients did not report any side effects and did not require pre-treatment.

Immediate anaphylactic and hypersensitivity reactions due to previous sensitization, although they have not been observed during the clinical trials, are a possibility. Epinephrine should be available for treatment of any acute anaphylactoid reaction. (See WARNINGS.)

DOSAGE AND ADMINISTRATION

Immunodeficiencies

For patients with primary immunodeficiencies, monthly doses of at least 100 mg/kg are recommended. Initially, patients may receive 200-400 mg/kg. As there are significant differences in the half-life of IgG among patients with primary immunodeficiencies, the frequency and amount of immunoglobulin therapy may vary from patient to patient. The proper amount can be determined by monitoring clinical response. The minimum serum concentration of IgG necessary for protection has not been established.

Idiopathic Thrombocytopenic Purpura (ITP)

For patients with acute or chronic Idiopathic Thrombocytopenic Purpura (ITP), a dose of 1 g/kg is recommended. The need for additional doses can be determined b clinical response and platelet count. Up to three doses m be given on alternate days if required.

Rate of Administration

It is recommended that initially a rate of 0.5 mL/kg/H be used. If infusion at this rate causes the patient n distress, the administration rate may be gradually increase but should not exceed 4 mL/kg/Hr.

A rate of administration which is too rapid may caus flushing and changes in pulse rate and blood pressur Slowing or stopping the infusion usually allows the symptoms to disappear promptly.

Administration

Immune Globulin Intravenous (Human), GAMMAGAR should be administered as soon after reconstitution a possible. Administration should begin not more than 2 hour after reconstitution.

The reconstituted material should be at room temperatur during administration.

Parenteral drug products should be inspected visual for particulate matter and discoloration prior to administration, whenever solution and container permit.

Follow directions for use which accompany the administration set. If a Hyland set is not used, make sure th administration set contains an adequate filter.

How Supplied

Immune Globulin Intravenous (Human), GAMMAGAR is supplied in either 2.5 g or 5.0 g single use vials. Eac vial of Immune Globulin Intravenous (Human), GAMMAGARD is furnished with a suitable volume of Sterile Wate for Injection, USP, a transfer device and an administratio set which contains an integral airway and a 15 micron filte

Storage

Immune Globulin Intravenous (Human), GAMMAGAR is to be stored at a temperature not to exceed 25°C (77°F Freezing should be avoided to prevent the diluent bott from breaking.

Blenoxane® . . . Integral Component

sterile bleomycin sulfate)

# of Chemotherapy Regimens in Non-Hodgkin's Lymphoma

Since Blenoxane is virtually non-myelosuppressive, continuing therapy with certain Blenoxane containing chemotherapy regimens e.g. BACOP) can prevent tumor regrowth between cycles of other chemotherapy regimens while allowing for bone marrow ecovery.[*2,3,4,6]

Blenoxane can produce, with cumulative doses, a syndrome of pulmonary fibrosis. It is usually dose-related, being seen infrequently n patients whose total dose of Blenoxane is less than 400 units.

Efficacy . . . Yesterday, Today, Tomorrow

Blenoxane® (sterile bleomycin sulfate)

Brief Summary of Prescribing Information (1) 10/84. For complete prescribing information please consult product literature.

WARNING

It is recommended that Blenoxane® be administered under the supervision of a qualified physician experienced in the use of cancer chemotherapeutic agents. Appropriate management of therapy and complications is possible only when adequate diagnostic and treatment facilities are readily available.

Pulmonary fibrosis is the most severe toxicity associated with Blenoxane. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Its occurrence is higher in elderly patients and in those receiving greater than 400 units total dose, but pulmonary toxicity has been observed in young patients and those treated with low doses.

A severe idiosyncratic reaction consisting of hypotension, mental confusion, fever, chills, and wheezing has been reported in approximately 1% of lymphoma patients treated with Blenoxane.

INDICATIONS: Blenoxane should be considered a palliative treatment. It has been shown to be useful in the management of the following neoplasms either as a single agent or in proven combinations with other approved chemotherapeutic agents:

Squamous Cell Carcinoma – Head and neck including mouth, tongue, tonsil, nasopharynx, oropharynx, sinus, palate, lip, buccal mucosa, gingiva, epiglottis, skin, larynx, penis, cervix, and ulva. The response to Blenoxane is poorer in patients with head and neck cancer previously irradiated.

Lymphomas – Hodgkin's, reticulum cell sarcoma, lymphosarcoma.

Testicular Carcinoma – Embryonal cell, choriocarcinoma, and teratocarcinoma.

CONTRAINDICATIONS: Blenoxane is contraindicated in patients who have demonstrated a hypersensitive or an idiosyncratic reaction to it.

WARNINGS: Patients receiving Blenoxane must be observed carefully and frequently during and after therapy. It should be used with extreme caution in patients with significant impairment of renal function or compromised pulmonary function.

Pulmonary toxicities occur in 10% of treated patients. In approximately 1%, the nonspecific pneumonitis induced by Blenoxane progresses to pulmonary fibrosis, and death. Although this is age and dose related, the toxicity is unpredictable. Frequent roentgenograms are recommended.

Idiosyncratic reactions similar to anaphylaxis have been reported in 1% of lymphoma patients treated with Blenoxane. Since these usually occur after the first or second dose, careful monitoring is essential after these doses.

Renal or hepatic toxicity, beginning as a deterioration in renal or liver function tests, have been reported, infrequently. These toxicities may occur, however, at any time after initiation of therapy.

Usage in Pregnancy: Safe use of Blenoxane in pregnant women has not been established.

ADVERSE REACTIONS: Pulmonary – This is potentially the most serious side effect, occurring in approximately 10% of treated patients. The most frequent presentation is pneumonitis occasionally progressing to pulmonary fibrosis. Approximately 1% of patients treated have died of pulmonary fibrosis. Pulmonary toxicity is both dose and age-related, being more common in patients over 70 years of age and in those receiving over 400 units total dose. This toxicity, however, is unpredictable and has been seen occasionally in young patients receiving low doses.

Because of lack of specificity of the clinical syndrome, the identification of patients with pulmonary toxicity due to Blenoxane has been extremely difficult. The earliest symptom associated with Blenoxane pulmonary toxicity is dyspnea. The earliest sign is fine rales.

Radiographically, Blenoxane-induced pneumonitis produces nonspecific patchy opacities, usually of lower lung fields. The most common changes in pulmonary function tests are a decrease in total lung volume and a decrease in vital capacity. However, these changes are not predictive of the development of pulmonary fibrosis.

The microscopic tissue changes due to Blenoxane toxicity include bronchiolar squamous metaplasia, reactive macrophages, atypical alveolar epithelial cells, fibrinous edema, and interstitial fibrosis. The acute stage may involve capillary changes and subsequent fibrinous exudation into alveoli producing a change similar to hyaline membrane formation and progressing to a diffuse interstitial fibrosis resembling the Hamman-Rich syndrome. These microscopic findings are nonspecific, e.g., similar changes are seen in radiation pneumonitis, pneumocystic pneumonitis.

To monitor the onset of pulmonary toxicity, roentgenograms of the chest should be taken every 1 to 2 weeks. If pulmonary changes are noted, treatment should be discontinued until it can be determined if they are drug related. Recent studies have suggested that sequential measurement of the pulmonary diffusion capacity for carbon monoxide (DL_{CO}) during treatment with Blenoxane may be an indicator of subclinical pulmonary toxicity. It is recommended that the DL_{CO} be monitored monthly if it is to be employed to detect pulmonary toxicities, and thus the drug should be discontinued when the DL_{CO} falls below 30 to 35% of the pretreatment value.

Because of bleomycin's sensitization of lung tissue, patients who have received bleomycin are at greater risk of developing pulmonary toxicity when oxygen is administered at surgery. While long exposure to very high oxygen concentrations is a known cause of lung damage, after bleomycin administration, lung damage can occur at lower concentrations than usually would be considered safe. Suggested preventive measures are:

1) Maintain FI O_2 at concentrations approximately that of room air (25%) during surgery and the post-operative period.
2) Monitor carefully fluid replacement, focusing more on colloid administration rather than crystalloid.

Idiosyncratic Reactions – In approximately 1% of the lymphoma patients treated with Blenoxane an idiosyncratic reaction, similar to anaphylaxis clinically, has been reported. The reaction may be immediate or delayed for several hours, and usually occurs after the first or second dose. It consists of hypotension, mental confusion, fever, chills, and wheezing. Treatment is symptomatic including volume expansion, pressor agents, antihistamines, and corticosteroids.

Integument and Mucous Membranes – These are the most frequent side effects, being reported in approximately 50% of treated patients. These consist of erythema, rash, striae, vesiculation, hyperpigmentation, and tenderness of the skin. Hyperkeratosis, nail changes, alopecia, pruritus, and stomatitis have also been reported. It was necessary to discontinue Blenoxane therapy in 2% of treated patients because of these toxicities.

Skin toxicity is a relatively late manifestation usually developing in the 2nd and 3rd week of treatment after 150 to 200 units of Blenoxane have been administered and appears to be related to the cumulative dose.

Other – Fever, chills, and vomiting were frequently reported side effects. Anorexia and weight loss are common and may persist long after termination of the medication. Pain at tumor site, phlebitis, and other local reactions were reported infrequently.

There are isolated reports of Raynaud's phenomenon occurring in patients with testicular carcinomas treated with a combination of Blenoxane and Velban®. It is currently unknown if the cause for the Raynaud's phenomenon in these cases is the disease, Blenoxane, Velban, or a combination of any or all of these.

SUPPLY: Each vial contains 15 units of Blenoxane as sterile bleomycin sulfate. NDC 0015-3010-20

AIDS
UPDATE

Reports in the New England Journal of Medicine confirm the early promise for many patients with AIDS and other serious HIV infections...

RETROVIR® (zidovudine)

Helps patients
live longer, live better

RETROVIR® is AZT™

Please see brief summary of prescribing information on last page of this advertisement.

RETROVIR®

(zidovudine)

Helps patients live longer, live better

New England Journal of Medicine reports

"[RETROVIR] AZT administration was therefore associated with a fourfold-to-sixfold reduction in the mortality rates in the study population at nine months."[1]

Patients live longer

A 90% survival rate was reported for AIDS and ARC patients treated with RETROVIR after one year—*v* 50% in a similar group of untreated patients[1,2]

Patients live better

Improves patients' general health and quality of life[1]

- Significantly reduces symptoms related to HIV infection
- Many patients can resume productive lives
- Reduces risk and severity of opportunistic infections
- Improves immune status

Improves patients' cognitive status[3,4]

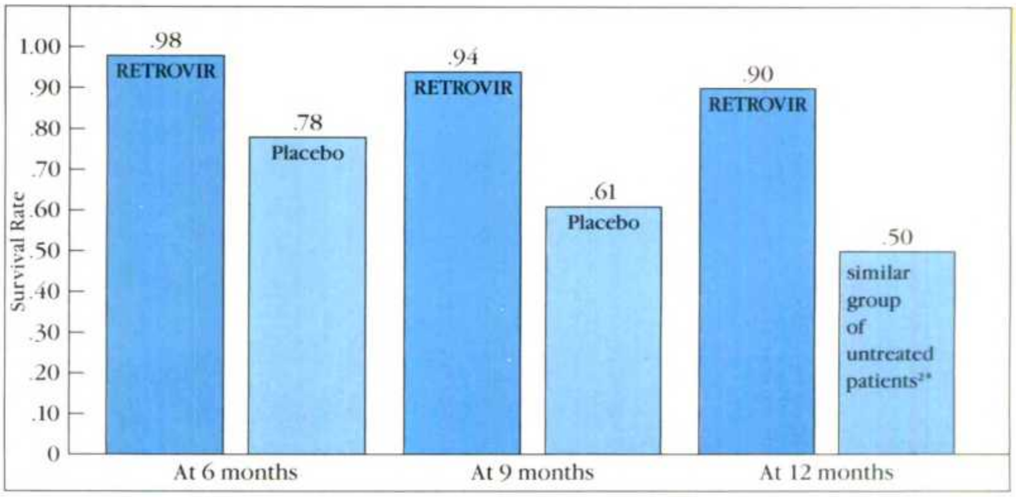
- Produced statistically significant improvements in long-term memory, motor function, concentration, and information-processing ability
- RETROVIR crosses the blood-brain barrier

IMPROVING LIVES THRO
ANTIVIRAL RESEARCH

BURROUGHS WELLCOME

Helps patients live longer

Survival rates for AIDS/ARC patients combined at 6, 9, and 12 months[1,2]

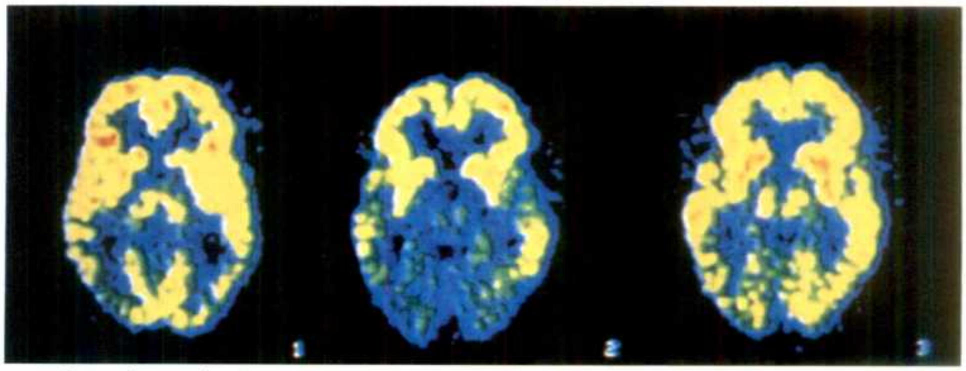


*Extrapolated from data of the Centers for Disease Control: *Morbidity and Mortality Weekly Report.*

Helps patients live better

Improvement following RETROVIR therapy demonstrated by positron emission tomography[3]

PET scans of normal control (1) and patient with HIV-related neuropathy and dementia before (2) and after (3) 13 weeks of RETROVIR therapy



Normal control (1)

Patient before RETROVIR therapy (2)

Patient following RETROVIR therapy (3)

A homogeneous pattern of glucose metabolism can be seen in the normal control (1) as compared with the heterogeneous pattern in the patient prior to RETROVIR therapy (2). After 13 weeks of treatment, the abnormal pattern has partly resolved (3).

Guidelines for successful management

- RETROVIR therapy is generally well tolerated by many patients, particularly those with higher T4 cell counts and more intact bone marrow function at the start of therapy
- Hematologic monitoring is recommended every two weeks; there is a possibility of bone marrow toxicity and subsequent RBC and WBC depression
- Concomitant use of acetaminophen with RETROVIR may potentiate granulocytopenia; other drugs that may interfere with RETROVIR metabolism should be avoided.

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OI'S) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper/inducer) lymphocyte count of less than 200/mm³ in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 160 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss ($\geq$ 15 lbs or $>$ 10% of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 cells/mm³ at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of $<$750/mm³. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count $<$ 1000/mm³ or hemoglobin $<$ 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 μg/ml and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/TK$^{+/-}$ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 μg/ml). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 μg/ml and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 μg/ml and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 μg/ml.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in th placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudin 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicitie was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entr and directly related to dose and duration of therapy. The frequency of granulocytopenia and anemi according to the patients' CD4 (T4) levels is shown in the following table:

	Pretreatment CD4 (T4) Levels			
	≤200/mm³		>200/mm³	
Abnormality	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia (< 750/mm³)	47%	10%	10%	3%
Anemia (Hgb < 7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudin examining the degree of change when compared to baseline, as shown in the table below, may be mo informative.

		Pretreatment CD4 (T4) Levels			
		≤200/mm³		>200/mm³	
Abnormality	% Decrease from Baseline	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	>50%	55%	19%	40%	13%
Anemia	>25%	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasi macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseli symptoms and clinical abnormalities. The following table summarizes those reported clinical adver events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nause insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4	NERVOUS		
Fever	16	12	Dizziness	6	4
Headache	42	37	Insomnia	5	1
Malaise	8	7	Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4	SKIN		
GI Pain	20	19	Rash	17	15
Nausea	46	18	SPECIAL SENSES		
Vomiting	6	3	Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are list below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudi recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pa lymphadenopathy.

Cardiovascular: vasodilation.

Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gum rectal hemorrhage, mouth ulcer.

Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.

Nervous: anxiety, confusion, depression, emotional lability, nervousness, syncope, loss of men acuity, vertigo.

Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.

Skin: acne, pruritus, urticaria.

Special senses: amblyopia, hearing loss, photophobia.

Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (t 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and durat of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serio anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of $<$7.5 g/dL or reduction of $>$25% of baseline) and significant granulocytopenia (granulocyte count of $<$750/mm³ or reduction of $>$50% from baseline) m require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anem dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occu following dose modification, gradual increases in dose may be appropriate depending on hematolo indices and patient tolerance.

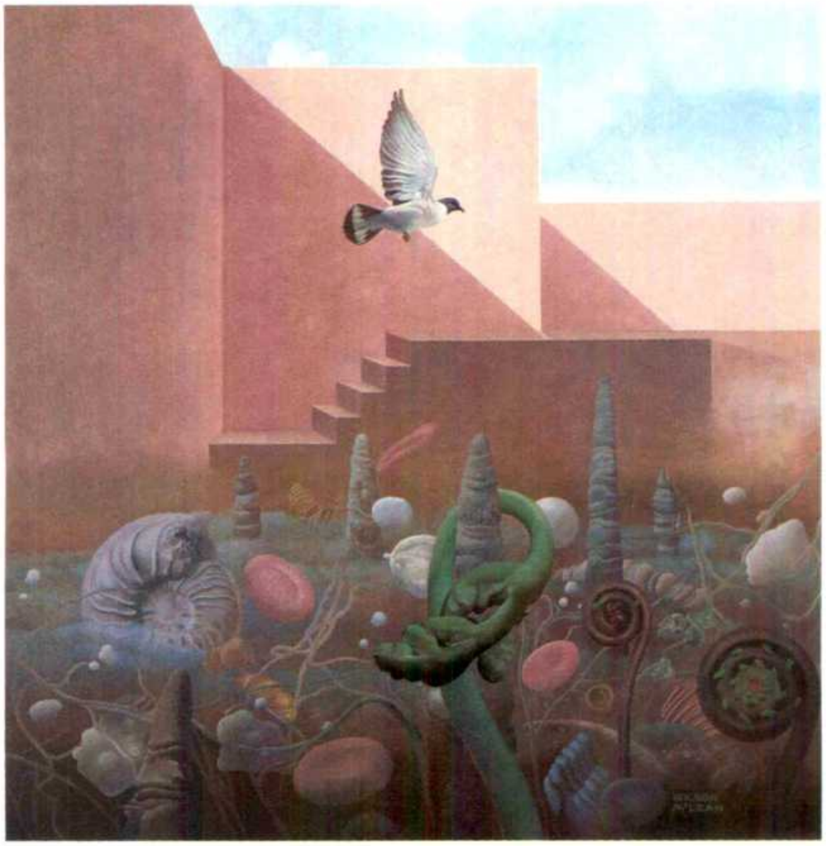
NOW THE WAY IS CLEAR FOR YOU TO PROVIDE LEUKOPOOR PLATELETS



...WITH THE CUTTER LEUKOTRAP™ PLATELET POOLING SYSTEM.

Now, leukopoor platelets can be routinely used for treatment of patients on platelet therapy to reduce or eliminate leukocyte-associated transfusion reactions. Leukotrap is the first commercially available system for *routine* production of leukopoor platelets.

MOST EFFICIENT METHOD

The Leukotrap System removes 90% of leukocytes and residual red cells with only 10% platelet loss.

Leukotrap™ Pooling Bag shown after completed procedure with leukocytes and residual red cells trapped in the pouch.

SIMPLE, FAST PROCEDURE

The Leukotrap System requires minimal technician time and a standard centrifuge.

Provide a better platelet product...with the Leukotrap Platelet Pooling System.

For more information, contact your Cutter Biological Representative or call our Professional Services Dept. at (800) 527-7200; in CA (800) 527-7222.

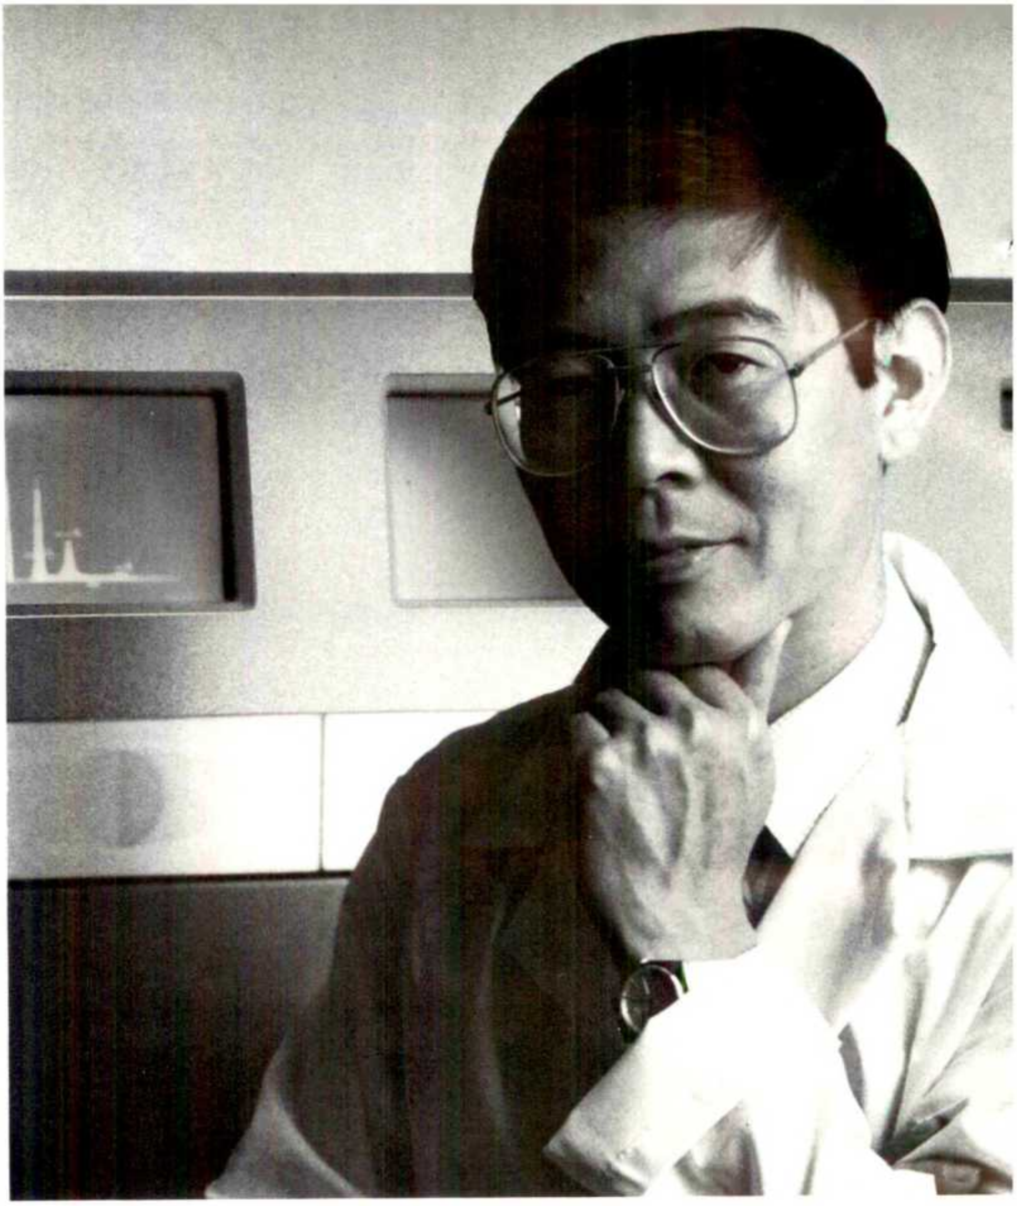
*"For
DNA analysis
of tumor cells, CVs
are very important.
If you don't have good
Vs, you sometimes can't
distinguish between
normal and
malignant cells."*



Peter Keng, Ph.D.
Associate Professor of Radiation Oncology
University of Rochester
School of Medicine and Dentistry

Dr. Keng was interviewed and photographed June 23, 1987, at his laboratory in the Cancer Center at Rochester, New York.

There's no substitute
for experienc

Dr. Peter Keng of the University of Rochester School of Medicine and Dentistry, New York, heads the Cancer Center flow cytometry laboratory where his primary research consists of DNA analysis of tumors. In this recent interview, Dr. Keng discusses the advantages of the EPICS® Profile clinical flow cytometry analyzer from his experience in terms of the particular needs and applications of his laboratory.

Profile facilitates DNA analysis

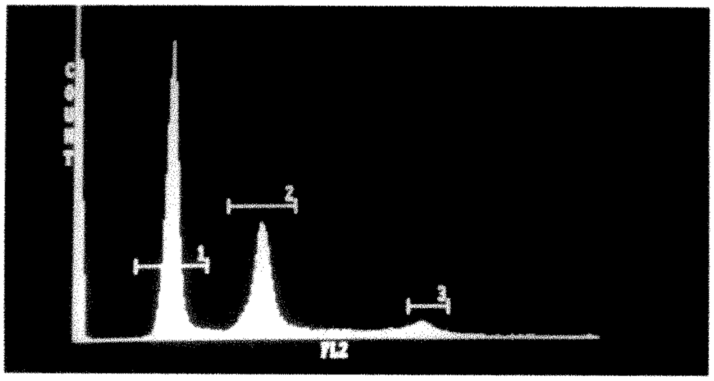
"We are investigating cell cycle kinetics of human tumors treated with radiation and chemotherapy. In order to have a good analysis of the percentage of G_1, S, G_2/M cells, you must have good CVs. In the past, we've always obtained excellent CVs with our EPICS® V; but with Profile, they are even better."

And productive multi-user environments

"There's nothing like Profile's convenience for a multi-user facility such as ours where speed and ease of use is so important. With 20 to 30 researchers using one analyzer, set up and execution are very rapid. The software allows one to enter the sample name and protocol as well as analyze the data in a few easy steps. Profile doesn't intimidate people. Once you use Profile, you feel comfortable with it. It really increases productivity."

Supported by Coulter's superior service

"I would rate Coulter servi the best among all the flow cytometry companies. The always respond very positiv and do everything to servic the instrument in the shorte possible time. Because of ou past experience with Coulte we know we can take servi for granted."



Propidium iodide stained nuclei from a dissociated human hepatoma tumor.
Region 1: Normal Resting Cells (G_0/G
Region 2: Aneuploid (malignant) population (G_0/G_1)
Region 3: Mitotic cells from malignant population (G_2/M)

Over 100 Profile instruments delivered worldwide since January, 1987.

For ITP Patients

GAMIMUNE® N
Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

For patients with acute and chronic idiopathic thrombocytopenic purpura (ITP), maintaining normal platelet levels may be a life-threatening problem. They often need fast, aggressive therapy that will elevate platelet counts rapidly. They need Gamimune® N.

IGIV treatment with Gamimune® N may effect a therapeutic increase in platelets in both children and adults with ITP and, in some cases, allows the possibility of major surgery.[1] In one study,[1] 62.5%(10 of 16) adult patients and 83.3% (5 of 6) pediatric patients demonstrated a substantial response to an initial course of therapy with Gamimune® N.[*][†]

Gamimune® N contains at least 98% gamma globulin and is the only ready-to-use liquid IGIV available. Cutter's patented fractionation method (based on Cohn-Oncley methods 6 and 9) assures Gamimune® N contains no heterologous proteins, with no detectable levels of protein aggregates or vasoactive enzymes.[2] And studies show *in vitro* inactivation of HIV (HTLV-III virus[‡] during production of Gamimune® N.

Gamimune® N. Enhancing the natural process with fast, aggressive therapy for ITP in both children and adults.

---

[*] It is not possible to predict which patients with ITP will respond to therapy.

[†] In patients who respond to therapy, a rise in platelet count is generally rapid (within one to five days), transient (most often lasting from several days to several weeks), and should not be considered curative.

[‡] The Cohn-Oncley process used to produce Gamimune® N has been challenged *in vitro* with a virus spike of 1 x 10^5 TCID (Tissue Culture Infectious Doses) of HIV (HTLV-III) and found to remove and/or inactivate the viral challenge. In addition, Gamimune® N undergoes an incubation step as a final container which has been shown to effect an additional 1 x 10^3 to 1 x 10^4 reduction TCID (Tissue Culture Infectious Doses) of HIV (HTLV-III).[3]

GAMIMUNE® N

Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25

CLINICAL PHARMACOLOGY

Gamimune® N supplies a broad spectrum of opsonic and neutralizing IgG antibodies for the prevention or attenuation of a wide variety of infectious diseases. As Gamimune® N is administered intravenously, essentially 100% of the infused IgG antibodies are immediately available in the recipient's circulation. A relatively rapid fall in serum IgG level in the first week post-infusion is to be expected; this decrease averages 50% of the peak level achieved immediately post-infusion and is mainly due to the equilibration of IgG between the plasma and the extravascular space. The in vivo half-life of Gamimune® N equals or exceeds the three week half-life reported for IgG in the literature, but individual patient variation in half-life has been observed. Thus, this variable as well as the amount of immune globulin administered per dose is important in determining the frequency of administration of the drug for each individual patient.

The intravenous administration of solutions of maltose has been studied by several investigators. Healthy subjects tolerated the infusions well, and no adverse effects were observed at a rate of 0.25 g maltose/kg body weight per hour. In safety studies conducted by Cutter Biological, infusions of 10% maltose administered at 0.27-0.62 g maltose/kg per hour to normal subjects produced either mild side effects (e.g., headache) or no adverse reaction. Following intravenous administrations of maltose, maltose was detected in the peripheral blood; there was a dose-dependent excretion of maltose and glucose in the urine and a mild diuretic effect. These alterations were well tolerated without significant adverse effects. The highest recommended infusion rate, 0.08 mL/kg body weight per minute (see DOSAGE AND ADMINISTRATION), is equivalent to 0.48 g maltose/kg body weight per hour.

The buffer capacity of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N is 16.5 mEq/L (~ 0.3 mEq/g protein); a dose of 150-400 mg/kg (3-8 mL/kg) body weight therefore represents an acid load of 0.0495-0.1320 mEq/kg body weight. The total buffering capacity of whole blood in a normal individual is 45-50 mEq/L of blood, or 3.6 mEq/kg body weight. Thus, the acid load delivered in the largest dose of Gamimune® N would be neutralized by the buffering capacity of whole blood alone, even if the dose were infused instantaneously. (An infusion usually lasts several hours.)

In Phase I human studies, no change in arterial blood pH measurements was detected following the intravenous administration of Gamimune® N at a dose of 150 mg/kg body weight; following a dose of 400 mg/kg body weight in 37 patients, there were no clinically important differences in mean venous pH or bicarbonate measurements in patients who received Gamimune® N compared with those who received a chemically modified intravenous immunoglobulin preparation with a pH of 6.8.

In patients with limited or compromised acid-base compensatory mechanisms, consideration should be given to the effect of the additional acid load Gamimune® N might present.

INDICATIONS AND USAGE

Immunodeficiency Syndromes: Gamimune® N is indicated for the maintenance treatment of patients who are unable to produce sufficient amounts of IgG antibodies. Usage of Gamimune® N may be preferred to that of intramuscular immunoglobulin preparations, especially in patients who require an immediate increase in intravascular immunoglobulin levels, in patients with a small muscle mass, and in patients with bleeding tendencies in whom intramuscular injections are contraindicated. It may be used in disease states such as congenital agammaglobulinemia (e.g., X-linked agammaglobulinemia), common variable hypogammaglobulinemia, X-linked immunodeficiency with hyper IgM and in severe combined immunodeficiency.

Idiopathic Thrombocytopenic Purpura (ITP): Investigations in both children and adults have shown that Gamimune® N may initiate a therapeutic increase in the platelet count. In clinical studies of Gamimune® N, five of six (83.3%) children and 10 of 16 (62.5%) adults with acute or chronic ITP demonstrated clinically significant increments in the platelet count during or following an initial treatment course with Gamimune® N at a dose of 400 mg/kg body weight daily for five days. The duration of the platelet rise following treatment of ITP with Gamimune® N was variable, ranging from several days up to 12 months or more. Several ITP patients demonstrated continuing responsiveness over many months to intermittent Gamimune® N 400 mg/kg body weight single dose maintenance courses. Two of three children with acute ITP treated with Gamimune® N rapidly went into complete remission. However, childhood ITP may respond spontaneously without treatment. Four patients with refractory ITP were able to undergo major surgical procedures as a result of the rapid rise in platelet count associated with Gamimune® N treatment.

In addition, one patient with severe thrombocytopenia due to post-transfusion purpura (PL^{A1} alloimmune antibody with platelet anti PL^{A1} specificity) also responded to treatment with Gamimune® N, at a dose of 400 mg/kg body weight daily for 5 days; there was a rapid rise in the platelet count commencing on the third day of treatment.

It is presently not possible to predict which patients with ITP will respond to therapy, although the increase in platelet counts in children seems to be better than that of adults. In clinical situations in which a rapid rise in platelet count is needed to control bleeding or to allow a patient with ITP to undergo surgery, administration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N should be considered; in patients in whom a response is achieved, the rise of platelets is generally rapid (within 1–5 days), transient (most often lasting from several days to several weeks) and should not be considered curative. In some patients who relapse, a maintenance dose of Gamimune® N administered every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels (see DOSAGE AND ADMINISTRATION).

CONTRAINDICATIONS

Gamimune® N is contraindicated in individuals who are known to have had an anaphylactic or severe systemic response to Immune Globulin (Human). Individuals with selective IgA deficiencies who have known antibody against IgA (anti-IgA antibody) should not receive Gamimune® N since these patients may experience severe reactions to the IgA which may be present.

WARNINGS

Gamimune® N should be administered only intravenously as the intramuscular and subcutaneous routes have not been evaluated.

Gamimune® N may, on rare occasions, cause a precipitous fall in blood pressure and a clinical picture of anaphylaxis, even when the patient is not known to be sensitive to immune globulin preparations. These reactions may be related to the rate of infusion. Accordingly, the infusion rate given under DOSAGE AND ADMINISTRATION should be closely followed, at least until the physician has had sufficient experience with a given patient. The patient's vital signs should be monitored continuously and careful observation made for any symptoms throughout the entire infusion. Epinephrine should be available for the treatment of an acute anaphylactic reaction.

PRECAUTIONS

General: Any vial that has been entered should be used promptly. Partially used vials should be discarded. Do not use if turbid. Solution which has been frozen should not be used.

Drug Interactions: If dilution is required, Gamimune® N may be diluted with 5% dextrose in water (D5/W). No other drug interactions or compatibilities have been evaluated. It is recommended that infusion of Gamimune® N be given by a separate line, by itself, without mixing with other intravenous fluids or medications the patient might be receiving.

Pregnancy Category C: Animal reproduction studies have not been conducted with Gamimune® N. It is not known whether Gamimune® N can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Gamimune® N should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS

In a study of 37 patients with immunodeficiency syndromes receiving Gamimune® N at a monthly dose of 400 mg/kg body weight, reactions were seen in 5.2% of the infusions of Gamimune® N. Symptoms reported with Gamimune® N included malaise, a feeling of faintness, fever, chills, headache, nausea, vomiting, chest tightness, dyspnea and chest, back or hip pain. In addition, mild erythema following infiltration of Immune Globulin Intravenous (Human) 5% (in 10% Maltose), pH 4.25—Gamimune® N at the infusion site was reported in some cases.

In further studies of Gamimune® N in the treatment of both adult and pediatric patients with ITP, systemic reactions were noted in only 4 of 154 (2.6%) infusions, and all but one occurred at rates of infusion greater than 0.04 mL/kg body weight per minute. The symptoms reported included chest tightness, a sense of tachycardia (pulse was 84 beats per minute), and a burning sensation in the head; these symptoms were all mild and transient. Erythema, pain, phlebitis, or eczematous reactions at the infusion site were also reported following infusion of Gamimune® N to adult ITP patients. These reactions occurred in 11.6% of the infusions of Gamimune® N and in 43.8% of the adult ITP population. No pediatric patients experienced localized reactions at the infusion site.

In the studies undertaken to date, other types of reactions have not been reported with Gamimune® N. It may be, however, that adverse effects will be similar to those previously reported with intravenous and intramuscular immunoglobulin administration. Potential reactions, therefore, may also include anxiety, flushing, wheezing, abdominal cramps, myalgias, arthralgia, and dizziness; rash has been reported only rarely. Reactions to intravenous immunoglobulin tend to be related to the rate of infusion.

True anaphylactic reactions to Gamimune® N may occur in recipients with documented prior histories of severe allergic reactions to intramuscular immunoglobulin, but some patients may tolerate cautiously administered intravenous immunoglobulin without adverse effects. Very rarely an anaphylactoid reaction may occur in patients with no prior history of severe allergic reactions to either intramuscular or intravenous immunoglobulin.

DOSAGE AND ADMINISTRATION

Immunodeficiency Syndromes: The usual dosage of Gamimune® N for prophylaxis in immunodeficiency syndromes is 100–200 mg/kg (2–4 mL/kg) of body weight administered approximately once a month by intravenous infusion. If the clinical response is inadequate, or the level of IgG achieved in the circulation is felt to be insufficient, the dosage may be given more frequently or increased as high as 400 mg/kg (8 mL/kg) body weight.

Idiopathic Thrombocytopenic Purpura: An increase in platelet count has been observed in children and some adults with acute or chronic ITP receiving Gamimune® N, 400 mg/kg body weight daily for five days. A response usually occurs within several days and is maintained for a variable period of time. In general a response is seen less often in adults than in children. In patients who have shown a response, a maintenance dose of Gamimune® N of 400 mg/kg body weight administered as a single dose every several weeks may be of benefit once the platelet count decreases to clinically hazardous levels.

Investigations indicate that Gamimune® N is well-tolerated and less likely to produce side effects when infused at the indicated rate. It is recommended that Gamimune® N be infused by itself at a rate of 0.01 to 0.02 mL/kg body weight per minute for 30 minutes; if well tolerated, the rate may be **gradually** increased to a maximum of 0.08 mL/kg body weight per minute. If side effects occur, the rate may be reduced, or the infusion interrupted until symptoms subside. The infusion may then be resumed at the rate which is comfortable for the patient.

Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration, whenever solution and container permit.

BE SPECIFIC.

Ask for Olympus. Because nobody offers a broader range of MAb's specific for human cytokines.

It's true. Olympus, your colleague in immunology, offers the broadest selection *anywhere* of monoclonal antibodies specific for interleukins 1 and 2, tumor necrosis factor, interferons beta and gamma, and granulocyte-monocyte colony stimulating factor. And for most of these, we provide two or three different MAb's, with different functional properties—providing the flexibility you need for any research application.

We also offer a wide selection of purified and conjugated MAb's specific for human leukocyte markers and a complete range of second-step reagents.

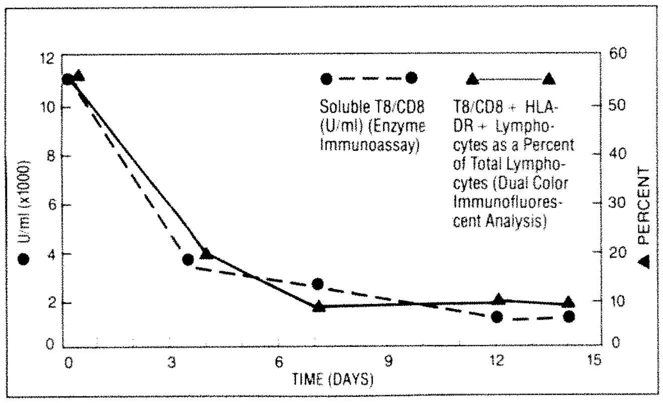
TECHNICAL UPDATE

Soluble T8/CD8: A New Assessment of T8/CD8+ Cell Function

CELLFREE® T8 Test Kit*

Soluble T8/CD8 Released Upon Activation

- Activated T8/CD8+ cells release the T8/CD8 protein into serum or supernatants
- First identified by Fujimoto *et al.* in 1983.(1)
- Soluble T8/CD8 is a homodimer of mw = 52 kD(2); 10 kD smaller than the cell surface molecule.(1,2)



Correlation of soluble CD8 with CD8 + HLA-DR + T Lymphoctyes (Patient E) (3)

A Measure of T8/CD8 + Cell Activation

- In disseminated disease, soluble T8/CD8 has been shown to vary with the number of activated T8/CD8 + cells in peripheral blood as measured by HLA-DR (3).
- Levels of soluble T8/CD8 parallel the decline of T8/CD8 + HLA-DR + cells during the resolution of disease (3).
- Measurement of soluble T8/CD8 may lead to a better understanding of T8/CD8 + suppressor/cytotoxic T cell activity.

Measure T8/CD8 with the CELLFREE® T8 Test Kit

- An easy-to-use enzyme immunoassay.
- Performed in microtiter wells.
- Reliable, consistent performance with fresh or frozen serum, plasma, or cell culture supernatants.
- Sample incubation to final result within one working day.

FOR RESEARCH USE ONLY. NOT FOR USE IN DIAGNOSTIC OR THERAPEUTIC PROCEDURES.

*Patents Pending

Radiogenic mucositis or herpes simplex?

Early intervention can prevent or reduce HSV complications

A high percentage of immunocompromised patients are at risk for developing HSV infections. Timely therapy with an antiviral agent can avoid the incidence of secondary complications, such as visceral dissemination, and prolonged hospital stay.

Appearances may be deceiving

Both slides are herpes simplex. In immunocompromised patients, mucositis and stomatitis that appear to result from radiation therapy or immunosuppression may actually be caused by herpes simplex. Differential diagnosis can be problematic, but appropriate laboratory tests can aid in the determination.

There is an effective therapeutic agent available

ZOVIRAX I.V. stops viral replication, speeds healing, and reduces pain. It is effective antiviral therapy for treatment of herpes simplex viral infections.

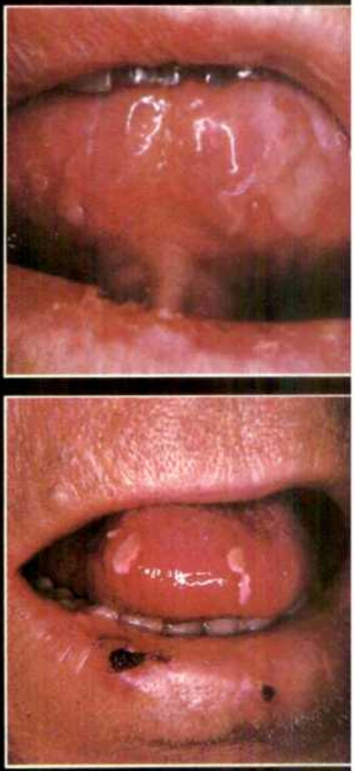
(acyclovir sodium)
STERILE POWDER / I.V. INFUSION

When the problem begins with a virus, end it with an antiviral.

Please see following page for brief summary of prescribing information.

The diagnostic challenge in immunocompromised patients...



ZOVIRAX® I.V. (acyclovir sodium)

STERILE POWDER / I.V. INFUSION

ZOVIRAX® I.V. INFUSION (acyclovir sodium) sterile powder

FOR INTRAVENOUS INFUSION ONLY

INDICATIONS AND USAGE: Zovirax Sterile Powder is indicated for the treatment of initial and recurrent mucosal and cutaneous Herpes simplex (HSV-1 and HSV-2) infections in immunocompromised adults and children. It is also indicated for severe initial clinical episodes of herpes genitalis in patients who are not immunocompromised.

These indications are based on the results of several double-blind, placebo-controlled studies which evaluated the drug's effect on virus excretion, complete healing of lesions, and relief of pain.

Herpes Simplex Infections in Immunocompromised Patients

A multicenter trial of Zovirax Sterile Powder at a dose of 250 mg/M^2 every 8 hours (750 mg/M^2/day) for 7 days was conducted in 97 immunocompromised patients with oro-facial, esophageal, genital and other localized infections (50 treated with Zovirax and 47 with placebo). Zovirax significantly decreased virus excretion, reduced pain, and promoted scabbing and rapid healing of lesions.[1,2,3]

Initial Episodes of Herpes Genitalis

A controlled trial was conducted in 28 patients with severe initial episodes of herpes genitalis with a Zovirax dosage of 5 mg/kg every 8 hours for 5 days (12 patients treated with Zovirax and 16 with placebo). Significant treatment effects were seen in elimination of virus from lesions and in reduction of healing times.[4]

In a similar study, 15 patients with initial episodes of genital herpes were treated with Zovirax 5 mg/kg every 8 hours for 5 days and 15 with placebo. Zovirax decreased the duration of viral excretion, new lesion formation, duration of vesicles and promoted more rapid healing of all lesions.[5]

Diagnosis

The use of appropriate laboratory diagnostic procedures will help to establish the etiologic diagnosis. Positive cultures for Herpes simplex virus offer a reliable means for confirmation of the diagnosis. In initial episodes of genital herpes, appropriate examinations should be performed to rule out other sexually transmitted diseases. Whereas cutaneous lesions associated with Herpes simplex infections are often characteristic, the finding of multinucleated giant cells in smears prepared from lesion exudate or scrapings may assist in the diagnosis.[6]

CONTRAINDICATIONS: Zovirax Sterile Powder is contraindicated for patients who develop hypersensitivity to the drug.

WARNINGS: Zovirax Sterile Powder is intended for intravenous infusion only, and should not be administered topically, intramuscularly, orally, subcutaneously or in the eye. Intravenous infusions must be given over a period of at least 1 (one) hour to prevent renal tubular damage (see PRECAUTIONS and DOSAGE AND ADMINISTRATION).

PRECAUTIONS:

General: The recommended dosage, frequency and length of treatment should not be exceeded (See DOSAGE AND ADMINISTRATION).

Although the aqueous solubility of acyclovir sodium (for infusion) is >100 mg/ml, precipitation of acyclovir crystals in renal tubules can occur if the maximum solubility of free acyclovir (2.5 mg/ml at 37°C in water) is exceeded or if the drug is administered by bolus injection. This complication causes a rise in serum creatinine and blood urea nitrogen (BUN), and a decrease in renal creatinine clearance. Ensuing renal tubular damage can produce acute renal failure.

Abnormal renal function (decreased creatinine clearance) can occur as a result of acyclovir administration and depends on the state of the patient's hydration, other treatments, and the rate of drug administration. Bolus administration of the drug leads to a 10% incidence of renal dysfunction, while in controlled studies, infusion of 5 mg/kg (250 mg/M^2) over an hour was associated with a lower frequency—4.6%. Concomitant use of other nephrotoxic drugs, pre-existing renal disease, and dehydration make further renal impairment with acyclovir more likely. In most instances, alterations of renal function were transient and resolved spontaneously or with improvement of water and electrolyte balance, drug dosage adjustment or discontinuation of drug administration. However, in some instances, these changes may progress to acute renal failure.

Administration of Zovirax by intravenous infusion must be accompanied by adequate hydration. Since maximum urine concentration occurs within the first 2 hours following infusion, particular attention should be given to establishing sufficient urine flow during that period in order to prevent precipitation in renal tubules.

When dosage adjustments are required they should be based on estimated creatinine clearance (See DOSAGE AND ADMINISTRATION).

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma. Zovirax should be used with caution in those patients who have underlying neurologic abnormalities and those with serious renal, hepatic, or electrolyte abnormalities or significant hypoxia. It should also be used with caution in patients who have manifested prior neurologic reactions to cytotoxic drugs or those receiving concomitant intrathecal methotrexate or interferon.

Exposure of HSV isolates to acyclovir *in vitro* can lead to the emergence of less sensitive viruses. These viruses usually are deficient in thymidine kinase (required for acyclovir activation) and are less pathogenic in animals. Similar isolates have been observed in 6 severely immunocompromised patients during the course of controlled and uncontrolled studies of intravenously administered Zovirax. These occurred in patients with congenital severe combined immunodeficiencies or following bone marrow transplantation. The presence of these viruses was not associated with a worsening of clinical illness and, in some instances, the virus disappeared spontaneously. The possibility of the appearance of less sensitive viruses must be borne in mind when treating such patients. The relationship between the *in vitro* sensitivity of herpesviruses to acyclovir and clinical response to therapy has yet to be established.

Drug Interactions: Co-administration of probenecid with acyclovir has been shown to increase the mean half-life and the area under the concentration-time curve. Urinary excretion and renal clearance were correspondingly reduced. Clinical experience has identified no other significant interactions resulting from administration of other drugs concomitantly with Zovirax Sterile Powder.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Acyclovir was tested in lifetime bioassays in rats and mice at single daily doses of 50, 150 and 450 mg/kg given by gavage. There was no statistically significant difference in the incidence of tumors between treated and control animals, nor did acyclovir appear to shorten the latency of tumors. In 2 *in vitro* cell transformation assays, used to provide preliminary assessment of potential oncogenicity in advance of these more definitive lifetime bioassays in rodents, conflicting results were obtained. Acyclovir was positive at the highest dose used in one system and the resulting morphologically transformed cells formed tumors when inoculated into immunosuppressed, syngeneic, weanling mice. Acyclovir was negative in another transformation system.

No chromosome damage was observed at maximum tolerated parenteral doses of 100 mg/kg acyclovir in rats or Chinese hamsters; higher doses of 500 and 1000 mg/kg were clastogenic in Chinese hamsters. In addition, no activity was found in a dominant lethal study in mice. In 9 of 11 microbial and mammalian cell assays, no evidence of mutagenicity was observed. In 2 mammalian cell assays (human lymphocytes and L5178Y mouse lymphoma cells *in vitro*), positive responses for mutagenicity and chromosomal damage occurred, but only at concentrations at least 25 times the acyclovir plasma levels achieved in man.

Acyclovir does not impair fertility or reproduction in mice at oral doses up to 450 mg/kg/day. In female rabbits treated subcutaneously with acyclovir subsequent to mating, there was a statistically significant decrease in implantation efficiency but no concomitant decrease in litter size at a dose of 50 mg/kg/day.

Pregnancy: Teratogenic Effects. Pregnancy Category C. Acyclovir was not teratogenic in the mouse (450 mg/kg/day, p.o.), rabbit (50 mg/kg/day, s.c.) or rat (50 mg/kg/day, s.c.).

Although maximum tolerated doses were tested in teratology studies, the plasma levels obtained did not exaggerate maximum plasma levels that might occur with clinical use of intravenous acyclovir.

There have been no adequate and well-controlled studies in pregnant women. Acyclovir should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when Zovirax (acyclovir sodium) sterile powder is administered to a nursing woman.

ADVERSE REACTIONS: The most frequent adverse reactions reported during controlled clinical trials of Zovirax in 64 patients were inflammation or phlebitis at the injection site following infiltration of the I.V. fluid in 9 (14.0%), transient elevations of serum creatinine in 3 (4.7%), and rash or hives in 3 (4.7%). Less frequent adverse reactions were diaphoresis, hematuria, hypotension, headache and nausea, each of which occurred in 1 patient (1.6%). Of the 63 patients receiving placebo, 3 (4.8%) experienced inflammation/phlebitis and 3 (4.8%) experienced rash or itching. Hematuria and nausea were experienced by placebo recipients at the same frequency.

Among 51 immunocompromised patients, one, a bone marrow transplant recipient with pneumonitis, developed seizures, cerebral edema, coma and expired with changes consistent with cerebral anoxia on postmortem biopsy; another immunocompromised patient exhibited coarse tremor and clonus.

Additional adverse reactions were reported in uncontrolled trials. The most frequent adverse reaction was elevated serum creatinine. This occurred in 9.8 percent of patients, usually following rapid (less than 10 minutes) intravenous infusion. Less frequent adverse experiences were thrombocytosis and jitters, each in 0.4% of patients.

Approximately 1% of patients receiving intravenous acyclovir have manifested encephalopathic changes characterized by either lethargy, obtundation, tremors, confusion, hallucinations, agitation, seizures or coma (see PRECAUTIONS).

OVERDOSAGE: Overdosage has been reported following administration of bolus injections, or inappropriately high doses, and in patients whose fluid and electrolyte balance was not properly monitored. This has resulted in elevations in BUN, serum creatinine and subsequent renal failure.

Precipitation of acyclovir in renal tubules may occur when the solubility (2.5 mg/ml) in the intratubular fluid is exceeded (see PRECAUTIONS). A six hour hemodialysis results in a 60% decrease in plasma acyclovir concentration. Data concerning peritoneal dialysis are incomplete but indicate that this method may be significantly less efficient in removing acyclovir from the blood. In the event of acute renal failure and anuria, the patient may benefit from hemodialysis until renal function is restored (see DOSAGE AND ADMINISTRATION).

DOSAGE AND ADMINISTRATION: CAUTION—RAPID OR BOLUS INTRAVENOUS AND INTRAMUSCULAR OR SUBCUTANEOUS INJECTION MUST BE AVOIDED.

Dosage: ***MUCOSAL AND CUTANEOUS HERPES SIMPLEX (HSV-1 and HSV-2) INFECTIONS IN IMMUNOCOMPROMISED PATIENTS***—5 mg/kg infused at a constant rate over 1 hour, every 8 hours (15 mg/kg/day) for 7 days in adult patients with normal renal function. In children under 12 years of age, more accurate dosing can be attained by infusing 250 mg/M^2 at a constant rate over 1 hour, every 8 hours (750 mg/M^2/day) for 7 days.

SEVERE INITIAL CLINICAL EPISODES OF HERPES GENITALIS—The same dose given above—administered for 5 days.

Therapy should be initiated as early as possible following onset of signs and symptoms.

PATIENTS WITH ACUTE OR CHRONIC RENAL IMPAIRMENT: Refer to DOSAGE AND ADMINISTRATION section for recommended doses, and adjust the dosing interval as indicated in the table below.

Creatinine Clearance (ml/min/1.73M^2)	Dose (mg/kg)	Dosing Interval (hours)
>50	5	8
25-50	5	12
10-25	5	24
0-10	2.5	24

Hemodialysis: For patients who require dialysis, the mean plasma half-life of acyclovir during hemodialysis is approximately 5 hours. This results in a 60% decrease in plasma concentrations following a 6 hour dialysis period. Therefore, the patient's dosing schedule should be adjusted so that a dose is administered after each dialysis.

Method of Preparation: Each 10 ml vial contains acyclovir sodium equivalent to 500 mg of acyclovir. The contents of the vial should be dissolved in 10 ml of sterile water for injection or bacteriostatic water for injection containing benzyl alcohol yielding a final concentration of 50 mg/ml of acyclovir (pH approximately 11). Shake the vial well to assure complete dissolution before measuring and transferring each individual dose. DO NOT USE BACTERIOSTATIC WATER FOR INJECTION CONTAINING PARABENS. It is incompatible with Zovirax Sterile Powder and may cause precipitation.

Coulter Counter® S-Plus STKR and S-Plus JR Interpretive Report providing a Histogram Differential consisting of lymphocytes, mononuclear cells and granuloctyes, in percent. Note that these three cell classifications add up to 100% for the total differential.

The plain fact is, you don't need a microscope to see the diff difference.

A simple comparison of the two printouts appearing on these pages should dispel an doubts you may have as to which analyzer provides you with the most comprehensive and understandable WBC differential dat

The TECHNICON H•1® system report form, on the right, gives you all five white cell types (l phocytes, neutrophils, monocytes, eosinoph and basophils) in both percentages and ab lute numbers; just the way they taught it in school.

The Coulter® report, on the left, however, only provides data on lymphocytes; two catch-all categories called mononuclear cells and granulocytes and (in their own words) "the suspected presence of eosi philia and basophilia." We believe you're entitled to accurate quantitation, not speculative suspicion.

A Recent Study Defines the Differen

A recent study* compared 71 laborato using the Coulter Histogram Differenti with 71 laboratories employing the TECHNICON H•1 system. In both case the labs processed, on average, 125 inpatient samples per day. The labs using Coulter systems reported that needed to perform additional manual diffs on 53 all samples. The labs with the TECHNICON H•1 system, however, only required manual diffs on of all samples. That's 40 fewer manual diffs a d you had the TECHNICON H•1! Figure out how m time, labor, and money that can save you.

TECHNICON H·1® system report providing a differential consisting of lymphocytes, neutrophils, monocytes, eosinophils and basophils in both percent and absolute numbers, giving a full five-part quantitative differential.

linician Acceptance of Automated ifferentials

ne of the most interesting findings of the study eported that 21% of Coulter system users cite hysician reluctance to accept an automated ifferential as the primary reason why some or ll diffs are performed manually in their labs. y contrast, only 5% of TECHNICON H•1 system users cite that reason. It would seem that linicians want their diagnostic results in terms ey understand and are comfortable with. e can't say we blame them.

hat this all boils down to is that the ECHNICON H•1 system provides your hysicians with a classical full five-part differential (and, by the way, an evaluation of latelet and red cell morphology) *and* educes significantly your need to waste dditional time and effort on tedious anual review procedures.

fter all, remember why you automated in the first place.

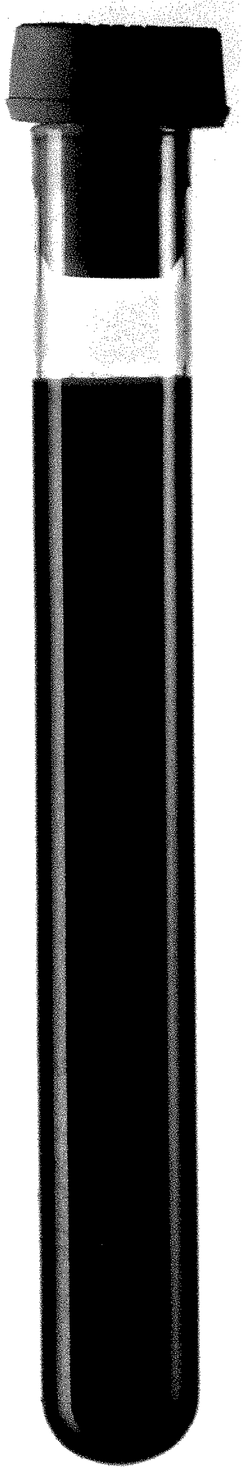
FROM WHOLE BLOO



Before now, sample preparation for all surface markers in flow cytometry represented a formidable barrier of incubations, centrifugations, and numerous pipetting and decanting steps. Frequently, selective cell loss occurred during pipetting and decanting. This tedious procedure remained the only major problematic aspect of flow cytometry left unresolved.

Just 90 seconds to a fixed sample

The COULTER® Q-Prep Workstation* does away with complex, time-consuming, error-prone sample preparation. Whole blood samples are ready for flow cytometric analysis in just 90 seconds – compared to the 1 to 3 hours at present.

Universally standardized for reproducible results

Q-Prep is specifically designed to universall standardize sample preparation methodology for consistently reproducible results – sample to sample, hist gram to histogram, laboratory to laborato

EPICS BREAKS THE SAM

O FLOW CYTOMETER

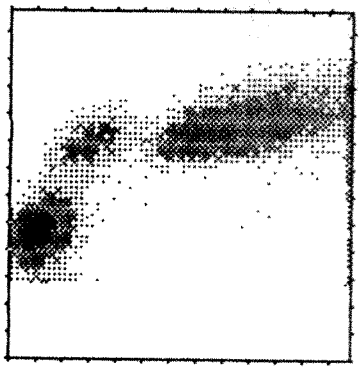
While minimizing human error and biohazard exposure

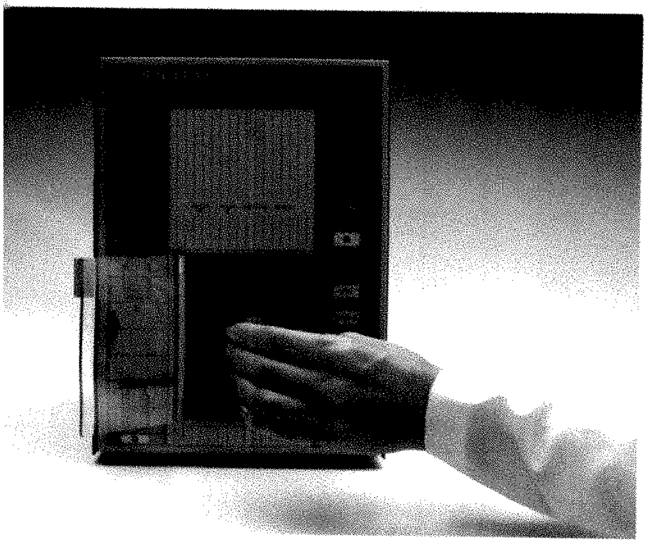
To improve lab personnel safety, sample handling is substantially reduced. In addition, the uniquely formulated reagents* are added and mixed automatically by Q-Prep – virtually eliminating technique errors. And with no decanting or aspirations, selective cell loss is avoided.

A final touch to a total system

Together with COULTER CLONE® Monoclonal Antibodies, EPICS™ Standards and Calibrators, EPICS® Profile and other EPICS® flow cytometers, Q-Prep completes the only total system for flow cytometric analysis.

Coulter technology continues to successfully address the major issues confronting complete cell analysis – repeatedly affirming Epics leadership in flow cytometry.





COULTER® Q-PREP

Only three simple steps

1. Add monoclonal antibody to 0.1 ml whole blood sample.
2. Place sample into Q-Prep workstation for 90 seconds.
3. Remove prepared sample from Q-Prep for flow cytometric analysis.

To experience sample preparation to flow cytometric analysis in just 90 seconds with the Q-Prep, call 1-800-ME-EPICS (1-800-633-7427), ext. 4866 and ask for Mary.

Hemophilia.
Home Hemophilia Services.
Caremark/Western Medical Specialties.

Just part of the picture.

Advances in the field of hemophilia research over the past twenty years have yielded sophisticated, yet uncomplicated treatment methods that allow persons with hemophilia to focus on a brighter future. Where once was a corridor of closed doors, now appears a wealth of new physical, mental and occupational growth possibilities. In concert with the care program designed for your patients with hemophilia, Western Medical Specialties can provide convenient, reliable delivery of all major brands of anti-hemophilic factor and ancillary supplies to your office, the patient's home or place of business. WMS bil third party insurers directly (includin both state and federal programs) an provides follow-up documentation w each shipment. Western Medical Specialties: Just part of the total-car picture for your patients with hemophilia.

HANDS OFF!

HANDS DOWN HANDS OFF SYSTEMS

Hands down . . . the new family of hematology systems from Coulter are the best—and the safest—ever developed.

Operator safe. Closed-vial sampling means minimal risk. Minimal exposure to aerosols and to infectious blood disease. Offered to you on the new COULTER® ST, on the new COULTER JS (with automated sample handling), and on the top-of-the-line COULTER STKR. The STKR is the finest example of hands off, walkaway automation to be found in *any* blood analyzer.

Patient safe. Bar code ID on all specimen tubes keeps patient results in order.

No muss, no fuss, no fear of open-vial blood exposure, and increased protection from sample to patient-result mix-up.

Plus the many other features you've come to expect from Coulter . . . the leader in laboratory blood analysis systems for almost 30 years. Today's automated, high-speed systems have been designed and developed to address today's lab concerns: increased costs, decreased budgets, prescribed reimbursement, more frequent requests for faster and more accurate results.

Workflow efficiency has been accorded top priority. The new COULTER systems totally automate tasks which technologists have been doing for years: preparing worklists, identifying specimens, introducing samples into the analyzer, and matching sample results to the correct report. This increased automation frees technologists for other important lab functions which require their professional skills.

HE SAFEST
EMATOLOGY
VER.

The total package. Instruments, diagnostics and consumables. Training, service and support. Attractive leasing and long-term warranties. Each regarded as the industry standard.

Take the next step. For a demo in your lab, or simply more information, call RoseMarie at 800-526-6932. In Canada, 416-639-4701 collect. We'd like the opportunity to show you why we say Coulter produces the best—and the safest—**hands off** systems available. **Hands down!**

Abnormality detection. The Coulter Histogram Differential with interpretive reporting detects all significant abnormalities—with less than 1% false negatives.* The Coulter CBC has the accuracy you can count on. And it's *complete*. COULTER systems detect and report abnormalities such as the suspected presence of eosinophilia and basophilia. Plus red cell morphology and a complete platelet profile.

AIDS RESEARCHERS:

DETECT HIV ANTIGEN

N LESS THAN 4 HOURS.

This assay is a dynamic breakthrough in specifically measuring HIV p24 core antigen levels, maximizing sensitivity, specificity, and accuracy while enhancing speed and convenience. Coulter Immunology is pleased to announce the availability of a new microplate HIV Antigen EIA that offers many improvements over existing test systems:

- **FASTER TURNAROUND:** The Coulter HIV Antigen Test delivers accurate results in less than four hours. Technologist time is only 40 minutes.
- **SUPERIOR SENSITIVITY:** Measures less than 10 picograms per milliliter of core-related proteins, primarily p24.
- **HIGH SPECIFICITY:** Monoclonal antibody capture with no cross-reactivity with HTLV-I, HTLV-II, Cytomegalovirus, Herpes Simplex I or II, Epstein-Barr virus, Legionnaires', Toxoplasmosis, Rheumatoid Factor, or Bilirubin.
- **CHOICE OF SPECIMENS:** Plasma, serum, or culture fluid with equal sensitivity.
- **EASIER TO RUN:** Color-coded reagents minimize pipetting error and allow internal and ongoing QC of test performance.
- **FLEXIBILITY/ECONOMY:** Removable 8-well strips permit assays of 8 to 96 wells per run. Therefore, one can perform 12 separate runs using just one plate.
- **MORE SAFETY FEATURES:** Employs non-infective sonified, detergent detoxified HIV. Lyse reagent detoxifies virus in sample during first step of procedure.

For more information about the Coulter HIV Antigen EIA (96-well microplate Kit), call us at 1-800-327-3778 (in Florida, 1-800-327-6531, Ext. 6880). Coulter Immunology, the company with the broadest line of human-specific cell surface monoclonal antibodies, provides solutions to investigations of the most pressing problems of the medical community.

REVIEW ARTICLE

The 5q− Abnormality

By Stephen D. Nimer and David W. Golde

LOSS OF A PORTION of the long arm of chromosome 5 is seen predominantly in therapy-related myelodysplastic syndromes and acute leukemias, as well as in a unique clinical disorder known as the 5q− syndrome. Recently, many growth factor and growth factor receptor genes have been localized to the long arm of chromosome 5, and several of these genes have been found to be deleted in patients with a 5q− chromosomal abnormality. These findings raise the possibility that alteration of expression of these genes may play a pathogenetic role in these hematologic disorders. In this review, we discuss the clinical and molecular biological findings associated with the 5q− abnormality.

THE 5Q− SYNDROME

Three patients with long-standing idiopathic refractory anemia and an interstitial deletion of the long arm of chromosome 5 were first described by van den Berghe et al in 1974.[1] Two additional patients were reported in 1975,[2] and a new hematologic syndrome was established, the 5q− syndrome. Scores of patients with refractory anemia and a 5q− chromosomal abnormality have since been reported,[3-6] and a distinct clinical entity has emerged. Although deletions of the long arm of chromosome 5 have been seen in a variety of clinical settings,[7,8] patients with the 5q− syndrome share similar morphologic, cytogenetic and clinical features. Precise diagnostic criteria for the 5q− syndrome have not been established. But patients typically present with refractory macrocytic anemia, an interstitial deletion involving the long arm of chromosome 5, and morphologic abnormalities of their megakaryocytes.

The first five patients reported with the 5q− syndrome ranged in age from 32 to 80 years old, and included four women and one man. Three had splenomegaly, and all presented with complaints related to their anemia.[1,2] Subsequent patients have had similar characteristics; ie, there is a marked female predominance, and the median age of the patients is in their mid to late 60s. Splenomegaly is seen in ~25%.[9]

Considerable variability in both bone marrow and peripheral blood findings have been noted in patients with the 5q− refractory anemia syndrome and, depending on the precise bone marrow findings, these patients can be assigned one of the French-American-British (FAB) subclassifications of myelodysplastic syndromes[10] as well. Bone marrow cellularity is usually increased or normal, and there are decreased numbers of erythroid precursors with moderate dyserythropoiesis. Although none of the initial five 5q− patients had ring sideroblasts noted in the marrow, patients with the 5q− syndrome may have increased numbers of ring sideroblasts, and some may be classified as having refractory idiopathic sideroblastic anemia (RISA). Occasional patients have a slight increase in the number of myeloblasts, but WBC maturation is usually normal. Rarely, patients have >5% myeloblasts in the bone marrow, and could be characterized as having a refractory anemia with excess blasts (RAEB), whereas patients without ring sideroblasts or excess myeloblasts would be classified as having refractory anemia (RA). The most consistent bone marrow finding in these patients is the presence of abnormal megakaryocytes containing small nonlobulated nuclei. Nearly all patients have abnormal megakaryocyte morphology, and most have an increased number of megakaryocytes as well.

Blood smears reflect the abnormalities seen in the bone marrow. Aniso- and poikilocytosis of the RBCs is found with many macro-ovalocytes. WBC morphology is generally normal, but marked platelet anisocytosis is present, with many giant platelets.

Electron microscopy was performed on bone marrow and blood from three of the original five patients.[2] RBCs were frequently adherent to one another, and marrow erythroblasts were seen in clusters, with intimate membrane contact between cells. Forty percent of neutrophils had an abnormally high number of primary granules, whereas specific granules were rare in both mature neutrophils and differentiated neutrophil precursors. Megakaryocytes were generally small, with nonlobulated round or oval nuclei, and liberation of platelets often appeared abnormal. Giant platelets were

frequently observed, and although specific granules were present, dense granules were frequently absent.

Few functional studies have been reported on mature blood cells from patients with the 5q− syndrome. Because of the consistent platelet and megakaryocyte abnormalities, platelet function was assessed in four of the five original patients. These patients had normal bleeding times in the presence of normal or elevated platelet counts, but platelets from three of the four patients demonstrated decreased adhesion to glass beads, and all demonstrated decreased platelet aggregation in response to collagen and epinephrine.[2]

In vitro culture of bone marrow from these patients has demonstrated normal numbers of CFU-GM,[3,11] but markedly reduced to absent BFU-E colonies.[11] This pattern seems to reflect the predominant peripheral blood abnormalities seen in the patients, namely that of refractory anemia.

Much interest developed in the 5q− syndrome because it represented a defined hematologic syndrome associated with a specific chromosomal abnormality. Cytogenetic investigations performed on the first five patients with the 5q− syndrome revealed the consistent deletion of approximately two-thirds of the long arm of chromosome 5, without apparent translocation of the deleted segment, in marrow cells cultured without PHA for 24 to 48 hours. The deletion was thought to be interstitial, possibly involving bands 5q12-5, 5q21-3. Additional data from other patients generally shows a proximal breakpoint in the region 5q13-q15, and a distal breakpoint in region 5q31-33,[12] although occasional patients with other breakpoints have been reported (a proximal breakpoint at q23, a distal breakpoint at q23), and at least sixteen patients have been described with a del(5)(q31q35).[13,14] No cytogenetic abnormalities have been reported in skin fibroblasts or PHA-stimulated peripheral blood mononuclear cells from patients with the 5q− syndrome, reflecting the acquired nature of the disorder and the fact that most circulating T lymphocytes are not part of the abnormal clone.

Although some variability occurs in the breakpoints of the 5q− chromosomes among different patients, several investigators have noted that the deleted long arm segments consistently occurred in the region of the band 5q22-q31, and postulated a localized genetic change that could contribute to the development or progression of either abnormal or frankly malignant cell growth.[4,15] Recently, various hematopoietic growth factor and growth factor receptor genes have been localized to the long arm of chromosome 5[16-20] in a region frequently deleted in patients with a 5q− abnormality. These findings have led to speculation regarding a pathogenetic role for these genes in the resulting clinical syndromes (vide infra).

None of the first five reported patients developed acute leukemia within the observation period of the study (up to 6 years),[2] but subsequent reports from Rowley and van den Berghe raised questions about the natural history of patients with this chromosomal abnormality.[21,22] Both reports described patients with 5q− chromosomal abnormalities and hematologic disorders that terminated in acute leukemia. Of the five patients with acute leukemia reported by van den Berghe,[21] three were elderly women, including one with a prior history of refractory anemia. The other two patients were a 59-year-old man with subacute myelogenous leukemia, and a thirteen-month-old boy with acute myelogenous leukemia (AML) and a short prodromal period. Rowley reported on five female patients with a 5q− abnormality who developed acute leukemia.[22] These patients all had different clinical histories, including one patient with agnogenic myeloid metaplasia, and one with multiple myeloma. Thus, these patients did not share a clinical syndrome, but rather a common chromosomal abnormality. In addition to deletion of the long arm of chromosome 5, all ten patients had additional chromosomal abnormalities that occurred at an unknown time in their clinical course. Patients with the classical 5q− syndrome have the 5q− chromosomal anomaly as an isolated abnormality[5,8,13]; thus the ten patients who developed leukemia were both clinically and karyotypically different than patients with the "5q− syndrome." Conclusions about the natural history of the 5q− syndrome cannot easily be made from patients with variant clinical and cytogenetic findings. The presence of a 5q− abnormality in a patient with acute leukemia does not establish the existence of an antecedent 5q− syndrome.

Patients with the characteristic 5q− syndrome have been reported to develop acute leukemia,[23,24] but the presence of the 5q− chromosomal deletion by itself, in a patient with a refractory anemia, does not appear to be associated with a high likelihood of subsequent acute leukemia (possibly 5% to 10%). In a 1983 review of 24 patients with an isolated 5q− chromosomal abnormality and refractory anemia, only three developed acute leukemia.[8] Patients with a 5q− deletion who either have additional chromosomal abnormalities at presentation, or who evolve chromosomal abnormalities in addition to an isolated 5q− deletion, appear to have a higher likelihood of evolution to acute leukemia than do patients with an isolated 5q− abnormality,[5,8] but a definitive statistical analysis proving this has not been done.

Management of patients with the 5q− syndrome is supportive. Since these patients do not generally manifest leukopenia, they are not unduly susceptible to infections. Their platelet counts are normal or elevated, and despite the reported abnormal in vitro platelet function tests, they do not experience abnormal bleeding nor unusual thrombotic episodes. Thus, the major manifestation of this syndrome relates to the refractory anemia and the need for RBC transfusions. The severity of the refractory anemia varies markedly from patient to patient. Some patients have not required transfusions during several years of follow-up, whereas others require frequent and regular transfusions to prevent the symptoms of anemia. Patients receiving repeated red cell transfusions are at risk for the infectious complications of blood transfusions, as well as iron overload. Subcutaneous administration of desferoxamine, an iron chelating agent, should be instituted in those patients requiring frequent transfusions.

Syngeneic bone marrow transplantation was performed for a 29-year-old man with a 5q− refractory anemia and iron overload, and was successful in eradicating the 5q− clone and allowing successful treatment of his iron overload.[25]

5Q– AND DE NOVO AML

Adult AML is associated with chromosomal abnormalities in 50% to ≥90% of the cases.[26] Approximately half of these patients have a mixture of normal and abnormal metaphases, whereas half have only abnormal metaphases. In one large survey, 85 of 496 patients with de novo AML had abnormalities of chromosome 5 and, in approximately half of these patients (47%), this abnormality was a 5q– chromosome.[15] Unlike the situation of 5q– refractory anemia where the 5q– is usually an isolated abnormality, most patients with de novo AML and a 5q– have additional chromosomal abnormalities, such as trisomy 8, 11, or 21, or monosomy 7 or 17.[9]

The Fourth International Workshop on Chromosomes and Acute Leukemia reported 660 patients with de novo AML and 50 patients (7.6%) had abnormalities of chromosome 5 (monosomy 5 or 5q–), with or without abnormalities of chromosome 7. The 29 patients with isolated abnormalities of chromosome 5 had a poor prognosis; only 28% achieved complete remission after aggressive induction chemotherapy. The median duration of remission was 4 months, and the overall median survival of these patients was 4 months, significantly worse than patients with other chromosomal abnormalities or those without chromosomal abnormalities.[27]

In several studies, patients with a history of occupational exposure to potential carcinogens have been shown to have a higher incidence of chromosomal abnormalities in their leukemic cells than those without such a history. An association between abnormalities of chromosomes 5 and 7 in patients with de novo ANLL and a significant history of occupational exposure was first noted by Mitelman et al,[28] and follow-up studies (Brandt et al in Lund, Sweden[29] and Golomb et al at the University of Chicago)[30] have confirmed this association. Combining their studies, 68 of 236 patients with de novo AML gave a history of significant exposure to chemicals, petroleum solvents, pesticides, or industrial metals. Abnormal karyotypes were noted in 75% of the exposed patients (51 of 68), compared with 36% in the nonexposed patients (60 of 168) ($P < .05$). Abnormalities of chromosomes 5 and 7 were seen in 37% of the exposed patients, compared with 12% in the nonexposed patients, again, a significant difference. In these studies, these specific chromosomal abnormalities were not prognostically different than other chromosomal abnormalities occurring in patients with de novo acute leukemia, which contrasts to the findings of the Fourth International Workshop on Chromosomes and Acute Leukemia.[27]

CHROMOSOME 5 ABNORMALITIES AND THERAPY-RELATED AML AND MYELODYSPLASTIC SYNDROMES

The occurrence of acute myeloid leukemia in patients who have been treated with chemotherapy and/or radiotherapy for other malignant diseases has been increasing, probably reflecting our improved success at prolonging survival with these therapies. Patients with Hodgkin's disease, non-Hodgkin's lymphoma, multiple myeloma, and ovarian carcinoma, as well as other malignancies, are at increased risk for the development of acute leukemia.[31-33] As reported by Rowley et al in 1981 and recently updated in 1986, patients with therapy-related acute leukemia or therapy-related myelodysplastic syndrome commonly have a clonal abnormality of chromosome 5 and/or 7 consisting of loss of all or part of the long arm of the chromosome.[34,35] Fifty-five of the 63 patients studied had such an abnormality (87%), and 31 of those 55 patients had either loss of chromosome 5, or the 5q–. In contrast, only ~16% of patients with de novo AML have loss of the long arm of chromosome 5 or 7. The difference between de novo acute leukemia and therapy-related acute leukemia was further supported by the observation that only one of 63 patients with therapy-related acute leukemia had a t(15;17) or t(8;21) translocation, two translocations commonly seen in patients with de novo acute leukemia.

In this study, 14 patients lost one copy of chromosome 5, whereas 17 patients had an interstitial deletion of the long arm of chromosome 5 (5q–). No association of this chromosomal abnormality or any other cytogenetic abnormality was seen with regard to the sex or age of the patients, in contrast to the predominantly elderly female population of patients with 5q– syndrome. No significant association was seen in this study between the type of primary therapy (ie, chemotherapy, radiotherapy, or combined modality therapy), and the occurrence of the 5q– abnormality. Survival of all patients was poor, with no correlation between median survival and the presence of any particular chromosomal abnormality.

Abnormalities of chromosome 5 were more frequent in patients with therapy-related myelodysplastic syndrome than in those with therapy-related AML and no preleukemic phase. The presence of a 5q– abnormality in a patient with therapy-related myelodysplastic syndrome, however, was not helpful in predicting whether the patient would evolve therapy-related AML.

Some have suggested that abnormalities of chromosomes 5 and/or 7 may be related to the form or intensity of therapy given for the primary disease.[36,37] For example, Arthur and Bloomfield found, by combining their study of 20 patients with 66 previously published cases, a significantly higher incidence of abnormalities of chromosomes 5 and/or 7 in patients who received combination chemotherapy (≥3 agents) or combined radiotherapy and chemotherapy, compared with patients who received radiotherapy alone, or single-agent chemotherapy alone.[37] Pederson-Bjeergard et al[38] suggested that characteristic karyotypic abnormalities could be identified in patients with therapy-related leukemia if one looked at those who had had a preleukemia phase, received chemotherapy, and became leukemic 30 to 60 months after the start of therapy. They suggested that karyotypic abnormalities occurring in other settings, such as after radiation therapy alone or after <24 months or >60 months after the start of primary therapy, occurred with no greater frequency than those occurring in patients with *de novo* acute leukemia. They, as well as others, have noted the more frequent occurrence of abnormalities of chromosomes 5 and/or 7 in patients receiving combination chemotherapy or combined modality treatment, but it appears as though these karyotypic abnormalities can be seen in therapy-related myelodysplastic syndromes or therapy-related acute leukemia, regardless of the type or intensity of primary therapy. As a rule, patients with therapy-related leukemia do quite poorly; therefore, the presence of a 5q− abnormality cannot be shown to be of prognostic significance in this setting.

THE 5q- ABNORMALITY IN OTHER DISORDERS

In addition to its occurrence in patients with the 5q- syndrome or AML, the 5q-deletion has also been reported in patients with a variety of myeloproliferative disorders. The 5q- abnormality has been found in patients with polycythemia vera,[8] and occasionally in patients with chronic myelogenous leukemia,[39] essential thrombocythemia,[7] and myeloid metaplasia.[40] It has also been reported in patients with pure red cell aplasia,[41] acute lymphocytic leukemia,[42] and rarely other lymphoproliferative disorders.

THE 5q- CHROMOSOME

Certain hematologic malignancies such as Burkitt's lymphoma and chronic myelogenous leukemia have been associated with specific chromosomal abnormalities: an 8;14 translocation in Burkitt's lymphoma, and the 9;22 translocation (Philadelphia chromosome) in CML.[43,44] Molecular biologic analyses have shown that these chromosomal abnormalities result in the translocation of known proto-oncogenes from one chromosome to another, which can result in either altered regulation of the proto-oncogene (as is the case for c-*myc* in Burkitt's lymphoma) or in the production of an altered gene product (as is the case for the p210-*bcr*-c-*abl* fusion product in CML).[45,46] It had long been postulated that abnormal chromosome patterns could be intimately associated with the malignant phenotype of the tumor cell, and now it is possible to link characteristic chromosomal abnormalities with specific alterations in the genes localized to the involved regions.

The association of an interstitial deletion of the long arm of chromosome 5 with a specific hematologic syndrome has prompted an investigation into what genes are located on the long arm of chromosome 5, and what role they may play in the resultant clinical syndrome.

As seen in Table 1, a variety of hematopoietic growth factor and growth factor receptor genes have been localized to the long arm of chromosome 5. Among these genes are the genes encoding three of the four myeloid colony-stimulating factors, as well as the genes encoding the PDGF receptor,[47] the β2 adrenergic receptor,[49] endothelial cell growth factor,[50] the glucocorticoid receptor,[51] dihydrofolate reductase,[52] and other genes as well (Table 1). Colony-stimulating factors were initially identified, based on their ability to promote the growth and maturation of murine myeloid progenitor cells in semisolid media culture. Four distinct murine CSFs were isolated and purified, and found to stimulate the proliferation of hematopoietic progenitor cells and enhance the functional capabilities of mature myeloid effector cells (reviewed in reference 53). These were named according to the predominant types of colonies that result when the factor is added to normal bone marrow progenitor cells: macrophage colony-stimulating factor (M-CSF), which acts on cells of the monocyte-macrophage lineage; granulocyte-macrophage colony-stimulating factor (GM-CSF), which acts on granulocytes (including eosinophils) and macrophages; granulocyte colony-stimulating factor (G-CSF), which acts on granulocytes; and multi CSF, or interleukin 3 (IL-3), which acts on erythroid, megakaryocyte, and a variety of myeloid progenitors. The four human counterparts of these myeloid CSFs have now been identified and cloned. The genes encoding three of these four hematopoietic growth factors have been localized to the 5q region, whereas G-CSF has recently been shown to be on 17q.[20]

Table 1. Genes Localized to the Long Arm of Chromosome 5

GM-CSF	5q21-32,[16] 5q23-31[17]
IL-3	5q23-31[19]
PDGF receptor	5q31-32[43]
β2-adrenergic receptor	5q31-32[44]
c-*fms*	5q33.2-33.3[17,20]
M-CSF	5q33.1[20]
ECGF	5q31.3-33.2[45]
Dihydrofolate reductase	5q11-22[47]
Glucocorticoid receptor	5q11-13[46]

The diphtheria toxin sensitivity, arylsulfatase B, chromate resistance and emetine resistance genes have also been localized to 5q.[48]

The first hematopoietic growth factor gene localized to the long arm of chromosome 5 was the gene encoding GM-CSF, which is ~2.5 kb in length, and contains four exons.[16] Human GM-CSF is expressed in activated but not resting T lymphocytes, and in HTLV-infected T lymphoblast cell lines.[54] Tumor necrosis factor or IL-1–stimulated fibroblasts and endothelial cells can also express GM-CSF,[55,56] as can stimulated peritoneal macrophages.[57]

Human GM-CSF is a 22,000 dalton (d) glycoprotein that stimulates the formation of pure neutrophil, pure eosinophil, pure monocyte, and mixed neutrophil/monocyte colonies from normal human bone marrow.[58] Activity on erythroid and megakaryocyte colony growth can also be documented under certain circumstances.[69-61] GM-CSF stimulates colony formation by the KG-1 and HL-60 leukemia cell lines,[58] and can enhance the function of mature neutrophils, eosinophils, and monocytes. In addition to these in vitro activities, in vivo activity of GM-CSF has now been demonstrated in both monkeys and man.[62,63] Using somatic cell hybrid analysis and in situ hybridization, the GM-CSF gene has been localized to the human chromosome region 5q21-q32.[16] A second group, also using in situ hybridization, localized the GM-CSF gene to 5q23-31, and reported three patients with 5q-interstitial deletions (two with refractory anemia, and one with acute myelogenous leukemia) who had deletion of one of their GM-CSF alleles.[17]

The gene encoding IL-3, or multi-CSF, contains five relatively small exons,[64] and the murine IL-3 gene has been located within ~230 kb of the murine GM-CSF gene on chromosome 11.[65] There is evidence that the human IL-3 gene, which has been localized to region 5q23-31, is located within 10 kb of the human GM-CSF gene.[66] IL-3 has effects on myeloid, erythroid, and megakaryocyte growth, presumably acting at an earlier stage in stem cell differentiation than does GM-CSF. The biological activities of human IL-3 are currently being examined, but enhancement of human eosinophil function by recombinant gibbon IL-3 has been demonstrated.[67] Thus far, production of IL-3 has been observed only by activated T lymphocytes, implying tight regulation of expression of the IL-3 gene.

M-CSF, or CSF-1, is quite different from the other three CSF molecules. It is a homodimer with a mol wt of ~45,000, whereas the other CSFs are ~20,000 d monomers. GM-CSF and G-CSF are not detectable in serum or urine, but M-CSF is readily detected.[68] M-CSF is encoded by a single gene consisting of many exons that are distributed over 18 to 22 kb. The M-CSF gene has been localized to 5q33.1.[20] Unlike IL-3 and GM-CSF, M-CSF is produced by many tissues and cells, including fibroblasts, endothelial cells, stimulated monocytes, and a variety of malignant cell lines, such as the Mia Paca pancreatic cancer cell line.[69] M-CSF stimulates bone marrow progenitors to become mononuclear phagocytes, and also promotes the proliferation of mature macrophages.[69,70]

It is interesting to note that the M-CSF gene and the c-fms proto-oncogene are both found on the long arm of chromosome 5, at 5q33-34 by in situ hybridization.[17,20] The c-fms gene product appears to be identical to the receptor for M-CSF.[71] Thus, both the hormone and its receptor are located closely together on chromosome 5. Expression of c-fms has been detected in human bone marrow cells and in peripheral blood mononuclear cells. c-fms expression is also seen in HL-60 cells differentiated towards macrophages (by TPA), but not in HL-60 cells differentiated towards neutrophils (by DMSO).[18] Time course studies using HL-60 cells suggest that expression of c-fms mRNA correlates temporally with the development of the differentiated monocyte-macrophage phenotype.[18]

The CSF-1 receptor has been found on monocytes and macrophages from many sources, including bone marrow, spleen, blood, peritoneal fluid, and the lung.[72] It mediates the effects of CSF-1 or M-CSF, a glycoprotein hormone that acts exclusively on cells of the monocyte-macrophage lineage. M-CSF affects the proliferation and maturation of monocyte-macrophage progenitors, and can stimulate the production of monokines, including IL-1.[70] These monokines can stimulate production of GM-CSF by fibroblast and endothelial cells, and can enhance the activities of a variety of growth factors.[56,73,74]

POSSIBLE LINK BETWEEN GROWTH FACTOR GENES AND CLINICAL SYNDROMES

The association of a specific interstitial deletion of the long arm of chromosome 5 with either malignant or disordered hematopoiesis raises the possibility that the deletion of the involved segment is critical to the process of transformation and clonal growth.[16,17] Several hypotheses have been offered to address the relationship between a specific interstitial deletion and abnormal gene expression.[17] One hypothesis suggests that as a result of this interstitial deletion, juxtaposition of two critical gene sequences occurs, leading to the process of abnormal hematopoiesis. This does not appear to be the case for the 5q-abnormality. There is marked variability in both the proximal and distal breakpoints in these interstitial deletions and, although there are several general classes of breakpoints, they could not result in the consistent juxtaposition of critical genetic elements. Thus, this mechanism is not likely to be involved in the process of transformation. Another hypothesis holds that an interstitial deletion within a chromosome affects genes critically involved in sustaining normal hematopoiesis. At the moment, the status of the GM-CSF, M-CSF, and c-fms genes has been explored in patients with 5q− abnormality, and in all instances, only a single allele has been found to be deleted.[17-20] Several potential mechanisms have been proposed to explain how deletion of one of two alleles of a hematopoietic growth factor gene could result in altered growth of hematopoietic cells.[17] One involves a dose effect, where cells with only a single copy of a gene make an inadequate amount of the gene product to allow for normal cell growth. In another scenario, loss of the wild-type gene results in the unmasking of a recessive mutant allele in a fashion similar to that observed for retinoblastoma and Wilms' tumor.

There are several obstacles in the way of firmly linking abnormalities of growth factor gene expression to the clinical syndromes associated with deletions of the long arm of chromosome 5. The first is that we are really not sure how these factors control the day-to-day production of blood cells, nor what signals regulate their synthesis. The second is that we do not know which cells are responsible for producing the growth factors needed to sustain the ongoing process of hematopoiesis. It is likely that multiple factors and a variety of cells are involved in the regulation of hematopoiesis, including macrophages, T lymphocytes, endothelial cells, and various stromal cells. Disruptions in these interactions could result in disordered hematopoiesis.

An additional difficulty in ascribing any particular gene abnormality to a resulting clinical syndrome is that, with the exception of c-fms, expression of these genes occurs in cells that do not have the 5q− chromosomal abnormality. Griffin et al reported that GM-CSF mRNA can be detected in as many as 50% of leukemia cells cultured in vitro from patients with AML,[75] but it is possible that some in vitro selection of GM-CSF–producing leukemia cells is occurring. If in vivo expression of GM-CSF by myeloblasts does occur, it would more likely be the result of disordered regulation of GM-CSF expression than the result of deletion of a single GM-CSF allele.

Of the genes localized to the long arm of chromosome 5, those encoding M-CSF and the M-CSF receptor (c-fms) could be implicated most plausibly in the variety of clinical findings seen in patients with 5q− abnormality. Simple deletion of a single GM-CSF allele or a single IL-3 allele would be unlikely to result in the abnormalities of myeloid or erythroid cell growth seen in either the 5q− syndrome or therapy-related AML. Expression of IL-3 has been demonstrated only in activated T lymphocytes, whereas the 5q− deletion has not been observed in T cells from patients with the 5q− syndrome. Similarly, GM-CSF expression has been observed only in activated T lymphocytes, and in stimulated fibroblasts, endothelial cells, and macrophages. Given that the 5q− anomaly is an acquired abnormality of myeloid cells, one would not expect fibroblasts (which do not contain a 5q− deletion) or endothelial cells to have abnormal GM-CSF expression, although macrophages with a 5q− deletion could have abnormal GM-CSF expression.

Deletion of c-fms in patients with a 5q− deletion has been shown by several groups.[17,18] All patients have had one copy of the c-fms gene present, although its functional capability is not known. If the 5q− deletion unmasked an abnormal c-fms allele or reduced the number of M-CSF receptors below some critical level, the ability of monocytes to respond appropriately to M-CSF may be impaired. This could result in either cell growth in the absence of growth factors (a step towards transformation), or an inability of the cells to respond appropriately to their growth factors. Differences in the precise molecular defect associated with the 5q− abnormality could determine which condition occurs. It is also possible that M-CSF production is abnormal in patients with the 5q− deletion, and the combined abnormalities result in the monocyte's inability to normally control hematopoiesis. Arguing against many of these speculations is the fact that granulopoiesis is generally normal in the 5q− syndrome, although it is obviously abnormal in AML.

The process of leukemogenesis is likely a multi-step one, and clearly requires more than autonomous growth factor production. Alterations must occur that transform the cell into an invasive cell unable to mature or regulate its growth. As studies looking at the status of these growth factor and growth factor receptor genes in specific clinical situations continue to be reported, it may become possible to implicate abnormalities of specific genes with specific clinical events.

ACKNOWLEDGMENT

We thank Wendy Aft for preparation of the manuscript and Judith Gasson for her helpful comments.

Molecular Analysis of Burkitt's Leukemia in Two Hemophilic Brothers With AIDS

By G. Rechavi, I. Ben-Bassat, M. Berkowicz, U. Martinowitz, F. Brok-Simoni,
Y. Neumann, A. Vansover, T. Gotlieb-Stematsky, and B. Ramot

In two hemophilic brothers infected by the human immunodeficiency virus (HIV), Burkitt's leukemia developed within 1 year. Both patients were treated by aggressive chemotherapy, and both are still in complete remission for 23 and 14 months, respectively. Sera from both brothers contained anti-HIV antibodies. However, DNA extracted from the tumor cells, when analyzed by Southern blot using a cloned HIV probe, did not reveal HIV-related sequences. Hybridization experiments with an Epstein-Barr virus (EBV) probe revealed the presence of EBV-specific sequences in the tumors' DNA. In both patients' tumors rearranged *c-myc* genes were found. The rearrangements occurred in both genes 3′ to the third exon of *c-myc*, thereby suggesting that a variant chromosomal translocation took place in both cases. Indeed, karyotype analysis of the malignant cells of one of the patients revealed the variant t(2:8) translocation. In contrast to the majority of Burkitt's tumors carrying this translocation, which are κ light-chain producers, cells of our patient expressed λ chains. Furthermore, in both cases the lymphoblasts carried IgG on the surface, again an unusual finding in Burkitt's tumors. Finally, because both patients had an identical HLA phenotype, the role of genetic factors in the development of such tumors should be considered.

© 1987 by Grune & Stratton, Inc.

MALIGNANCIES LIKE KAPOSI'S sarcoma or lymphoma are known manifestations of the acquired immunodeficiency syndrome (AIDS).[1-7] The B cell lymphomas in these patients are frequently high-grade B cell malignancies, involve extra nodal sites, and run an aggressive course. Most cases of B cell tumors have been reported in homosexuals and drug addicts, whereas only a few have been described among hemophilic patients with AIDS.[7-11]

Hereby, we report two hemophilic brothers with AIDS who developed Burkitt's leukemia within 1 year. The role of viral infections and genetic factors in the evolution of lymphomas in such patients will be discussed.

PATIENTS AND METHODS

Patients. Patient no. 1 is a 16-year-old boy with severe hemophilia A who had been treated for years with factor VIII concentrates. In March 1983 he presented with a rapidly disseminating cutaneous and visceral varicella-zoster virus (VZV) infection. He had a 1-year history of weight loss, cervical lymphadenopathy, splenomegaly, and oral candidiasis. In January 1985 the lymphadenopathy progressed and became generalized. Anti–human immunodeficiency virus (HIV) antibodies were first assayed at that time and found to be present. A cervical lymph node biopsy specimen taken on March 1985 was diagnosed as diffuse small noncleaved (Burkitt's) lymphoma. A bone marrow aspirate revealed infiltration by lymphoblasts with an L3 morphology that amounted to 30% of the cells. Treatment was begun according to a modified National Institute of Health protocol 7704. After 2 months of receiving chemotherapy, a complete remission was achieved, and treatment was stopped in December 1985. He has remained since then in good general condition except for recurrent infections.

Patient no. 2 is a 21-year-old hemophiliac and the elder brother of patient 1 who had also been treated for many years with factor VIII concentrates. In January 1984, he started to suffer from recurrent upper respiratory infections. In April 1985, anti-HIV antibodies were first found. Concomitantly, a persistent lymphopenia (0.5×10^9/L) and thrombocytopenia (35 to 85×10^9/L) were observed. In December 1985, he presented with severe skeletal pain, and bone marrow biopsy material and aspirates showed heavy infiltration by L3 lymphoblasts that amounted to 80% of the cells. Computed tomography of the abdomen did not reveal any masses. The patient was treated by a modified German Multicenter Trial (BFM) protocol for B cell leukemia, and 1 month later he was in complete remission. Treatment was stopped after 4 months, and since April 1986 he remains in complete remission. An informed consent for bone marrow aspiration and chemotherapy administration was obtained from both patients and their parents.

Methods. Antibodies to HIV were assayed by an enzyme-linked immunosorbent method and confirmed by Western blot with a commercial kit (Du-Pont, Wilmington, DE) according to the manufacturer's instructions.[12,13] Antibodies to Epstein-Barr virus (EBV) early antigen (EA) and viral capsid antigen (VCA) were detected by an indirect immunofluorescence test.[14] Immunophenotyping of the tumor cells, HLA typing, and karyotype analysis were performed as described.[15,16] DNA was extracted from the tumor cells,[17] digested with the appropriate restriction enzymes, separated according to size by electrophoresis in 0.7% agarose, and analyzed by Southern blot hybridization with the relevant radiolabeled probe.[18,19] The *c-myc* probe was the 1.4-kilobase (kb) *Cla*I-*Eco*RI insert of the plasmid pMC41-3RC containing exon 3 of *c-myc*.[20] The EBV probe contains the 4.8-kb *Bam*HI K fragment of EBV, which was cloned in pBR322 and encodes for the first EBV-associated nuclear antigen.[21] The cytomegalovirus (CMV) probe pCM5018 contains the *Eco*RI J fragment that encodes for the 1.9-kb major immediate early RNA.[22] The VZV probe contains the *Eco*RI A fragment.[23] The herpes simplex virus (HSV1) probe (pSG28) contains the *Eco*RI E to K fragments cloned in pBR325.[24] The probe for HIV was the pPol (Du-Pont), derived from the human T-lymphotropic virus III clone λBH10 and contains the 4.9-kb *Bgl*II-*Bgl*II fragment.[25]

RESULTS

Antibody assays. Serum samples from both brothers were positive for anti-HIV antibodies. Figure 1 depicts the Western blots confirming the serological tests. Both sera showed strong reaction with several HIV proteins, but differences in the pattern of reactivity could be demonstrated: the serum of patient no. 1 did not react against the gag-gene product p17 or against p51.[26,27] The results of determination of the titers of antibodies to EBV-EA and -VCA are summarized in Table 1. The antibody response is consistent with reactivation of EBV infection, as can be found in many AIDS patients.

Both patients had antibodies in high titers to CMV, VZV, and HSV.

Immunophenotype analysis. Bone marrow lymphoblasts from patient no. 1 were HLA-DR+, CALLA$-$, My906$-$, WT1$-$, OKT3$-$, OKT4$-$, OKT6$-$, OKT8$-$, OKT11$-$, Tac$-$, $\gamma+$, $\mu-$, $\delta-$, $\kappa+$ and $\lambda-$.

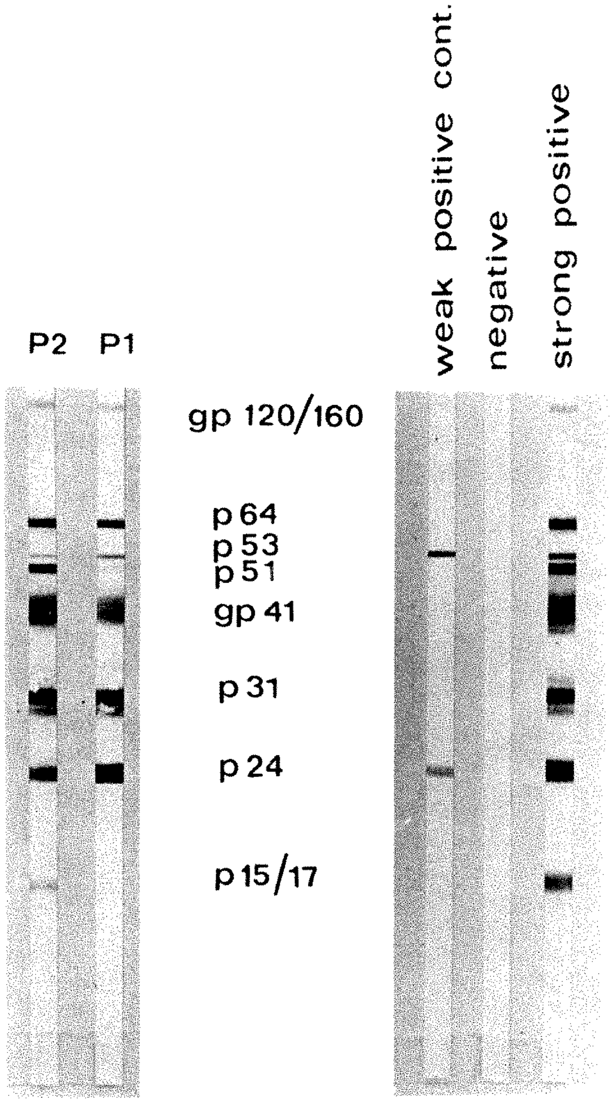

Fig 1. Western blot analysis of sera obtained from both patients. Control samples are shown on the right. On the left: P1, patient no. 1; P2, patient no. 2. Corresponding viral proteins (p) and glycoproteins (gp) are shown in the middle.

*At diagnosis of Burkitt's leukemia.

Bone marrow lymphoblasts from patient no. 2 were OKT11$-$, $\gamma+$, $\mu-$, $\delta-$, $\kappa-$ and $\lambda+$.

DNA hybridization studies. DNA extracted from the tumor cells was assayed by Southern blot analysis using as a probe a cloned HIV DNA fragment that contains the pol gene. No HIV-related sequences could be demonstrated (data not shown). Similarly, Southern blot hybridization to CMV, VZV, and HSV probes did not detect hybridizing sequences to any of them (data not shown). DNA hybridization with a ^{32}P-labeled EBV probe revealed the presence of EBV-specific sequences in DNA extracted from the tumors of both siblings (Fig 2).

Figure 3 depicts the Southern blot hybridization to a ^{32}P-labeled *c-myc* probe. In both DNA samples extracted from the tumor tissues, rearranged *c-myc* bands were found. In the tumor of both siblings, the rearranged *c-myc* bands were found in the *Hind*III digest but not in the *Eco*RI digest. The change in the length of the *Hind*III-*Hind*III *c-myc* fragment without alteration of the *Eco*RI-*Eco*RI *c-myc* fragment localizes the breakpoint to the *Eco*RI-*Hind*III fragment downstream to exon 3 of *c-myc* (Fig 3, insert).

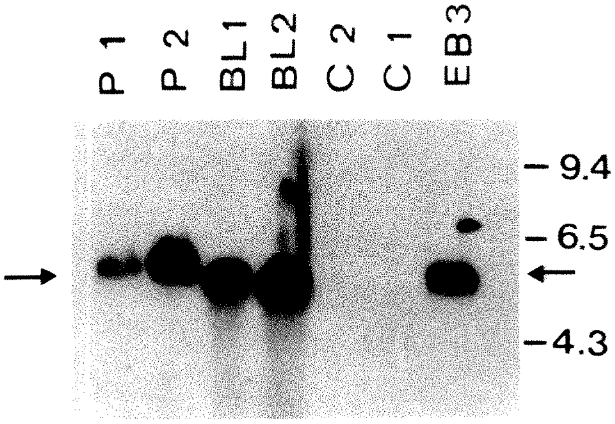

Fig 2. Detection of EBV sequences in DNA samples extracted from the patients' tumor cells. DNA samples were cleaved with *Bam*HI, subjected to electrophoresis through 0.7% agarose gel, and transferred to nitrocellulose paper. The paper was hybridized to a ^{32}P-labeled *Bam*K fragment of EBV. Hybridizing EBV sequences (arrows) were found in DNA samples from the patients' leukemic cells (P1 and P2) and in three EBV-positive Burkitt's lymphoma cell lines (BL1, BL2, and EB3). C1 and C2 are two negative controls. Numbers on the right are size markers in kilobases (bacteriophage λ, *Hind*III fragments).

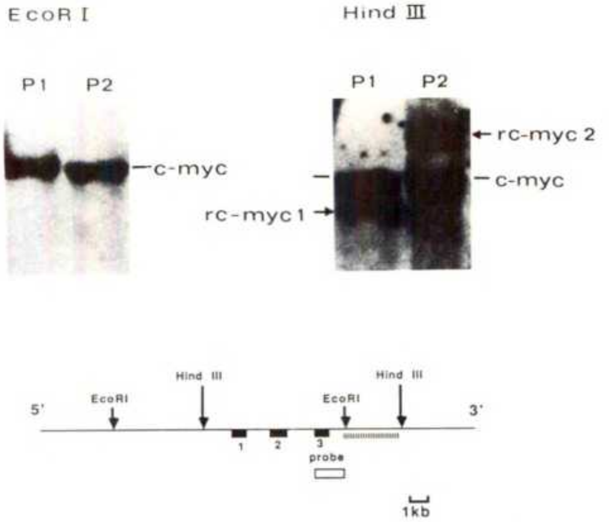

Fig 3. *C-myc* rearrangements in DNA samples from the patients' leukemic cells. DNA samples (15 μg) were digested by *Eco*RI (left) and *Hind*III (right). DNA fragments were separated by electrophoresis and transferred to nitrocellulose paper. The paper was hybridized to a ^{32}P-labeled *c-myc* probe. Hybridizing bands corresponding to *c-myc* germline genes are marked by dashes. Horizontal arrows indicate the rearranged *c-myc* genes detected in *Hind*III patient no. 1 (*rc-myc* 1) and patient no. 2 (*rc-myc* 2). The insert at the bottom depicts the restriction enzyme map of the human *c-myc* gene. The black rectangles 1, 2, and 3 correspond to exon 1, 2, and 3 of *c-myc*. Short vertical arrows point to the restriction sites of *Eco*RI and the long vertical arrows to the *Hind*III restriction sites. The interrupted line denotes the *Hind*III-*Eco*RI fragment that contains the breakpoints in both *rc-myc* genes. The open rectangle illustrates the *c-myc* probe (*ClaI-EcoRI* fragment containing exon 3).

Karyotype and HLA studies. Karyotype analysis was performed on the malignant cells of patient no. 2. A variant translocation t(2;8) was found (Fig 4), thereby suggesting the involvement of the chromosomal loci carrying the immunoglobulin κ light-chain genes and the cellular oncogene *c-myc*.[28,29]

The HLA phenotypes of the two affected brothers were identical: A11, A29, B53, B7, Cw2, Cw4, DR6, DR10.

DISCUSSION

The two hemophilic brothers developed AIDS-associated Burkitt's leukemia during the same year, and their tumor DNA contained EBV genomes and had rearranged *c-myc*. Both patients are still in complete remission 23 and 14 months, respectively. This favorable response in Burkitt's leukemia, especially in immunocompromised hosts, is surprising in view of the usually dismal course of the disease.[30]

In AIDS two factors may predispose the patients to B cell proliferation: HIV and EBV infections. It has been reported that HIV can cause direct B cell proliferation.[31] Furthermore, in some animal tumors, a direct role for the retroviral genome in the activation of cellular oncogenes has been demonstrated.[32,33] Therefore, we searched for HIV sequences in the patient's tumors and were able to confirm the absence of HIV genome in the tumors of both patients, as previously reported by Groopman et al and Pelicci et al.[34,35] It seems, therefore, that the HIV genome does not contribute directly to the malignant transformation.

On the other hand, the finding of the EBV sequences in the tumors suggests a role for this virus in the pathogenesis of AIDS-associated B cell lymphomas similar to other immunocompromised hosts.[36-40]

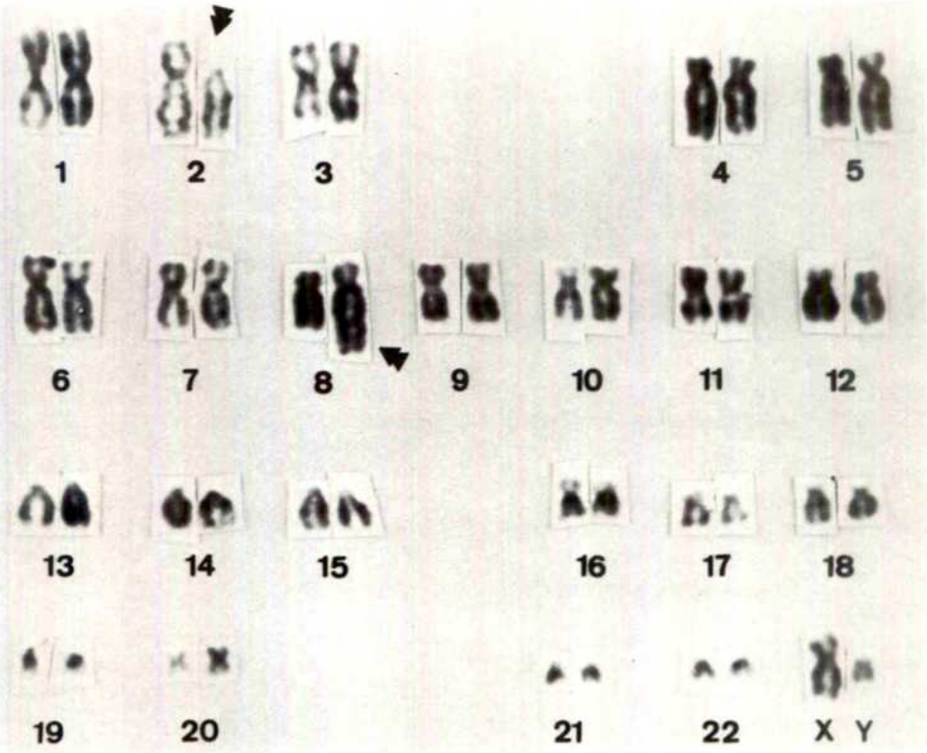

Fig 4. A representative karyotype of a bone marrow tumor cell from patient no. 2. The translocated chromosome 2 and 8 are indicated by arrows.

Most Burkitt's lymphomas analyzed thus far were found to carry a rearranged *c-myc* gene,[41,42] and the two tumors described here are no exception. In lymphomas carrying the classic t(8:14) translocation, the chromosomal breakpoints on chromosome 8 are 5′ to the two coding exons (2 and 3) of the *c-myc* oncogenes. In lymphomas carrying the variant translocations t(8:22) and t(2:8), the breakpoints are 3′ to exon 3 of *c-myc*. Our studies locate the breakpoints at 3′ of exon 3 of *c-myc*, thereby suggesting that in both our patients variant translocations are responsible for the *c-myc* activation. Karyotype analysis of the malignant cells of patient 2 indeed revealed the existence of t(2:8). Such variant translocations are found only in a minority of Burkitt's lymphomas, and their occurrence in the reported two brothers is interesting. Cytogenetic studies have been performed only in a small number of AIDS-associated lymphomas, and three cases of the variant t(8:22) translocation were reported in such tumors.[43-46] Analysis of more lymphomas from AIDS patients are necessary to conclude whether the occurrence of variant translocations is more prevalent in this group. The pattern of antibodies to EBV in our patients as well as other immunocompromised hosts is consistent with reactivation of a latent virus. In African Burkitt's patients, tumors develop at a young age where the expanded pool of activated B cells at risk for *c-myc* rearrangement is composed mainly of IgM-producing lymphocytes. Therefore, the majority of Burkitt's lymphomas express IgM.[47] In the patients with AIDS, as expected in secondary response, there is a large pool of IgG-transformed lymphocytes, and therefore it is not unexpected that some of the tumors will be IgG producers as in our cases.

It has been shown by Lenoir et al[48] that Burkitt's tumors and cell lines carrying the t(2:8) translocation usually express κ light chains whereas those with the t(8:22) translocation synthesize λ light chains. It was suggested, therefore, that the type of *c-myc* transposition is in correlation with the level of differentiation of the B cell.[48] Lymphoblasts of patient no. 2 are unusual in that they carry t(2:8) but express λ light chains. Similarly, Magrath et al reported that the lymphoma cells of a homosexual with AIDS and t(8:22) expressed κ light chains.[43] Taken together, the expression of IgG, the possibly higher incidence of variant translocations, and the lack of correlation between the type of light-chain expression and type of translocation suggest that the sequence of events resulting in B cell tumors in these patients may be different from that of African Burkitt's lymphomas. The two brothers reported on here had an identical HLA phenotype, and although this could have been a mere coincidence, it is tempting to speculate that genetic factors played an important role in the infection with HIV[49-51] and in the evolution of the lymphatic malignancy.[52-54]

ACKNOWLEDGMENT

DNA probes were kindly donated by Drs R.C. Gallo, G. Miller, B. Fleckenstein, S. Strauss, and M. Levine. We are indebted to Rivka Amit for expert manuscript preparation and to Nili Shaked and Michael Arieli for preparation of the graphic presentation. We are grateful to Dr Shlomit Orgad, Fanny Holtzman, Miriam Biniaminov, Esther Rosenthal, and Esther Rosner for their help.

Incidence of Aplastic Anemia: The Relevance of Diagnostic Criteria

By the International Agranulocytosis and Aplastic Anemia Study

The incidence of aplastic anemia was estimated in a 4-year study conducted in Israel and seven areas in Europe. Strict definition criteria were used, and all data and bone marrow specimens were reviewed by a panel of experienced hematologists. Complete ascertainment of cases was attempted by establishing a telephone network including all relevant hospitals in the study areas. The incidence of aplastic anemia was estimated to be less than three per million per year, a figure lower than previously reported. The most likely explanation for the differences among studies is variation in diagnostic criteria, which might lead to an overestimation of the incidence in some previous studies.

© 1987 by Grune & Stratton, Inc.

APLASTIC ANEMIA is a rare but serious blood dyscrasia that may be induced by environmental factors such as drugs or viral infections. There are only limited data on its incidence, which appears to vary according to the period of observation and geographic area.[1-6] It is possible that the variation is due to genetic differences and to varying prevalences of exposure to potentially myelotoxic agents. However, methodological problems such as the completeness of case ascertainment or stringency of diagnostic criteria may also be responsible for at least some of the differences observed. In this paper we report incidence data obtained in a multicenter study of agranulocytosis and aplastic anemia that was carried out from 1980 to 1984 in Israel and seven regions of Europe. The aim of the study was to quantify associations among drugs, especially antiinflammatory and analgesic agents, and two blood dyscrasias, agranulocytosis and aplastic anemia.

METHODS

The methods of the study have been described.[7] Here the description is limited to aspects of particular relevance to estimating the incidence of aplastic anemia. The study base included the entire population of eight defined geographic regions: Ulm, FRG; Berlin; Barcelona, Spain; Milan, Italy; Budapest; Sofia, Bulgaria; Stockholm/Uppsala; and Israel. The total population was 20.5 million, as determined from census data obtained from official national sources. Case ascertainment began in July 1980 and ended in June 1984 (not all regions participated for the full 4-year period).

Efforts were made to identify all cases of aplastic anemia occurring in the regions. A study center in each region obtained information on potential cases from hospitals within a defined area; these hospitals included all clinical institutions known to treat diseases of the severity of aplastic anemia. The study centers maintained regular liaison with the cooperating hospitals at intervals of no more than 2 weeks. In each hospital, an appropriate individual, usually a hematologist or technician, was contacted by telephone to ascertain all cases of aplastic anemia. Once notification of a potential case was received, a specially trained nurse or physician monitor was sent to collect more detailed clinical information and histopathologic specimens. A consulting hematologist reviewed the information in each of the eight regional centers. If the case clearly did not comply with the definition of aplastic anemia as required by the protocol, it was excluded locally. All remaining potential cases were reviewed subsequently by the Hematology Review Committee (HRC, see the Appendix) using clinical summaries, hematologic data, and microscopic examination of bone marrow and peripheral blood specimens. This panel had no information on previous exposures to drugs or chemicals.

For confirmation of diagnosis, the following conditions were obligatory: peripheral blood (at least two of the following three criteria): (*a*) hemoglobin, ≤ 100 g/L, or hematocrit, $\leq 30\%$; (*b*) platelets, $\leq 50 \times 10^9$/L; and (*c*) leukocytes $\leq 3.5 \times 10^9$/L, or granulocytes, $\leq 1.5 \times 10^9$/L. For bone marrow to confirm the diagnosis, there had to be an adequate bone marrow biopsy specimen or histology specimen obtained at autopsy showing the following: (*a*) a decrease in cellularity with the absence or depletion of all hematopoietic cells or normal cellularity due to focal erythroid hyperplasia with depletion of granulopoietic cells and megakaryocytes and (*b*) the absence of significant fibrosis or neoplastic infiltration. Cases with pancytopenia due to cytostatic drugs or irradiation were excluded.

If there were equivocal data that did not permit a definite diagnosis, the following additional information was sought from the local hematologist for second review: follow-up blood counts including reticulocyte counts, subsequent bone marrow specimens, and autopsy reports. If one of the two peripheral blood criteria to be fulfilled was hemoglobin, ≤ 100 g/L, or hematocrit, $\leq 30\%$, a reticulocyte count of less than 30×10^9/L was required.

All patients were observed until death, recovery, or bone marrow transplantation, or for a period of at least 2 years.

RESULTS

There were 315 cases initially identified as aplastic anemia and four cases originally identified as agranulocytosis but subsequently confirmed as aplastic anemia. Of the 319 potential cases, 34 were clearly misdiagnosed and were therefore ruled out by the consulting hematologists at the local centers (Fig 1). Among the 285 potential cases reviewed by the HRC, 168 were confirmed as definite aplastic anemia; nine cases were included even though a bone marrow biopsy specimen was not available because at least two bone marrow aspirations were typical and all clinical data over a prolonged period of observation were compatible with the diagnosis. Among the potential cases excluded by the HRC were 40 patients in whom a definite diagnosis could not be made due to insufficient documentation, in the majority due to the absence or inadequate technical quality of the biopsy specimen. Seven cases of moderate pancytope-

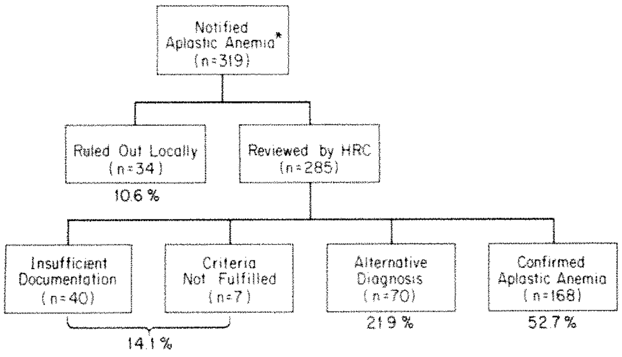

Fig 1. Initial diagnosis of aplastic anemia and results of expert review. *Includes four cases that were diagnosed as agranulocytosis but confirmed as aplastic anemia.

nia did not fulfill the minimum criteria; in these patients, the bone marrow showed only patchy or borderline hypocellularity.

There were 70 potential cases identified as having pancytopenia due to another disease. The largest group (17 cases) consisted of pancytopenia with normal or hypercellular bone marrow that could not be further classified from the data available to the HRC; ten of these were recognized as transient pancytopenia on further follow-up. In 13 patients, a definite diagnosis of leukemia could not be made, but increased cellularity of the bone marrow and morphological aberrations of myelopoietic precursors permitted their identification as myelodysplasias that were potentially preleukemic. Nine cases were identified as aleukemic myeloid or myelomonocytic leukemia, usually of an oligoblastic or smouldering type. There were seven cases with severe neutropenia and additional anemia or thrombocytopenia; review of the bone marrow biopsy specimens, details of clinical presentation, and subsequent patterns of blood counts revealed that the anemia or thrombocytopenia was due to secondary events such as bleeding or infection and that the correct diagnosis was agranulocytosis or chronic neutropenia. Non-Hodgkins malignant lymphoma involving the bone marrow (including two cases of aleukemic hairy cell leukemia) was identified in six cases. Five cases were determined to have hypersplenism or liver disease, and the remaining 13 cases included diagnoses such as megaloblastic anemia, chronic renal disease, and multiple myeloma, none of which accounted for more than three individuals.

The overall incidence of aplastic anemia, based on the total of 166 complete and confirmed cases, was estimated to be 2.2 cases per million per year (Table 1). (Data from Stockholm/Uppsala are not included in the overall incidence rates because clot sections from aspirated bone marrow spicules are often taken instead of a core biopsy, thereby resulting in a larger proportion of potential cases in that region being excluded due to insufficient documentation in terms of the study criteria.) The region-specific incidence estimates ranged from 0.6 per million in Budapest (based on only three cases) to 3.1 per million in Milan. A test for heterogeneity in the region-specific rates among the five centers contributing at least 18 cases was not statistically significant.

Table 1. Annual Incidence of Aplastic Anemia According to Region, July 1980 to June 1984

Region	Population (10^6)	Interval (mo)	n	Incidence (per 10^6/yr)*

†October 1980 to June 1984.

‡December 1981 to June 1984.

§August 1982 to June 1984.

‖January 1983 to June 1984.

¶The incidence was not calculated for Stockholm/Uppsala for methodological reasons (see the text).

#The total population does not include Sweden.

**Calculated as a population- and time-weighted average of the age- and sex-standardized region-specific rates.

††Including a large region surrounding the city.

The incidence according to age and sex is given in Table 2. The sex ratio for all regions combined was close to unity. Among females, the incidence of aplastic anemia increased steadily with age to a peak of 6.3 per million above the age of 60. Among males, the highest incidence was in the 15- to 24-year-old age group. However, nine of the 22 cases were from one military brigade in Barcelona; this result will be reported more fully elsewhere. If the latter age group is ignored, the incidence in males was highest (3.2 per million) over the age of 60 years. No attempt was made to compare age or sex-specific incidence rates between the study regions due to the limited number of cases. The fatality rate 2 years after diagnosis was 49%.

DISCUSSION

The overall incidence of aplastic anemia as estimated in this study is considerably lower than both incidence and mortality estimates obtained from other studies.[1-6,8-11] Aoki et al[1] and Hayakawa and Kurihara[3] used death certificate statistics to compare mortality rates in different regions.

Table 2. Annual Incidence of Aplastic Anemia According to Age and Sex

	Male		Female	
Age (yr)	n	Incidence (per 10^6/yr)*	n	Incidence (per 10^6/yr)*
<15	12	1.7	5	0.7
15-24	22†	3.5	4	0.9
25-44	12	1.1	18	1.8
45-59	11	1.8	15	2.0
≥60	16	3.2	51	6.3
Total	73	2.1	93	2.4

*Standardized to the regional distribution of the study population.

†Includes nine cases from Barcelona.

High rates for aplastic anemia were reported from Japan, compared with most European countries and the United States. It is unknown what proportion of deaths attributed to aplastic anemia in these reports were actually aplastic anemia. In the studies of Wallerstein et al[6] and Szklo et al,[5] outpatient and hospital charts, autopsy records, or laboratory material was used to confirm the diagnosis in cases selected by a review of death certificates. In no more than 60 of 290 and 60 of 111 cases, respectively, could aplastic anemia be confirmed, although it is possible that a proportion of those who failed to satisfy study criteria lacked sufficient documentation. Even larger discrepancies may exist in countries with less adequate diagnostic facilities than in the United States. Uncontrolled mortality statistics, therefore, give at best only a very rough estimate of the true incidence of the disease.

Even the highest regional incidence in the present study (3.1 per million in Milan) is lower than previous estimates, which range from 4 to 25 cases per million per year (Table 3). The latter figures are based on data derived from both mortality and morbidity statistics collected in different regions and at different times. Potential methodological problems and other possible explanations must be considered in interpreting the apparent differences.

The estimate of Wallerstein et al[6] was obtained in the course of quantifying the risk of aplastic anemia in relation to exposure to chloramphenicol; incidence estimates were derived from mortality data, assuming a 50% disease-specific death rate. The limitations of death certificate data have already been mentioned. In addition, it is not clear that the assumption of a 50% death rate is correct. We observed a similar death rate in our series after only 2 years of follow-up, and it is probable that the rate would have been higher with a longer follow-up. Thus, the total incidence could have been overestimated by Wallerstein et al.

It is important to consider whether the lower incidence of aplastic anemia observed in our study, and based on recent data, reflects a true decrease over the last 20 years (for example, because of decreased use of potentially harmful drugs such as chloramphenicol). This explanation seems unlikely because no clear trend has been observed in mortality statistics from different areas between 1950 and 1980[3] or between 1970 and 1979 in a study by Szklo et al using morbidity data.[5]

It also does not seem likely that differences in age between the study populations can completely account for the observed differences in incidence. Presumably, the age distributions in the study regions have not changed materially over time; if anything, the populations have aged, thus increasing rather than decreasing the incidence of a disease with the age dependency of aplastic anemia. Evidence against differences in age distributions was suggested by a comparison of the study population of Szklo et al[5] with our data: the age and sex characteristics of the population of metropolitan Baltimore were virtually identical to those in our study.

There is no evidence that the lower incidence in our study is due to lower ascertainment than in previous studies. Utmost care was taken to obtain regular information from all the cooperating hospitals in the telephone network. Although it is possible that some patients with aplastic anemia from the defined geographic areas had been referred to hospitals outside of these areas, this is also true for the other studies listed in Table 3. There were 47 cases excluded because of insufficient documentation or not fulfilling our study criteria; if the assumption is made that all of those excluded were actually cases of aplastic anemia, the incidence rate would only have increased from 2.2 to 2.8 per million per year.

We suggest that the major reason for the differences observed between the present study and those listed in Table 3 is differences in the stringency of diagnostic criteria among studies. Quantitative estimation of bone marrow cellularity is of paramount importance for the diagnosis of aplastic anemia, as against other blood dyscrasias resulting in pancytopenia. This is particularly relevant for the differential diagnosis between aplastic anemia and the various myelodysplastic syndromes. An adequate bone marrow biopsy specimen is therefore regarded as mandatory for a definitive diagnosis of aplastic anemia[8,9,12] and is a requirement for inclusion in therapeutic trials.[13,14] In this study, the results of the review by the HRC of the cases originally diagnosed as aplastic anemia, including an examination of blood films and bone marrow specimens, demonstrated that it is not sufficient to rely on the diagnosis as derived from hospital reports. The primary reason for the exclusion of potential cases was a bone marrow specimen of insufficient quantity or quality or an inadequate histopathologic evaluation. Only 5% of the cases were accepted without a bone marrow biopsy. Biopsy was not required in the studies of Wallerstein et al,[6] Böttiger and Westerholm,[10] or Szklo et al[5]; and in the study of Modan et al[4] there was no bone marrow examination at all. Thus, it appears that pancytopenias other than aplastic anemia may have been included as true aplastic anemia in previous studies and that the incidence estimates were erroneously high.

Table 3. Incidence Estimates of Aplastic Anemia From Various Studies

Author	Study Period	Area	Population $(\times 10^6)$	n	Incidence (per 10^6/yr)
Modan et al[4]	1961-1965	Israel	2.4	93	7.8
Wallerstein et al[6]	1963-1964	California	17.5	60	4.8
Böttiger et al[10]	1964-1968	Sweden	1.2	80	13
Szklo et al[5]	1970-1978	Baltimore	1.6*	62	4.1*
Böttiger et al[11]	1973-1977	Sweden	1.3	157	25
Present series	1980-1984	Europe/Israel (see Table 2)	20.5	166	2.2

*White population only.

Our criteria confined the definition of aplastic anemia to severe and moderate cases; borderline cases, of somewhat less concern due to good prognosis and low mortality, were not included. Such cases may have been included in other series, but this also cannot explain completely the differences shown in Table 3. Blood counts were described as "pancytopenia" or "severe panctyopenia" in the reports of Böttiger et al[10,11] and Wallerstein et al,[6] respectively. Upper thresholds for hematocrit and neutrophil values as indicated by Szklo et al[5] and Modan et al[4] were similar to ours.

The most striking difference exists between our data and the incidence estimates of Böttiger et al.[10,11] According to the detailed information in their more recent paper,[11] they have included cases of bone marrow failure other than aplastic anemia such as hematopoietic neoplasia, myelofibrosis, or pancytopenia due to cytostatics. Exclusion of these cases would reduce the incidence rate from 25 to 12.3 cases per million per year. Because only 10% of the cases of "true" aplastic anemia are attributed to drugs other than cytostatics,[11] differences in diagnostic criteria rather than different drug exposure rates may explain the discrepancy between Böttigers' data and those reported here and from the Baltimore area.[5]

The possibility of misclassification of a substantial fraction of cases may have important implications for the validity of data concerning the drug etiology of aplastic anemia (as well as the effects of other chemicals) that are derived from many previous reports. Most hematologists would agree that in practice, knowledge of exposure to potentially myelotoxic drugs can often influence the physician in making a diagnosis of aplastic anemia when a patient has pancytopenia. This could result in bias due to selective reporting of exposure-positive pancytopenia as drug-induced aplastic anemia irrespective of whether the diagnosis is correct.

In conclusion, we suggest that the lower incidence reported in our study is closer to the actual incidence than the estimates obtained from previous studies. Revisions of the commonly accepted assumptions of risk due to environmental factors may therefore be necessary.

ACKNOWLEDGMENT

This study would not have been possible without the cooperation of over 300 hospitals in the participating centers. Hermann Heimpel, Wolfgang Heit, Giorgio Lambertenghi-Deliliers, Aaron Polliack, and Judith Parsells Kelly prepared the manuscript.

Monoclonal Antibody–Specific Immobilization of Platelet Antigens (MAIPA): A New Tool for the Identification of Platelet-Reactive Antibodies

By V. Kiefel, S. Santoso, M. Weisheit, and C. Müeller-Eckhardt

The analysis of sera containing different platelet-reactive antibodies, eg, autoantibodies, platelet-specific alloantibodies like anti-Pl^{A1}, -Pl^{A2}, -Bak^{a}, and HLA antibodies, is still difficult. Recently, monoclonal antibodies against major platelet membrane constituents (glycoproteins IIb/IIIa and Ib and HLA class I molecule) have become available. In this report we describe a new assay that takes advantage of these highly specific reagents to investigate selectively platelet reactive antibodies against epitopes on different glycoproteins. The reliability and specificity of this assay is demonstrated with known platelet-reactive autoantibodies and alloantibodies (anti-Pl^{A1}, -Bak^{a}, -Pen). The discovery of a Pl^{A2} antibody in a serum of a polytransfused patient underscores the efficiency of this technique. Possible applications of this assay are discussed in detail.

© 1987 by Grune & Stratton, Inc.

IMMUNE-MEDIATED PLATELET DESTRUCTION in conditions such as neonatal alloimmune thrombocytopenia, posttransfusion purpura, platelet transfusion refractoriness, and autoimmune thrombocytopenia is caused by a variety of platelet-reactive antibodies. Their serological dissection is essential for proper diagnosis and treatment. Of particular importance is the discrimination between platelet-specific antibodies, ie, anti-Pl^{A1} (anti-Zw^{a}), anti-Bak,^{a} and HLA antibodies that are frequently encountered in the same serum specimens. Of similar interest is the assignment of antigenic determinants to certain platelet membrane constituents. Thus, known platelet-specific antigens reside on the glycoprotein complex IIb/IIIa (GP IIb/IIIa) ie, Pl^{A1},[1] PEN,[2,3] Yuk^{a} and Yuk^{b}[4,5] on GP IIIa and Bak^{a} (Lek^{a}) on GP IIb,[6,7] whereas in several cases of chronic immune thrombocytopenia autoantigens have been localized on the GP IIb/IIIa complex or on GP Ib.[8-12]

Presently available techniques for antibody differentiation and/or antigen recognition use stripping of HLA antigens from platelets by chloroquine pretreatment,[13,14] solid-phase radioimmune assay,[8,9] or Western blotting procedures.[15] All these assays have their limitations in that they either are indirect (chloroquine method), destroy HLA antigens (Western blotting), or are insensitive due to high background values (solid-phase radioimmune assay).

Therefore we have developed an enzyme immunoassay that overcomes most of these difficulties. It takes advantage of the selective specificity of platelet-specific monoclonal antibodies and achieves high sensitivity by avoiding direct contact between the serum to be investigated and the solid phase. In this report we give a detailed description of the method and demonstrate some of its applications.

MATERIALS AND METHODS

Human antibodies. Six human sera containing various platelet-reactive antibodies were selected for this study. Their origin and predetermined specificities are listed in Table 1. All sera had been prescreened against lymphocytes and platelets from a large panel of donors with known HLA, PL$^{A1/A2}$, and Bak^{a} antigens by the lymphocytotoxicity test (LCT),[16] the platelet complement fixation test (PCFT),[17] and the platelet adhesion immunofluorescence test (PAIFT).[18]

Monoclonal antibodies. The following murine monoclonal antibodies (MoAb) were used: MoAb Gi5, raised and characterized in our laboratory,[19] directed against the human platelet GP IIb/IIIa complex; MoAb FMC25, a gift from Dr Zola, Adelaide, Australia, specific for GP IX,[20] a glycoprotein tightly complexed to GP Ib; and MoAb w6.32 specific for a monomorphic epitope on the heavy chain of HLA class I molecules.[21]

MoAb-specific immobilization of platelet antigens (MAIPA). Platelets were isolated by differential centrifugation from EDTA-anticoagulated blood and washed three times. A volume of washed platelets, stored at 4°C for at least 12 hours in isotonic saline containing 0.1% sodium azide, was pelleted to give a total of 1×10^{8} platelets. The pellet was resuspended in 50 μL phosphate-buffered saline (PBS), pH 7.2, supplemented with 2% bovine serum albumin (BSA). Ten to 40 μL of a platelet glycoprotein–specific MoAb diluted at a concentration of 0.02 mg/mL in PBS-BSA, and 5 to 200 μL of the serum to be investigated was added. The mixture was incubated at 37°C for 30 minutes. The platelets were then washed three times in isotonic saline and solubilized in 100 μL of 0.01 mol/L Tris-buffered saline (TBS) containing 0.5% Nonidet P40 for 30 minutes at 4°C. Then all samples were centrifuged at 15,000 g for 30 minutes at 4°C. Fifty microliters of the supernatants was diluted 1:5 in TBS wash buffer (TBS with 0.5% Nonidet P40, 0.05% Tween 20, and 0.5 mmol/L $CaCl_2$). One hundred microliters of the respective diluted supernatants was added to each well of a microtiter tray (Greiner, Nürtingen, FRG) that had been coated with 100 μL goat antimouse IgG (Dianova, Hamburg, FRG; final antibody concentration, 3 μg/mL in 0.05 mol/L carbonate buffer) by overnight incubation at 4°C, washed, and blocked for 15 minutes at 4°C with 200 μL TBS wash buffer per well. The trays were incubated for 90 minutes at 4°C and washed four times, and 100 μL alkaline phosphatase–labeled goat antihuman IgG (Fc) (Dianova) diluted 1:5,000 in TBS wash buffer was added. After incubation for 120 minutes at 4°C the tray was washed six times, and 100 μL substrate solution (paranitrophenylphosphate in diethanolamine buffer, pH 9.8) was added. The color reaction was stopped after 30 minutes with 3 N NaOH and read at 405 nm in a Titertek photometer. All tests were run in duplicate. Results were expressed as ΔE values, ie, the difference of extinction (optical density) values between the mean of test samples and blanks (wells devoid of platelet lysate). A positive color reaction indicates a reaction of a human antibody with an epitope on the same molecule recognized by the MoAb. Reactions with other membrane constituents give no visible signal.

†Titer.

‡Titer when tested with Bak^a-negative cells.

§Titer when tested with Bak^a-positive cells.

Inhibition of calcium-dependent proteases in platelet lysates has no effect on antibody assessment. In experiments using leupeptin and sera no. 1 and 3, the results with platelets from four donors were identical whether platelets were lysed in the presence (1 mg/mL) or absence of leupeptin.

The intraassay and interassay reproducibility of results is very satisfactory. Representative figures ($\bar{x}$ ± 1 SD) for an antibody-containing serum compared with a negative control serum with platelets from the same donor were as follows: intraassay variability, 0.913 ± 0.041 *v* 0.05 ± 0.017 (n = 8); and interassay variability, 1.426 ± 0.240 *v* 0.06 ± 0.015 (n = 8).

RESULTS

Glycoprotein assignment of platelet antibodies. In a first series of investigations, the antigenic determinants on different platelet membrane molecules of operationally "monospecific" platelet antibodies were evaluated. The results of representative experiments are illustrated in Figs 1 and 2. When serum 1 containing pure Pl^{A1} antibodies was assessed against a panel of platelets with different Pl$^{A1/A2}$ types, it reacted only with determinants on GP IIb/IIIa complexes of Pl^{A1}-positive but not PL^{A1}-negative platelets if MoAb Gi5 was used for immobilization. No reactivity was noted with molecules carrying HLA determinants immobilized with MoAb w6.32 (Fig 1). In contrast, serum 2, which solely held multispecific HLA antibodies, was strongly positive with HLA determinants immobilized by MoAb w6.32, irrespective of the PL^{A} type of panel platelets used. There was no reactivity with GP IIb/IIIa determinants.

In Fig 2, the discriminatory capacity of the MAIPA with regard to epitopes on different platelet glycoproteins is demonstrated. Three platelet-specific antibodies (sera 1, 3, and 4) were assayed against antigens either on the GP IIb/IIIa complex or on the GP Ib complex, which were immobilized by MoAbs Gi5 or FMC25, respectively. Although serum 1 (known Pl^{A1} antibodies) reacted only with determinants of Pl^{A1}-positive donors on the GP IIb/IIIa complex but not on the GP Ib complex, the reverse pattern was seen with serum 3. Immunoblotting studies had shown

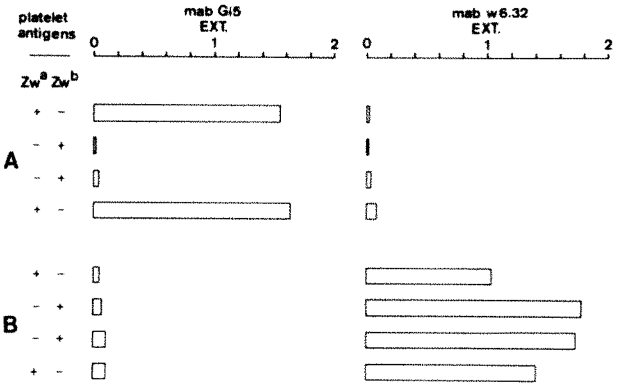

Fig 1. Reaction of a platelet-specific alloantibody, anti-Pl^{A1} (Zw^a), with an antigen present on Pl^{A1}-positive cells immobilized by MoAb Gi5 (A) and of a polyspecific HLA antibody with an antigen on the platelet surface immobilized by MoAb w6.32 (B). Ext, extinction: optical density at 405 nm.

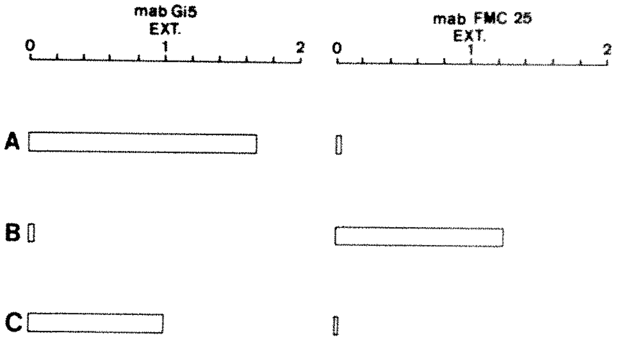

Fig 2. Specific reactions of platelet alloantibodies with the GP IIb/IIIa complex: anti-Pl^{A1} (A), anti-Pen (C) and of a platelet autoantibody (B) reacting with the GP Ib complex immobilized by MoAb FMC25.

that this serum contained only platelet autoantibodies reacting with GP Ibα specificity.[12] This was confirmed by MAIPA. Serum 4 (kindly provided by Dr R.H. Aster, Milwaukee) had Pen antibodies that reacted in PAIFT with a high-frequency platelet antigen. It detected antigenic determinants present on the GP IIb/IIIa complex (immobilized by MoAb Gi5) but not on the GP Ib complex (immobilized by FMC25), which confirmed the results of Furihata et al.[3]

Dissection of mixtures of platelet-reactive antibodies. Two typical examples are depicted in Fig 3. Serum 5, a gift from Professor A. Waters (London), was known to contain high-titered multispecific HLA antibodies (positive with 29/29 panel cells in LCT) and, in addition, Bak^a antibodies. In PAIFT, no definite distinction of these two types of antibodies was possible at lower dilutions. When using the MAIPA, both antibody specificities were clearly discernible: the Bak^a antibodies reacted in an antigen-specific fashion with their epitope on GP IIb/IIIa immobilized by MoAb Gi5, whereas the HLA antibodies were positive with MoAb w6.32–immobilized HLA antigens.

Serum 6 was unusual in that it so far had been considered to contain only strong multispecific HLA antibodies. On MAIPA analysis, an additional Pl^{A2} antibody was detected that reacted with MoAb Gi5–immobilized GP IIb/IIIa determinants in a Pl^{A2}-specific pattern. The Pl^{A2} specificity was further confirmed in dosage determinations by using platelets of Pl^{A2} homozygous and $Pl^{A1/A2}$ heterozygous donors (data not shown).

DISCUSSION

The identification of platelet-reactive antibodies is still a notoriously difficult task. This is particularly due to the fact that most sera contain mixtures of antibodies. Because the majority of patients with immune platelet disorders are women and have been pregnant and/or received blood or platelet transfusions, they are often immunized against HLA-A, -B antigens. For instance, eight of 14 patients with posttransfusion purpura we thus far have diagnosed had strong lymphocytotoxic antibodies in conjunction with Pl^{A1} antibodies, and in the serum of one patient, HLA antibodies were identified exclusively.[22] Recent reports on patients with posttransfusion purpura due to rare antibody specificities, ie, anti-Bak^a,[23] anti-Lek^a,[24] and anti-Pl^{A2},[25] have indicated that these sera were also heavily contaminated with HLA antibodies. In patients receiving multiple platelet transfusions it is estimated that the refractory state of approximately 25% to 30% of patients is caused by platelet-specific antibodies, although their specificity has not been identified.[26]

Some progress in differentiating HLA from other platelet-reactive antibodies has recently been made by the method of chloroquine stripping of HLA antigens from platelets.[13] By this technique, Nordhagen and Flaathen[14] successfully discriminated HLA from Pl^{A1} and Bak^a antibodies by using the platelet suspension immunofluorescence test. Unfortunately, chloroquine treatment can be applied only to fresh platelets and is fraught with the disadvantage of unspecific uptake of the fluorescent dye after cell damage. In our hands, weak platelet-specific antibodies often escape identification by this technique.

Another approach to antibody identification is the use of immunoblotting techniques.[15,27] Although some platelet-specific alloantigens and autoantigens can readily be demonstrated,[6,7,10-12,28] HLA-A, -B antigens and possibly other as yet unidentified antigens are often destroyed by sodium dodecyl sulfate treatment of the platelet lysate. This is corroborated by the observation that some monoclonal platelet antibodies fail to bind to immunoblots. Moreover, the use of panels of several solubilized platelet suspensions in immunoblotting is laborious and time-consuming, and its results are difficult to interpret.

The microtiter assay described by Woods et al[8,9] used MoAbs fixed to a solid phase. It allowed us to demonstrate platelet autoantigens on GP IIb/IIIa or GP Ib, respectively. However, in our experience this assay is rather insensitive, most likely as a consequence of low binding ratios. Even strong Pl^{A1} antibodies yielded rather low binding ratios that were apparently caused by high background activity due to unspecific adsorption to the solid phase of components to be investigated.

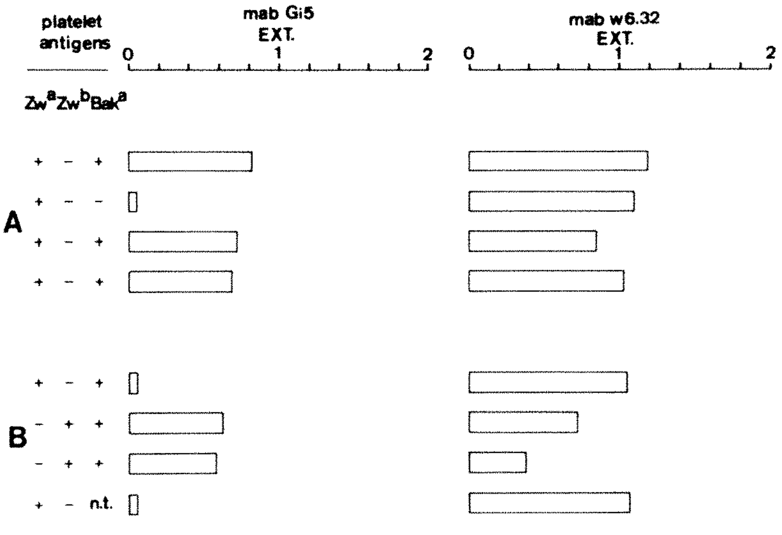

Fig 3. **Analysis of sera containing mixtures of platelet-specific alloantibodies and HLA alloantibodies with a panel of known donor platelets. When using MoAb Gi5 for immobilization, platelet alloantibodies anti-Bak^a (A) and anti-Pl^{A2} (anti-Zw^b) (B) were detected through their typical pattern of reactivity, whereas the antigens immobilized by MoAb w6.32 carried HLA alloantibodies present in the same samples.**

Antibody detection by MAIPA as described here circumvents most of these difficulties. It is based on the detection of trimolecular complexes formed by a MoAb, the human platelet-reactive antibody, and a platelet membrane molecule carrying the respective epitopes of either antibodies. Because antibody binding of both the monoclonal and the human antibody occurs on the surface of the intact platelet before solubilization, all antigens are preserved. Washing platelets after the sensitization phase removes excess MoAb as well as unbound serum. This ensures specific immobilization of the MoAb-platelet antigen complexes to the solid phase as well as specific binding of the labeled antibody to the human immunoglobulins associated with them. Hence, the background is usually low, and therefore, the specific binding values (difference between test and blank sample) are high. By using a set of MoAbs for different membrane constituents and a platelet panel with known alloantigens, platelet-reactive antibodies can be characterized in a single experiment with regard to both localization of the epitopes (eg, HLA class I molecule, GP IIb/IIIa complex, GP Ib complex, ie, GP Ib and GP IX) and the serological specificities. A possible false-negative result might be expected if monoclonal and human antibody have the same or a closely adjacent epitope for which they compete and therefore mutually hinder their binding. In these cases a MoAb directed against a different epitope on the same molecule is recommended. However, we have not observed such an interference between MoAb Gi5 and the platelet alloantigens tested thus far (Pl^{A1}, Pl^{A2}, Bak^{a} (Lek^{a}), Pen, Yuk^{a}, Yuk^{b}). Other advantages of this assay relate to its simplicity: unfixed platelets may be stored for weeks at 4°C without a loss of reactivity. Performance of the assay only requires six to seven hours. No sophisticated equipment is necessary.

The method we have described is a practical and sensitive tool for detailed analysis of sera with ambiguous serological findings. It allows reliable typing of donors for platelet alloantigens (eg, Pl^{A1} (Zw^{a}), Pl^{A2} (Zw^{b}), Bak^{a} (Lek^{a}), Pen) even with those sera that do not discriminate between negative and positive cells in the platelet immunofluorescence test due to HLA antibodies. Moreover, MAIPA will be a suitable method for platelet compatibility testing before platelet transfusion because it gives information about both HLA-specific (including noncytotoxic) and platelet-specific alloantibodies.

This assay takes advantage of the unique properties of MoAbs for diagnostic purposes. We are convinced that it will allow us to elucidate many of the unclear findings so often encountered in platelet serology.

Serial Measurement of Lymphocytotoxic Antibody and Response to Nonmatched Platelet Transfusions in Alloimmunized Patients

By Edward J. Lee and Charles A. Schiffer

Serial evaluations of lymphocytotoxic antibody (LCTAb) and responsiveness to random donor platelet transfusion were reviewed in 234 patients who had developed LCTAb at some time during their treatment course. Seventy (30%) of these patients had significant falls in antibody levels. In 44 patients these declines occurred after further antigenic exposure was reduced either because no transfusions were administered or only histocompatible platelets were transfused. Forty patients with declines in LCTAb levels who were previously refractory to platelet transfusion were rechallenged with random donor platelets. Thirty-four of 35 clinically evaluable patients had good responses to these unmatched transfusions for 2 weeks to 36 months, and in 21 patients antibody did not return despite repeated transfusions. Thus, serial LCTAb measurements are helpful in the management of alloimmunized patients. Many patients will have decreases or a loss of LCTAb, either permanently or transiently, and can be successfully supported with more easily available unmatched random donor platelet transfusions.

© *1987 by Grune & Stratton, Inc.*

ALLOIMMUNIZATION represents one of the most challenging problems in the supportive care of patients with acute leukemia. Approximately 30% to 40% of patients with acute leukemia undergoing intensive chemotherapy will become alloimmunized to random donor platelet transfusions and require transfusion support from HLA-matched donors.[1,2] Few data exist on the long-term course of alloimmunized patients with respect to transfusion support or serological studies. Lymphocytotoxic antibody (LCTAb) is a serological marker that correlates with clinical alloimmunization.[3] In an earlier report, we described 114 patients in whom serial measurements of LCTAb were made.[1] Sixty-one of these patients never developed LCTAb and remained clinically responsive to random donor platelet transfusions. Forty-eight of these 114 patients (42%) developed LCTAb after their initial induction therapy. Of these 48 patients, eight patients had a significant fall in LCTAb activity at some time during their subsequent course. In this report, we expand this observation and demonstrate that a decline in LCTAb activity is more common than previously suspected. We also report that patients in whom LCTAb disappears can regain their responsiveness to random donor platelet transfusions and thus may be supportable for a period of time with more easily available standard platelet products. This in turn allows conservation of important resources such as HLA-matched donors[4] or autologous frozen platelet concentrates (AFPC)[5] and more safely allows delivery of intensive post-remission or reinduction chemotherapy.

MATERIALS AND METHODS

Patients. The records of patients who received serial platelet transfusions during treatment at the University of Maryland Cancer Center between the years of 1975 and 1986 who survived greater than 4 weeks were reviewed. Only patients who survived >4 weeks were considered to permit an adequate duration of time for patients to mount an antibody response. Of a total of 579 evaluable patients, 397 had acute nonlymphocytic leukemia (ANLL), 68 had acute lymphocytic leukemia (ALL), 43 had chronic myelogenous leukemia (CML), and 71 had other malignant diseases (Table 1). LCTAb levels were measured on admission for all patients with leukemia and serially thereafter. Nonleukemic patients had LCTAb activity measured at times at which they developed clinical problems suggesting that they might be alloimmunized. Thus, this nonleukemic population is skewed and overrepresents patients who had poor responses to platelet transfusions.

Patients were considered part of the study population if they had two consecutive specimens >20% positive (see the next section) followed by two consecutive measurements of LCTAb that were <20% positive at some time during their course. All such patients were then evaluated for the presence of clinical refractoriness.

LCTAb. LCTAb studies were performed by Dr Paul Terasaki, Los Angeles, through 1982 and thereafter by the Rh Typing Laboratory, Baltimore. A positive LCTAb is defined as cytotoxicity against >20% of the wells in a standard lymphocytotoxicity assay as described previously.[3,6]

Criteria for alloimmunization. The corrected count increment (CCI) was calculated according to the following formula: CCI = (posttransfusion platelet count − pretransfusion platelet count) × body surface area (m^2)/no. of platelets transfused ($\times 10^{11}$). Alloimmunization was defined clinically as a CCI of <7,500 one hour after platelet transfusion in the absence of any alternative explanations for a poor response such as splenomegaly, coagulopathy, fever, infection, or active bleeding[7] followed by a good response (one hour posttransfusion CCI >10,000) to an HLA-matched platelet transfusion.

RESULTS

Of the 397 patients with ANLL, 174 (44%) developed LCTAb at some time during their course. Twelve of 68 patients with ALL (18%), 17 of 43 patients with CML (40%), and 31 of 71 patients (44%) with other malignancies who had poor responses to platelet transfusions developed LCTAb. It should be emphasized that the overall rate of alloimmunization in nonleukemic patients was considerably <44% in that these patients were tested for LCTAb only if poor responses to platelet transfusions were observed. The patients with ANLL were significantly more likely to

Table 1. Patient Characteristics

	n	Positive LCTAb
Total patients	579	234 (40%)
ANLL	397	174 (44%)*
ALL	68	12 (18%)*
CML, blast crisis	43	17 (40%)
Others	71	31 (44%)

*$P = .00002$, Fisher exact probability test.

develop LCTAb ($P = .00002$, Fisher exact probability test) than patients with ALL. Overall, 234 of 579 patients (40%) developed significant levels of LCTAb (Table 1).

Seventy of these 234 (30%) patients had decreases in the activity of LCTAb to <20%, whereas in 70% the LCTAb activity remained high. These reductions occurred in 44 patients after a period of time during which either no transfusions were administered or HLA-matched and/or AFPC were given and in 26 patients despite continued transfusion with random donor platelets.

Of these 70 patients, 12 had never been refractory to unmatched platelets and continued to respond to random donor platelet transfusions (Table 2). Notably, of these 12 patients, nine had only transient elevations of LCTAb levels during one period of supportive care. Eighteen of the remaining 58 patients did not receive unmatched platelet transfusions after a decline in LCTAb levels was noted either because no further transfusions were given (12 patients) or only HLA-matched or autologous platelet transfusions were given (six patients).

Five of the other 40 patients were rechallenged with random donor platelet transfusions, but at a time when complicating clinical factors such as splenomegaly, septicemia with hypotension, or disseminated intravascular coagulation were present. The poor responses of these five patients to random donor platelet transfusions were therefore uninterpretable.

One of the 35 evaluable refractory patients who was rechallenged had low increments after a transfusion of random donor platelets. This patient had a rapid, anamnestic rise in LCTAb levels. Thirty-four of the remaining 35 patients received between one and 83 (median, five) random donor platelet transfusions with good posttransfusion platelet increments. Six patients received more than 20 such transfusions. Thirteen of these 34 patients responded to nonmatched platelet transfusions for 2 weeks to 9 months, but 12 of the 13 thereafter again became refractory, which was associated with increases in LCTAb levels. In contrast, 21 patients never became refractory again despite repeated transfusions for up to 3 years, and only three developed subsequent increases in LCTAb activity. In ten of these patients, responsiveness could be evaluated for only 2 weeks because five of these patients died within 2 weeks and five did not require further platelet transfusion.

Table 2. Outcome in 70 Patients With Decreases in LCTAb Activity to <20%

70 patients with decreasing LCTAb activity
  12 never refractory
  58 refractory
    18 not rechallenged
    40 received further platelet transfusions
      34 good response to random-donor platelet transfusions
        21 never again refractory
          10 patients supported for up to 2 wk
          11 patients supported for 3 mos to 3 yr
        13 became refractory 2 wk to 9 mo later
      6 no response
        5 clinically unstable, no increase in LCTAb activity
        1 evaluable for response, rapid increase in LCTAb activity

DISCUSSION

LCTAb, which in most although not all patients was associated with refractoriness to random-donor platelet transfusion, developed at some time during the life of 40% of this large series of patients with acute leukemia. Of note is that the incidence of alloimmunization was significantly lower in patients with ALL than ANLL ($P = .00002$, Fisher exact test). This may reflect a difference in the disease process itself but more likely represents an effect of high-dose corticosteroids routinely used in ALL patients during initial therapy and antigenic exposure.

Serial evaluations revealed considerable fluctuation in antibody positivity. Importantly, random-donor platelet transfusions were effective in 34 of 35 previously refractory patients in whom decreases in LCTAb activity were detected. These responses to random-donor platelet transfusions suggest that serial measurements of LCTAb levels should be done in alloimmunized patients and that a decrease in LCTAb activity can be used to select patients who will respond well to random-donor platelet transfusion. It is striking that some patients could be supported for more than a year with random-donor platelet transfusions after having been alloimmunized and that some patients never again become refractory.

Other literature, particularly that describing patients with chronic renal insufficiency, has also described fluctuations in LCTAb.[2,8] Declines occurred predominantly in patients with only moderate levels of antibody activity. In contrast, in many of our patients high levels of LCTAb disappeared. Thus, 16 of the 34 patients who subsequently responded to random-donor platelet transfusions after a decline in LCTAb activity had been profoundly alloimmunized as documented by CCIs of ≤1,000.

The mechanism by which this decline in LCTAb activity occurs is unclear. In some patients, the decline followed a period in which no transfusions were given. With the lack of immunologic stimulus, it is not surprising that the levels of antibody would fall. In an analogous fashion, patients supported solely with either autologous or closely HLA matched platelet transfusions might be expected to have reductions in LCTAb levels. It is more striking, however, that 26 patients developed the reduction in LCTAb activity while they were actively receiving random-donor platelets. There were no common events that occurred in these patients such as the use of a particular chemotherapeutic approach or the presence or absence of a severe infectious process or complication. In these patients, neither the decrease of LCTAb activity nor the improved response to random-donor platelet transfusions was expected.

The provision of histocompatible platelet transfusions is a time-consuming and expensive undertaking. These data document the value of serial measurements of LCTAb levels in alloimmunized patients with leukemia who are undergoing chemotherapy so as to identify patients in whom random-donor platelet transfusions may be useful. Thus, it may be possible to conserve resources such as AFPC and HLA-matched, single-donor platelet transfusions for particular patients who are difficult to support with platelets. This may in turn extend the duration of time that a given patient may be effectively supported and more safely permit aggressive chemotherapy.

Tumor Necrosis Factor: Receptors on Hematopoietic Cells

By Reinhold Munker, John DiPersio, and H. Phillip Koeffler

Tumor necrosis factor (TNF) is a monokine that is cytotoxic/cytostatic for a variety of tumor cells and has multiple effects on normal cells. We demonstrate that normal and malignant human myeloid cells express a single class of high-affinity receptors (400 to 1,900 per cell, K_D 20 to 90 pmol/L) for TNF. Mitogen-stimulated lymphocytes have a similar number of TNF receptors, whereas resting lymphoid cells have fewer receptors. RBCs and platelets have no detectable TNF receptors. No correlation is observed between the receptor number, receptor affinity, and the cytoxic effect of TNF on myeloid cell lines. Significant cytotoxic effects of TNF on the most sensitive myeloid cell line (HL-60 promyelocytes) could be seen at concentrations tenfold lower than those concentrations at which one half of the TNF receptors were occupied. Our data show that significant biologic effects of TNF can occur at low levels of receptor occupancy and resistance to TNF is not related to the absence of TNF receptors on certain myeloid leukemic cell lines.

© 1987 by Grune & Stratton, Inc.

INTEREST IN THE BIOLOGIC EFFECTS of tumor necrosis factor (TNF) has increased since the gene was cloned and the recombinant protein has become available. Besides being cytotoxic or cytostatic for certain tumor cells, TNF exerts multiple effects on normal cells.[1-3] We and others recently studied the action of recombinant TNF on normal and malignant myeloid cells and found that TNF inhibited clonal growth of most myeloid leukemia cells, whereas normal myeloid progenitors (CFU-GM) were relatively less sensitive to the cytostatic effects of TNF.[4,5] In the present study we successfully iodinated TNF to high specific activity with full preservation of biologic activity. Iodinated TNF, after establishment of equilibrium binding conditions, was used to correlate TNF receptor number and affinity with its cytostatic effect on both sensitive and resistant myeloid leukemic cell lines.

MATERIALS AND METHODS

Recombinant, highly purified (≥99%) human TNF (generous gift of M. Shepard and B. Aggarwal, Genentech, Inc, San Francisco) had an activity of 3.8×10^7 U/mg when assayed on L-929 fibroblasts in the presence of 1 μg/mL of actinomycin. TNF was iodinated by the Iodogen method as described.[6] Briefly, 10 μg of purified recombinant protein was incubated for ten minutes at 4°C in an Iodogen (Pierce Chemical Co, Rockford, IL) coated glass tube with 1 mCi of ^{125}I-NA (Amersham Corp, Arlington Heights, IL). Free iodide was separated from TNF on a Sephadex G-25 column. An aliquot of the iodinated protein (~10^5 cpm) was run on 12% sodium dodecyl sulfate-polyacrylamide gel (SDS-PAGE) under reducing and nonreducing conditions, and autoradiography was performed according to standard procedures.[7] For the binding assays, 8×10^5 cells typically were incubated with dilutions of iodinated TNF (5×10^3 to 2×10^6 cpm) in a total volume of 220 μL for 90 minutes at 24°C. The binding medium was α culture medium (Flow Laboratories, McLean, VA) supplemented with 10% fetal calf serum (Irvine Scientific, Santa Ana, CA), 1% penicillin-streptomycin (Irvine Scientific) and 20 mmol/L HEPES (Sigma Chemical Co, St Louis). The incubation was performed in Flacon microtest multiwell plates (Becton Dickinson, Oxnard, CA). After the incubation the cells were washed three times in Eppendorf tubes with binding medium. To decrease binding to plastic, the tubes used for washing the cells were changed twice. Finally, the cell-associated radioactivity was determined with a Beckman Gamma 300 counter (Beckman Instruments Fullerton, CA). To determine nonspecific binding, the cells were also incubated in the presence of a 100-fold excess of unlabeled TNF. The specific activity of ^{125}I-TNF was determined by self-displacement analyses in which KG-1A cells were incubated with 0.4 to 10 ng unlabeled TNF in the presence of 4×10^4 to 5×10^5 cpm ^{125}I-TNF.[8] After establishing equilibrium binding conditions (24°C, two hours), TNF receptor number and affinity expressed on a variety of normal and leukemic cell types were determined by the method of Scatchard.[9]

Mononuclear cells from bone marrow and peripheral blood were isolated from normal and leukemic donors on Ficoll gradients. Informed consent was obtained from each donor. Leukemic cells isolated from peripheral blood or bone marrow contained ≥90% malignant cells as determined by morphological examination of Giesma-stained cytocentrifuged preparations. Bone marrow mononuclear cells were adhered to plastic for >3 hours to remove macrophages; the final cell mixture contained about 65% early myeloid cells (myelocytes and less mature granulocyte precursors) and 30% erythroid percursors. Normal granulocytes were obtained after dextran sedimentation for 90 minutes, Ficoll sedimentation, and hypotonic lysis of the remaining red cells. Thymocytes were isolated from thymus specimens from children undergoing cardiac surgery.

Myeloid cell lines were cultured as described.[10] For binding studies, the cells obtained during exponential growth phase were washed twice in tissue culture medium supplemented with 10% fetal calf serum and 1% penicillin-streptomycin.

RESULTS

Under reducing conditions, iodinated recombinant TNF migrated as a single band on SDS-PAGE with an approximate molecular weight (mol wt) of 17,000 (Fig 1). Under nonreducing conditions an additional faint band at approxi-

Blood, Vol 70, No 6 (December), 1987: pp 1730-1734

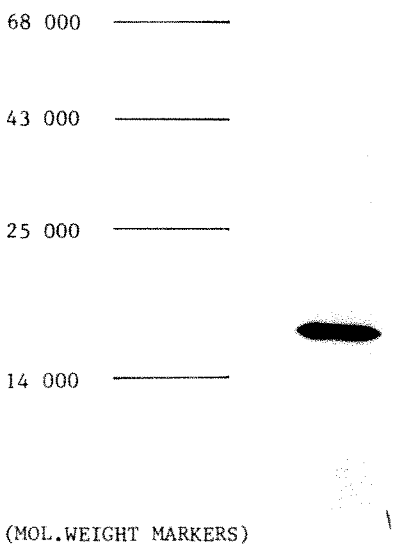

Fig 1. Autoradiogram of ^{125}I-TNF separated by 12% SDS-PAGE under reducing conditions. On the left, the position of mol wt markers is indicated.

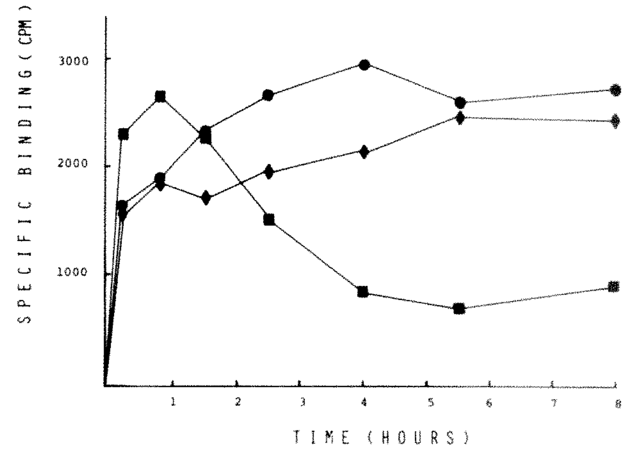

Fig 3. Time and temperature dependence of the specific binding of ^{125}I-TNF to the myeloid cell line HL-60. The binding experiments were performed at 0°C (♦), 23°C (●), and 37°C (■). All values are corrected for nonspecific binding obtained at a 100-fold excess of unlabeled TNF.

mately 34,000 was observed. Iodinated TNF retained its biologic activity (>85%) measured by the inhibition of colony formation of HL-60 cells (data not shown) and was stable for about 2 months. By using the myeloid leukemia cell line KG-1A, the specific activity of ^{125}I-TNF was determined by self-displacement (Fig 2) and was found to be approximately 4.2 × 10^5 cpm/ng (7.1 × 10^6 cpm/pmol/L, 3,227 Ci/mmol/L TNF). The binding of TNF to myeloid cell lines occurred rapidly (Fig 3). At 0°, 23°, and 37°C approximately 60% to 90% of the maximal binding occurred by 15 minutes of incubation. At 37°C maximum specific binding was reached at 45 minutes, with a decline over the next seven hours, presumably due to intracellular uptake and degradation. At 23°C and 4°C the peak of specific binding was reached more slowly, with a plateau around 1.5 to five hours. All subsequent experiments were performed at 23°C with a 90-minute incubation. Depending on the cell type, 70% to 95% of the binding was to a single class of high-affinity, specific receptors. Equilibrium binding data for the myeloid cell line KG-1 analyzed by the method of Scatchard[9] are shown in Fig 4.

The number and affinities of TNF receptors expressed on a variety of normal cell types, myeloid cell lines, and fresh leukemic blasts from patients with various leukemias are shown in Table 1. We found that all hematopoietic cells except RBCs and platelets expressed a single class of high-affinity receptors for TNF with a dissociation constant ([K_D] ~ 43 pmol/L). Granulocytes have about three times as many receptors (450 receptors/cell) than peripheral blood

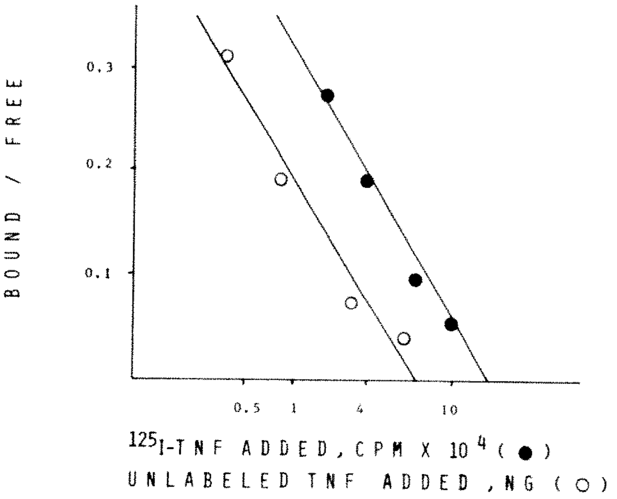

Fig 2. Determination of specific activity of ^{125}I-labeled TNF by self-displacement analysis. The bound/free ratios are plotted against the total radioactivity (0.5 × 10^4 to 10^5 cpm) added (●) and against the amount of unlabeled TNF added (0.5 to 10 ng) (○). A total of 8 × 10^5 KG-1A cells was used.

Equilibrium saturation binding curves were determined on the cells as described in both Material and Methods and Fig 4. Scatchard plots were made, and the K$_D$ (concentration that gave half-maximal binding) and the number of binding sites per cell was obtained from the x-intercept. The ED$_{50}$ is the concentration of TNF required to inhibit half the cells using the conditions of our standard clonogenic assay, and the ED$_{50}$ results are from Munker and Koeffler.[5] Results represent means and SD; n represents the number of experiments. Each experiment was carried out in triplicate.

lymphocytes (150 receptors/cell). Mitogen-stimulated peripheral blood lymphocytes expressed about three times more TNF receptors than unstimulated lymphocytes. All the myeloid leukemia cell lines had receptors for TNF (range, 520 to 1,870 receptors/cell). No correlation was noted between the number or affinity of TNF receptors expressed per cell and the in vitro cytostatic effect of TNF. For example, sensitive myeloid cell lines (HL-60, EM-3, U937) expressed fewer receptors than the relatively resistant cell line THP-1 (Table 1). The K$_D$ for the TNF receptors ranged between 19 to 95 pmol/L on those cells that expressed TNF receptors and was not significantly different on sensitive and resistant myeloid cell lines.

Of interest was that the concentrations of TNF required to inhibit 50% of the in vitro clonal growth of the HL-60, EM-3, and U-937 myeloid cell lines was three- to tenfold lower than the K$_D$s obtained by equilibrium binding.

We also examined leukemic cells from two patients with acute myelogenous leukemia (AML) and two patients with chronic lymphocytic leukemia (CLL) of the B lymphocyte cell type for their expression of TNF receptors. The leukemic cells from the AML patients had numbers of TNF receptors comparable to those found on myeloid leukemia cell lines. Cells from the two cases of CLL had heterogeneous binding of ^{125}I-TNF, with cells of one patient (J.A.) having 510 TNF receptors per cell and the other having 22 TNF receptors per cell. The leukemic cells from all four patients expressed a single class of high-affinity TNF receptors (K$_D$, 30 to 90 pmol/L).

DISCUSSION

Recently, the receptors for a variety of lymphokines and monokines including interferons (INF),[11,12] interleukin 1,[13] colony-stimulting factors,[14,15] and TNF[6,16-20] have been preliminarily characterized. These receptors are involved in the stimulation and downregulation of cellular growth processes.[21] Receptors for TNF were demonstrated on fibroblasts,[16,17] endothelial cells, adipocytes, myocytes, liver membranes,[18,19] granulocytes,[22,23] and several tumor cell lines.[6,20] These cell types expressed approximately 1,000 to 5,000 TNF receptors with K$_D$s between 3 and 600 pmol/L.[16,24]

We demonstrate that normal human hematopoietic cells, malignant myeloid and lymphoid cells, and myeloid leukemic cell lines have receptors for TNF. The binding of TNF to all the cells is extremely rapid, specific, and reversible. All cell types express a single class of high-affinity TNF binding sites. The affinity of binding of TNF did not vary greatly between the cell types. The decrease in specific binding after ≥1.5 hours that we observed at 37°C is consistent with the internalization and intracellular degradation of ^{125}I-TNF as previously shown by others.[16,17,24] We found that the numbers of receptors expressed on normal myeloid cells (300 to 500/cell) and on myeloid leukemia cells (500 to 1,800/cell) were higher than on peripheral blood lymphocytes and thymocytes (90 to 140 receptors/cell). Also, activated lymphocytes express about threefold more TNF receptors than resting lymphocytes or thymocytes (approximately 400 *v* 100 receptors, respectively). The mechanisms involved in the increased expression of TNF receptors on activated lymphoid cells are unclear but may include local membrane effects of the stimulating agents used (eg, PHA and 12-0-tetradecanoylphorbol-13-acetate) or through the production of INFs. INFs have been shown by others to both upregulate the number of TNF receptors and to enhance the biologic effects of TNF on responsive cell types in vitro.[21,22,25,26] Platelets and RBCs do not express detectable TNF receptors. The affinity constants determined for the TNF receptors expressed by the hematopoietic cells described here were comparable (20 to 90 pmol/L) to those reported for TNF receptors expressed by a variety of nonhematopoietic cells.[6,16]

The expression of TNF receptors on hematopoietic cells suggests that TNF may have an action on these cells. Studies have shown that aggregation, superoxide generation, phagocytosis, and polarization of neutrophils can be enhanced by TNF.[22,23] TNF at very low concentrations has a cytotoxic or cytostatic effect on normal activated lymphocytes[27] and myeloid leukemia cells.[4,5] In addition, TNF has been shown to enhance the killing of schistosoma by mature eosinophils.[28,29]

We found no correlation between the number of TNF receptors expressed on the myeloid leukemic cell lines and the biologic sensitivity of these cell lines to the growth-inhibitory effects of TNF. Several lines including HEL, K562, and THP-1 were resistant to TNF but expressed comparable numbers of receptors when compared with the numbers expressed by the sensitive lines presented here. Similar findings have been reported for several other tumor lines.[20] We have also found that several small cell lung cancer cell lines do not express detectable TNF receptors and are totally resistant to the cytotoxic/cytostatic effects of TNF.[30] Taken together, these results suggest that expression of TNF receptors is necessary but not sufficient for the biologic effect of TNF. In addition, we found no correlation between the ED_{50} of clonal inhibition mediated by TNF and the K_D determined for the TNF receptor on the sensitive myeloid leukemic cell lines HL-60, KG-1, KG-1a, EM-3, and U937. Furthermore, our studies suggest that in the three most sensitive myeloid leukemic cell lines (HL-60, EM-3, U937), the biologic and cytostatic effects of TNF occur at concentrations of TNF where only a few of the TNF receptors could be occupied. For example, the concentration of TNF needed to inhibit the clonal growth of HL-60 cells by 50% (4 pmol/L) was tenfold lower than that required to saturate 50% of the TNF receptors (42 pmol/L) on these same HL-60 cells. Silberstein et al[28,29] have recently shown that the concentration of TNF required to induce 50% maximal killing of schistosoma by normal human eosinophils was approximately 1×10^{-13} mol/L. This is approximately 1,000-fold lower than that concentrated required to saturate 50% of the TNF receptors on these eosinophils. These results would imply that significant biologic effects can occur at extremely low levels of receptor occupancy or that a separate higher-affinity TNF receptor exists on HL-60 cells that could not be detected by conventional equilibrium binding studies presented here. Peetre et al[24] has suggested the presence of such higher-affinity TNF receptors on several human myeloid leukemic cell lines. In addition, the extreme sensitivity of myeloid leukemic cell lines to TNF may also result from the production of synergistic factors such as γ- and β_2-INF or TNF itself. Both γ- and β_2-IFN have been shown to sensitize cells to the effects of TNF.[20,23,24,28,29,31] This enhancement could not be totally explained by a change of TNF receptor affinity or by the slight increase in the receptors expressed after γ-IFN treatment of myeloid cells.[31]

During the time we were completing our studies, several reports also showed that myeloid leukemic cells have TNF receptors.[24,31] Scheurich et al found that HL-60, U937, and K562 expressed TNF receptors, whereas a K562 variant (K562 C1) did not have detectable receptors.[31] Preliminary characterization of the TNF receptor by chemical cross-linking studies by these investigators demonstrated that myeloid cells expressed a single TNF receptor protein with an apparent mol wt of 76,000 daltons. Similar cross-linking studies using murine fibroblasts yielded two specific bands, which implied mol wts of 95 kd and 75 kd for the TNF receptor.[16] Our binding studies were done at 23°C. Cells from myeloid leukemia lines had about 550 to 1,900 TNF receptors per cell with K_D of 20 to 95 pmol/L. In contrast, Peetre et al[24] and Scheurich et al[31] found at 0°C that cells from myeloid leukemia lines had approximately 1,500 to 3,000 TNF receptors per cell with K_D of 150 to 300 pmol/L. Our finding of fewer TNF receptors with a higher affinity on the same myeloid cell lines might have occurred because of a difference in either reagents, the temperature at which the binding studies were performed, or possibly a difference in the cells. Nevertheless, each investigative group found that TNF was able to exert cytostatic effects on the TNF-sensitive myeloid cells at concentrations of TNF at which very low levels of receptor occupancy exists.

Myeloid cells can be induced to synthesize TNF[32,33]; at the same time these cells express receptors for TNF. Further studies are required to determine whether TNF can have a biologic effect on the myeloid cells that synthesize TNF under normal and abnormal circumstances, which would suggest a type of autocrine regulation. Recently, Cannistra et al[34] have shown that U937 cells incubated with GM-CSF rapidly die in culture, probably due to the induction of TNF synthesis by these cells. In addition, a better understanding of postreceptor events involved in transmembrane signal tranduction may help explain the more lethal effects of TNF on leukemic compared with normal myeloid cells and how TNF can exert profound biologic action at low levels of receptor occupancy.

Purification of Human Megakaryocytes by Fluorescence-Activated Cell Sorting

By Aaron Tomer, Laurence A. Harker, and Samuel A. Burstein

For direct studies of growth control, a method was developed to purify viable human megakaryocytes to homogeneity from routine normal bone marrow aspirates. An initial separation of marrow over a 1.050 g/mL Percoll density cut was used to enrich megakaryocytes. After washing, the cells were specifically labeled with a fluoresceinated monoclonal antibody or F(ab')$_2$ fragment to the platelet glycoprotein (GP) IIb/IIIa complex. Megakaryocytes were selectively sorted by using Becton Dickinson FACStar flow cytometer on the basis of a fluorescence intensity >50-fold that of control cells. To increase resolution and purity the sorting rate was adjusted to one cell in 13 formed drops, and negative events that coincided with positive ones were aborted. Two thirds of the isolated cells were large, morphologically recognizable megakaryocytes with a forward light scatter fourfold that of the main cell population. Microscopic examination showed these cells to be ≥98% megakaryocytes with a diameter of 20 to 46 µm and a ploidy range of 2N to 64N with a mode of 16N. The small highly fluorescent cells were 10 to 21 µm in diameter, and their ploidy range from 2N to 32N with main ploidy classes of 2N and 4N. The majority of these small cells also positively reacted with monoclonal antibody to platelet GPIb. The isolated cells were cultured in either Iscove's or leucine, lysine-deficient RPMI 1640 medium with 10% human plasma. The cells were maintained in culture more than three days and were capable of synthesis of both DNA and protein as assessed by radiolabeled thymidine and amino acid incorporation. Moreover, the isolated megakaryocytes were capable of responding to recombinant granulocyte-macrophage colony-stimulating factor. The data show that human megakaryocytes can be purified from routine marrow aspirates on the basis of a lineage marker and that they are capable of growth in vitro.

STUDY OF THE BIOLOGY of megakaryocytes has proved difficult, in part due to their rarity (constituting about 0.05% of all nucleated bone marrow cells), fragility, and their tendency to aggregate.[1-3] Thus, a large number of marrow cells and a highly selective method for megakaryocytic identification are needed for their isolation or analysis. Consequently, most studies of isolated megakaryocytes have used marrow flushed or scraped from the bones of experimental animals to achieve high cell yield with little admixture with blood and activated coagulation factors.[4-13] For studies of human megakaryocytes this source is limited to surgical amputations.[1,14-16]

Both human and animal megakaryocytes have been isolated with variable results by using velocity centrifugation, which separates cells based primarily on their size, and density gradient centrifugation.[1,3-5,14-17] Using marrow from human ribs Rabellino et al[1,14] and Sitar[16] obtained recoveries of 63% to 89% and purities of 68% to 94%. Notwithstanding these encouraging results, this method is limited by the need for ribs and the lack of specific megakaryocytic markers independent of size, which might result in a preferential selection of cells within the megakaryocytic population.[2,3,11]

Counterflow centrifugal elutriation (CCE) is an alternative approach. This procedure is based on the differences in sedimentation velocity between megakaryocytes and smaller cells.[2,7,8,18] Enrichment by CCE results in 60% to 70% recovery and about 25% purity, which may be increased up to 50% to 65% when combined with density centrifugation.[12,19] This method also inherently selects for larger megakaryocytes.

To overcome some of these technical limitations, flow cytometry has been introduced for the analysis of megakaryocytes.[5,6,9-11] This method has been shown to be sensitive and rapid for the analysis of infrequent cell populations, even in complex cell mixtures such as exists in bone marrow.[20] To prepare highly pure, viable human megakaryocytes isolated on the basis of a lineage marker on a routine basis, we have developed a method using fluorescence-activated cell sorting of normal bone marrow aspirates after labeling with a monoclonal antibody to the glycoprotein IIb/IIIa (GPIIb/IIIa) complex. In this report we describe the technique, its advantages and limitations, together with its applicability to studies of megakaryocytopoiesis in vitro.

MATERIALS AND METHODS

Marrow preparation. Six to 8 mL of bone marrow was collected from a single site (with one reposition of the needle) from the posterior iliac crest of normal volunteer donors. The marrow was aspirated after obtaining informed consent according to the guidelines of the Human Subjects Committee of the Research Institute of Scripps Clinic. Cells were collected into 10-mL plastic syringes containing $\frac{1}{10}$ vol acid-citrate-dextrose, formula A (ACD-A) EDTA, and prostaglandin E$_1$ (PGE$_1$; Sigma Chemical Co, St Louis) to a final concentration of 2.5 mmol/L and 2.2 µmol/L respectively. The marrow was gently pipetted, passed through a 200-µm monofilament nylon filter, and diluted with cold Ca^{++}- and Mg^{++}-free phosphate-buffered saline (PBS) containing 13.6 mmol/L sodium citrate, 2.2 µmol/L PGE$_1$, 1 mmol/L theophylline, 3% bovine serum albumin (BSA, fraction V; Calbiochem, La Jolla, CA), and 11 mmol/L glucose, and adjusted to a pH of 7.3 and an osmolarity of 290 mOsm/L. Hereafter, this supplemented PBS is designated MK medium.

In initial studies bone marrow was aspirated into heparin (40 U/mL, preservative-free)-containing syringes and diluted subse-

quently with medium containing citrate, adenosine, and theophylline in Hank's buffer[4] (CATCH). This resulted in frequent cell aggregation in the Percoll gradient and cell clumping in the subsequent washing step. To reduce the likelihood of cellular aggregation, the heparin was replaced with ACD-A solution containing 2.5 mmol/L EDTA and 2.2 μmol/L PGE$_1$ (which was also used to rinse the aspiration needle). When 10 μmol/L of the synthetic thrombin inhibitor, D-phenylanalyl-L-propyl-L-arginine-L-chloromethylketone was added to the aspiration mixture, fibrin clot formation was reduced, but at the expense of increased cellular aggregation within the Percoll gradient. The dilution medium was supplemented with 3% BSA and initially with 2.5 mmol/L EDTA. This concentration of EDTA was subsequently found to be unnecessary, as was the addition of DNase. Indeed, it is unlikely that this divalent cation–requiring nuclease is active in citrate- and/or EDTA-containing buffers. To improve viability, the theophylline concentration was reduced from 2 mmol/L (the original concentration in CATCH medium) to 1 mmol/L, and the adenosine component of CATCH medium was omitted with no observable increase in aggregation tendency.

Cell count, viability, and size measurement. Marrow cells were enumerated with a Hematology Series 15 Cell Counter (Baker Instruments, Allentown, PA) or a hemocytometer. Viability was assessed by trypan blue exclusion. The diameters of megakaryocytes freshly isolated by cell sorting (see the following sections) were measured with an ocular micrometer as previously described.[21]

Fractionation of marrow cells. The cell suspension was adjusted to 20 × 10^6 cells/mL, mixed with Percoll (Pharmacia Fine Chemicals, Piscataway, NJ) to a final density of 1.020 g/mL (isotonic 83.1% Percoll diluted with PBS containing 13.6 mmol/L sodium citrate), layered over 12 mL Percoll of density 1.050 g/mL, and subsequently overlayered with 10 mL MK medium. After centrifugation at 400 g for 20 minutes at 15°C, the upper medium layer was removed, and the cells were collected from the upper Percoll layer and the interface ($\leq$1.050 g/mL). The collected cells were then washed by mixing with 1.5 vol of cold MK medium containing 6% BSA and centrifugated at 300 g for ten minutes at 15°C. The supernatant was decanted and the cell pellet was resuspended in the same medium and stored on ice for antibody labeling.

Adjustment of the cell concentration to no greater than 20 × 10^6/mL and admixture of the cells with Percoll to a final density of 1.020 g/mL (before layering over the 1.050 g/mL Percoll) was found to be helpful in preventing aggregate formation during centrifugation, presumably because the cells were dispersed in a larger volume rather than being concentrated at the interface. To prevent cell clumping during the successive washing step, the concentration of BSA was increased to 6%.

Megakaryocyte labeling. Megakaryocytes were directly labeled with saturating concentrations of fluoresceinated IgG1 mouse monoclonal antibodies (or F(ab')$_2$ fragment thereof) directed to the platelet GPIIb/IIIa complex. The antibodies reacted only with platelets and megakaryocytes.[21] These antibodies (designated P$_1$ and P$_4$) were a gift from Dr Z.M. Ruggeri of the Research Institute of Scripps Clinic and were fluoresceinated to an F/P ratio of 3:1 by standard techniques.[22] The cell count was adjusted to 10^7/mL with MK medium containing 6% BSA and then incubated with 8 μg/mL antibody for 30 minutes on ice. Dead cells as well as unbound antibody were removed by centrifugation at 100 g for seven minutes at 15°C over 10% BSA.[23] The cell pellet was then resuspended with MK medium containing 10 mmol/L HEPES buffer and 50 U/mL penicillin-streptomycin solution. The saturating concentration of the monoclonal antibodies was determined by quantitative flow cytometric measurements of the fluorescence of large megakaryocytes. An aliquot of the cell suspension was incubated under identical conditions with a fluoresceinated IgG1 mouse monoclonal antibody to human thyroglobulin and used as the control cells. The total time required to prepare the marrow cells for sorting was two to 2.5 hours.

Flow cytometry. Megakaryocytes were sorted with a FACStar flow cytometer (Becton Dickinson, Mountainview, CA) equipped with a 2 W Coherent, Innova 70 argon ion laser and a 120-μm-diameter nozzle. The sheath pressure was adjusted to the minimum level allowing stable drop formation (6.2 psi), with a sample pressure of 2 psi. The drop formation frequency was set to about 13.1 kHz, and the cell concentration was adjusted to allow sorting of no greater than 1,000 events/s. The number of drops collected for a single positive event was set to three to improve the yield without compromising the purity because only one of 13 drops contained detected particles. Purity was also enhanced by aborting negative events coinciding with positive ones. The stability of the fluid jet and the drop delay setting were monitored frequently. Small particles up to 7 μm were electronically gated out on the basis of forward-angle light scatter (FSC) by using 5.3-, 7.8-, and 10.2-μm standard polystyrene beads (Becton Dickinson), human RBCs, and peripheral blood lymphocytes. The laser emission was adjusted to deliver 200 mW at 488 nm for excitation.

A 570-nm dichroic mirror was used to separate the fluorescence emissions of the fluorescein (green) and the propidium iodide (red) when it was used for concurrent ploidy measurement (see the next section). The green fluorescence was further filtered by a 530/30-nm-band pass-filter, and red fluorescence was passed through a 625/35-nm-band pass-filter before detection by the photomultipliers.

Megakaryocytes were identified by their distinct high green fluorescence (>50-fold that of the main cell population or that of the control cells). Megakaryocytes formed a discrete subset when the fluorescence emission was plotted against FSC (either by dot plot or contour histogram). Small megakaryocytes were defined by FSC levels corresponding to cell diameters up to 20 μm. The levels of fluorescence intensity, FSC, and side scatter of each cell were collected by a Hewlett Packard 9144 computer, and the data were analyzed with a Consort 30 computer program (Becton Dickinson). When cells were collected for culture, the fluidic system was first sterilized with 70% ethanol followed by sterile PBS, and the cells were sorted into MK medium. The sample tubes were kept on ice and the collecting tubes were kept at 4°C. The adjustment of the flow cytometer required about one hour when experience was achieved. Sorting of an average cell sample required about two hours.

Cell ploidy determination. Cell ploidy was determined by flow cytometric measurement of the relative cell DNA content after staining by propidium iodide in hypotonic citrate solution as described by Krishan.[24]

Immunoenzymatic staining for GPIb. Small cells, isolated on the basis of high fluorescence level only (and thus high expression of the epitope identified by P$_1$ or P$_4$), were examined for the additional lineage marker GPIb. The isolated cells were cytocentrifuged onto poly-D-lysine–coated slides, dried, fixed with acetone-ethanol (3:17) and stored at −20°C. The following procedure was carried out in a dark, humid chamber at room temperature, using PBS for all washing steps. The slides were rehydrated for 20 minutes and incubated with 2% horse serum for 30 minutes. After washing, a 1:1,000 dilution in 0.15% BSA (crystalline grade, Sigma) of a mouse monoclonal antibody (a gift from Dr Z.M. Ruggeri) directed to GPIb was added for 120 minutes. Control samples were incubated with mouse monoclonal antibody to human thyroglobulin. The slides were then washed extensively and incubated with a 1:25 dilution of biotinylated horse antimouse IgG (Vector Laboratories, Burlingame, CA) for 30 minutes. After washing, the slides were incubated with an avidin-biotin–alkaline phosphatase complex (Vectastain, ABC-AP; Vector) for 30 minutes and then with the enzyme substrate (kit I) for 20 minutes, washed with water, and counterstained with hematoxylin.

Megakaryocyte culture. Isolated marrow megakaryocytes were concentrated by centrifugation at 100 g for five minutes at 15°C and resuspended in 120 μL of MK medium. A diluted cell sample was counted, and the viability was assessed by trypan blue dye exclusion. Five hundred to 3,000 viable megakaryocytes were plated in duplicate microculture wells (Corning Glass Works, Corning, NY) containing 200 μL Iscove's medium (Irvine Scientific, Irvine, CA) for studies of thymidine incorporation or leucine, lysine-deficient RPMI 1640 medium (Irvine) for studies of amino acid incorporation. Both media were supplemented with 10% dialyzed normal human plasma, 200 mmol/L L-glutamine, and 50 μmol/L 2-mercaptoethanol. In some experiments the serum was replaced with 1% Nutricyte (J. Brooks Laboratories, San Diego) and 3% crystalline BSA (Sigma).

In subsequent experiments, cells were collected directly into tissue culture chambers mounted on plastic slides (Lab-Tek, Miles Scientific, Naperville, IL) containing culture medium. Cultures were incubated in a humidified 5% CO_2 tissue culture incubator at 37°C.

Radioisotope incorporation. To investigate the capacity of megakaryocytes to synthesize DNA and protein, cultures were labeled with 2 μCi of either ^{3}H-thymidine (^{3}HTdR, 87 Ci/mmol) or a ^{3}H-leucine-lysine mixture (120 Ci/mmol and 77 Ci/mmol respectively; Amersham Corp, Arlington Heights, IL). Similar amounts of radioisotopes were added to control wells containing no cells. After 20 hours in culture, the cells were harvested into 10% cold trichloroacetic acid (TCA). TCA-precipitable material was collected on 2.4-cm-diameter GF/C glass microfiber filters (Whatman, Maidstone, England), washed with 10% TCA, and counted with a liquid scintillation counter (model LS 7000, Beckman Instruments, Fullerton, CA). In some experiments aminopterin and hypoxanthine (4×10^{-7} mol/L and 1×10^{-4} mol/L final concentrations, respectively) were added to the culture medium to enhance the incorporation of thymidine. The significance of differences between incorporation rates was assessed with Student's *t* test.

Granulocyte-macrophage colony-stimulating factor (GM-CSF). To assess the response of isolated megakaryocytes to hematopoietic growth factors, sorted megakaryocytes were cultured in the presence of human recombinant GM-CSF, a gift from Dr Ken Kaushansky, University of Washington, Seattle. The factor was high-performance liquid chromatography–purified from serum-free medium conditioned by COS monkey kidney cells tranfected with human GM-CSF cDNA. The final preparation was about 70% pure, and its specific activity as assayed on human bone marrow was approximately 1×10^4 U/mL. The preparation was diluted to 25 U/mL with 2% human platelet-poor plasma in PBS.

RESULTS

Cell separation. As shown in Table 1, the yield of nucleated bone marrow cells from 6 to 8 mL of aspirated marrow was $434 \pm 280 \times 10^6$ (n = 18). It was estimated that morphologically identifiable megakaryocytes constituted about 0.05% of this cell fraction.[1-3,21] Percoll density gradient fractionation resulted in the depletion of 97.5% ± 0.5% of the total marrow cells and an increase in megakaryocytic frequency to 2.1 ± 0.4, which represents a 40-fold enrichment. The light-density ($\leq$1.050 g/mL) fraction contained >90% of morphologically recognizable megakaryocytes.[1,3,14,21] After the labeling procedure with the antibody and two washing steps, the yield of the cells initially recovered from the light-density fraction was 50% (the yield of cells from the dense Percoll fraction >1.050 g/mL was 70%). Cell viability before sorting was about 90%.

Selection of GPIIb/IIIa-positive cells. Figure 1 demonstrates the fluorescence distribution of megakaryocyte-enriched bone marrow labeled with the GPIIb/IIIa-specific monoclonal antibody (A, the intact antibody; B, the $F(ab')_2$ fragment) compared with the same sample labeled with the control monoclonal antibody to human thyroglobulin (C). A peak of highly fluorescent cells was detected in the sample labeled with the specific probe. These cells constitute about 2.5% of the total cell population (similar to the percentage of megakaryocytes estimated on this cell preparation using morphologic criteria) and exhibit a fluorescence intensity of 50- to 180-fold that of the major cell population (the higher level being observed with the $F(ab')_2$ fragment, B).

To improve megakaryocytic identification and to set criteria for reproducible selection, the fluorescence intensity was plotted against FSC, a parameter reflecting, in large part, cell size (Fig 2).[20] The bidimensional plot revealed a discrete subset with both high fluorescence intensity and an FSC fourfold that of the major cell population (Fig 2, upper right quadrant). After sorting and staining with hematoxylin, these cells appeared to be morphologically pure megakaryocytes (Fig 3). Sorting and staining of the unselected marrow cell population (Fig 2, lower quadrants) revealed that the number of megakaryocytes in this fraction was between 2.5% and 5% of that found in the selected population.

The yield of megakaryocytes from an average marrow

Table 1. Isolation of Megakaryocytes

	Nucleated Cells		Megakaryocytes			
Fraction	Number (× 10^6)	Percentage of Total	Percentage of Nucleated Cells	No. (× 10^3)	Percentage of Total	Viability (%)

§Cells collected directly into chamber slides containing medium.

‖Cells colected into tubes and concentrated by centrifugation.

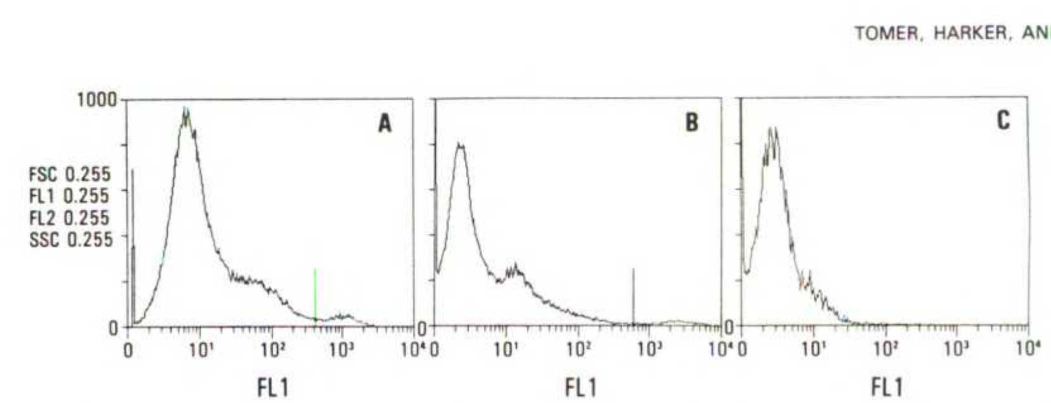

Fig 1. Fluorescence distribution of megakaryocyte-enriched marrow cells labeled with P_1 (A), the $F(ab')_2$ fragment (B), or antihuman thyroglobulin (C). The abscissa represents the relative fluorescence intensity and the ordinate cell number per channel. The numbers to the right of the flow cytometric parameters show the channel ranges that are opened, which indicates that the presented populations are unselected. The vertical lines (in A and B) indicate the gate position for selection of the highly fluorescent subset. Each curve represents an analysis of 50,000 cells.

aspirate of 4 × 10^8 cells was about 40,000 (Table 1) and was dependent upon the efficiency of sorting and manipulation of the collected megakaryocytes. The efficiency of sorting at optimal settings as defined by either resorting of a collected sample or comparing the electronically sorted events with the actual number of cells collected directly on slides was 80% to 90%. Concentrating the purified megakaryocytes in the collecting tube by centrifugation resulted in about a 50% loss. Subsequently, megakaryocytes were sorted directly into plastic chambers containing medium. This modification enhanced the yield up to 80,000 cells.

Sorting of the entire highly fluorescent cell population (Fig 2, horizontal solid line) resulted in inclusion of small cells which constituted 20% to 30% of the total selected cells. Only one third of these cells were morphologically recognizable megakaryocytes based on cell size and nuclear lobulation. To define further their state of differentiation, these cells were stained immunocytochemically with a monoclonal antibody to GPIb. Of 1,000 cells examined, 70% to 80% reacted positively.

Differentiation between small and large megakaryocytes was based on FSC (which was then translated to an electronic gate). By using standard beads, RBCs, and peripheral blood lymphocytes, small cells were defined as cells exhibiting FSC up to the level corresponding to a 20-μm diameter. About 97% to 98% of the total marrow cell population was included in this size range (vertical solid line in Fig 2). The size of the small megakaryocytes was

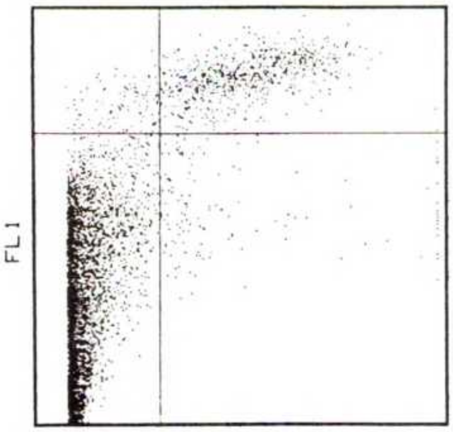

Fig 2. Distribution of megakaryocyte-enriched marrow cells by fluorescence (FL1) *v* FSC. The horizontal line represents the fluorescence gate setting to select the highly fluorescent cells. The vertical line represents the FSC gate setting to distinguish between small (<20 μm) and large megakaryocytes.

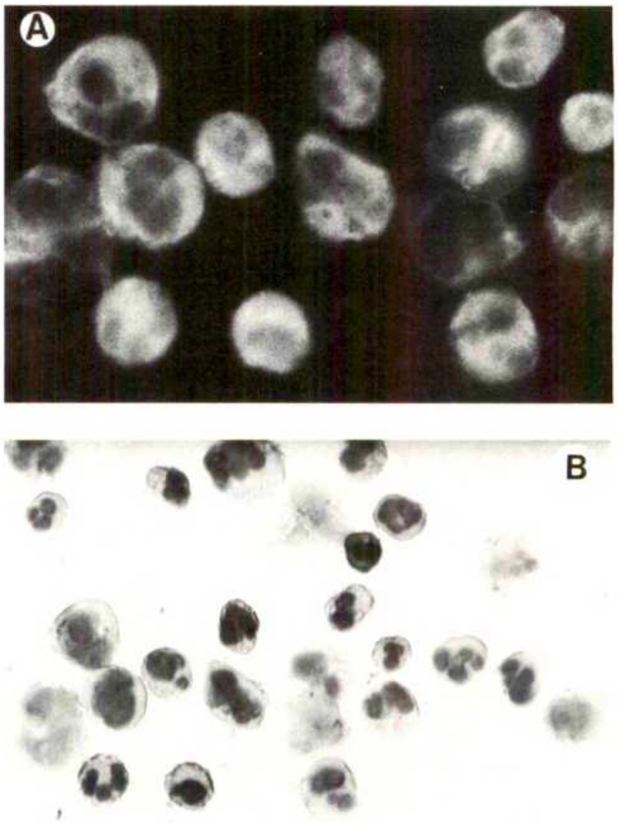

Fig 3. Highly fluorescent large cells sorted according to the gate settings shown in Fig 2. Cells were sorted directly onto glass slides, fixed, and viewed under a fluorescence microscope (A) (original magnification × 400; current magnification × 280). The same preparation was stained with hematoxylin (B) (original magnification × 250; current magnification × 176).

Table 2. Ploidy Distribution of Small and Large Megakaryocytes

Megakaryocytes	Ploidy					
	2N	4N	8N	16N	32N	64N
Small	29.3*	27.4	20.2	19.0	4.1	
Large	4.2	7.9	12.1	40.6	30.0	5.2

Small and large cells were defined as described in the text. Four thousand small cells and 14,000 large cells were examined for this study.

*Percentage of total.

estimated to be 15.2 ± 4.8 μm (n = 4,000). Because the relationship between FSC and the size of large cells had not been established, the mean diameter of unfixed large cells was measured microscopically and averaged 34.2 ± 11.8 μm (n = 150). Table 2 demonstrates the ploidy distribution of both the large and the small megakaryocytes as measured by propidium iodide staining. The modal ploidy of the large cells was 16 (40.6%), with 30.0% of cells being 32N, whereas about 60% of the small cells were 2N to 4N.

Cell culture. Megakaryocytes were cultured in liquid medium in microwell plates or slide chambers (Fig 4, culture of large cells). The viability, as assessed by trypan blue dye exclusion, ranged between 50% for the large cells and 75% for the small ones. Cells were maintained in culture more than three days. Twenty-four hours after the initiation of culture, only 50% to 70% of the cells appeared to be viable, showing a round shape, refractile cytoplasm, and nondiscernable nuclear outline.

To examine the biosynthetic ability of the isolated cells, incorporation of ^{3}HTdR and a ^{3}H-leucine-lysine mixture into TCA-precipitable material was measured. Thymidine incorporation was significantly higher by the small cells than by the large ones ($P < .05$; Table 3). The incorporation rate of all megakaryocytes was between that of the small and the large cells. The addition of hypoxanthine and aminopterin to the culture medium resulted in a six- to sevenfold increase in the incorporation rate. A low incorporation rate was observed in plasma-free medium, although the effect of aminopterin supplementation to this medium was not tested (data not shown). No increase in cell number during the culture period was observed. The relative incorporation rate of amino acids by the different cell types was similar to that observed with thymidine (Table 4) and was significantly lower in plasma-free medium (data not shown). As shown in Table 5 for untreated cells at time 0 and 20 hours, the addition of either radiolabeled precursor 20 hours after the initiation of culture resulted in a reduction of the incorporation rate by 30% to 50%.

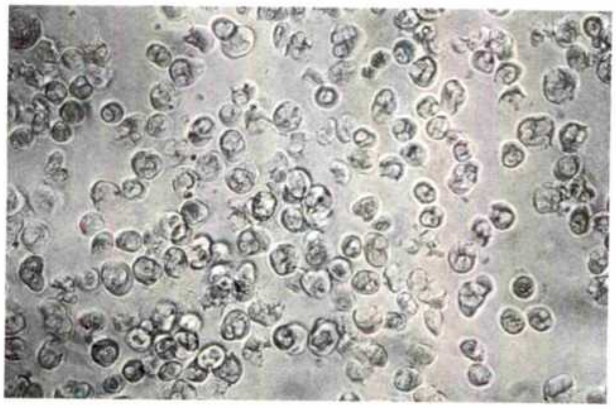

Fig 4. Phase-contrast photomicrograph of sorted large megakaryocytes after 24 hours in culture (original magnification × 200; current magnification × 150).

Table 3. ^{3}HTdR Incorporation by Isolated Megakaryocytes

Culture Conditions	Cells		cpm (± 1 SD)	cpm/Cell (Mean)
	Type	Number		
10% plasma	Small	1,500	1,950 ± 282	1.3
	Large	2,000	1,560 ± 211	0.8
	All	3,000	3,357 ± 349	1.1
10% plasma + AH*	Small	1,500	13,842 ± 1,633	9.2
	Large	1,500	7,212 ± 1,175	4.8
	All	650	4,225 ± 548	6.5

Cells were cultured in 200 μL of the specified medium and labeled with 2 μCi ^{3}HTdR for 20 hours. Cells were harvested into 10% cold TCA, filtered through GF/C glass fiber filters, washed, and the precipitable material was counted. Background counts of samples containing no cells were subtracted. The average background was 185 cpm.

*Aminopterin (A) was added to a final concentration of 4×10^{-7} mol/L and hypoxanthine (H) to 1×10^{-4} mol/L.

Response to GM-CSF. To determine whether isolated megakaryocytes would respond to hematopoietic growth factors, the response of megakaryocytes to rGM-CSF in culture was examined. Only the small megakaryocytes responded with significant increments in the thymidine or amino acid incorporation rates (2.3- and 1.5-fold respectively, $P < .01$; Table 5) with no siginificant change in the incorporation rate by the large cells (data not shown). The effect was pronounced only in cultures that were treated with the factor for about 20 hours before pulse-labeling with the radioisotopes. No increase in cell number was observed during the culture period.

DISCUSSION

Purified viable human megakaryocytes are required to study some aspects of the biology of these cells such as biosynthesis of specific proteins or the response to growth factors. Based on recent studies demonstrating the utility of fluorescence-activated cell sorting for analysis of animal megakaryocytes,[5,6,9-11] we have established a technique for

Table 4. Amino Acid Incorporation by Isolated Megakaryocytes

Culture Conditions	Cells		cpm (± 1 SD)	cpm/Cell (Mean)
	Type	Number		
10% plasma*	Small	2,000	15,040 ± 1,095	7.5
	Large	2,000	10,520 ± 1,237	5.2
	All	2,000	12,020 ± 2,209	6.0

Cells were cultured in 200 μL medium and pulse-labeled with 2 μCi mixed ^{3}H-leucine and ^{3}H-lysine (1:1) for 20 hours. The cells were then harvested, and TCA-precipitable material was counted. Background counts of samples containing no cells were subtracted. The average background was 470 cpm.

*Lysine, leucine-deficient RPMI 1640 medium supplemented with 10% dialyzed normal human plasma.

Table 5. Incorporation of ^{3}HTdR and ^{3}H-Lysine-Leucine Into Megakaryocyte Cultures Treated With rGM-CSF

GM-CSF Treatment	Time of Addition of Radiolabel	Cells Plated	Radiolabeled Precursor	cpm (± 1 SD)
–	0	2,000	^{3}HTdR	18,000 ± 2,969
+				19,510 ± 2,725
–		1,500	^{3}H-Leu/Lys	10,510 ± 1,334
+				9,820 ± 1,519
–	20	2,000	^{3}HTdR	15,420 ± 3,049
+				36,080 ± 6,500
–		1,500	^{3}H-Leu/Lys	5,075 ± 681
+				7,830 ± 1,028

Small megakaryocytes were cultured in 200 μL of either Iscove's medium plus AH for ^{3}HTdR incorporation or leucine- lysine-deficient RPMI 1640 medium for ^{3}H-amino acid incorporation, both supplemented with 10% normal human plasma. Recombinant GM-CSF was added at 1 U/mL at the outset of culture. The radiolabeled precursors were added immediately or 20 hours after the addition of rGM-CSF. Eighteen hours later the cells were harvested, and TCA-precipitable material was counted as described. The data represent means (± 1 SD) of three experiments.

the preparative sorting of human megakaryocytes. Using this method, we have shown that megakaryocytes (*a*) can be isolated on the basis of an intrinsic cell surface marker rather than physical characteristics, (*b*) can be characterized and separated further by size, (*c*) are biosynthetically intact with the small cells more active than the large cells, and (*d*) respond to at least one characterized hematopoietic growth factor, GM-CSF.

The method described herein presents several advantages. (*a*) Bone marrow aspirates are used as the starting material, thereby avoiding dependence on amputated bones and permitting serial studies to investigate cell physiology as well as clinical disorders of megakaryocytopoiesis. (*b*) The technique ensures a nearly pure and biosynthetically viable (50% to 70%) cell population. (*c*) Selection of megakaryocytes by size, ploidy, or the expression of specific surface markers can be made for analytic as well as growth regulation studies.

To sort megakaryocytes, monocellular suspensions are critical. The major obstacle in the preparation of a single-cell suspension of human marrow megakaryocytes was cellular aggregation. Any clot formation during marrow aspiration exacerbated this phenomenon. To obviate cell clumping, a number of modifications of the collection and dilution media were made. An ACD-A, EDTA, and PGE_1 mixture was used for marrow collection. The citrated dilution medium was supplemented with BSA and PGE_1. However, the adenosine was omitted, and the concentration of theophylline was reduced to improve viability. The marrow suspension was admixed with Percoll to 1.020 g/mL before the density centrifugation, and the collected cell fraction was washed in the presence of a higher concentration of BSA (6%). These changes resulted in optimal dispersion and preservation of cells. Nevertheless, in some experiments detectable cellular aggregation was observed due to some additional, as yet undefined mechanism(s).

The recovery of megakaryocytes was dependent on the number of washing steps and the total time required for the purification procedure. The presorting steps required two to 2.5 hours and resulted in a 50% yield of the enriched marrow cells. The efficiency of sorting was dependent on the accuracy of the optical and fluidic settings. At optimal settings an efficiency of 80% to 90% was obtained. Surprisingly, concentrating the purified megakaryocytes in the collecting tube by centrifugation resulted in about a 50% loss. To increase the yield and to improve viability, megakaryocytes were subsequently sorted directly into culture vessels. As a result, the overall yield from an average bone marrow aspirate (about 4×10^8 cells) under optimal sorting conditions was increased to 80,000, which constituted about 40% of the initial number. Higher yields of human megakaryocytes have been reported. However, the use of marrow aspirates for separation by CCE resulted in approximately 63% recovery but only 19% purity.[18] Amputated ribs offer a higher starting number of cells[3] with less admixture with blood. Separation by density followed by two velocity centrifugations resulted in up to 85% recovery and 70% to 95% purity.[1,16] The need for ribs and the selection of cells on the basis of size limits to some degree the applicability of that method.[2,3,12] Although higher recoveries have been reported by others, the major aim of this work was to optimize the sorting technique to obtain pure and viable cells for subsequent studies in culture. It is likely that with optimization of the presorting steps the final yield would be significantly improved. However, as shown by the incorporation studies, the present yield is sufficient to permit studies of growth factor responsiveness.

The purity of the isolated megakaryocytes approached 100% as observed in Figs 3 and 4. Achievement of this purity is governed by the specificity of the cell labeling and the accuracy of the sorting settings. As previously shown, the monoclonal antibody we used has been shown to react only with platelets and megakaryocytes in marrow.[21] Although epitopes of GPIIb and IIIa are found in other cell types, those studies indicated that the monoclonal antibodies used in the present study identify epitopes found in platelets and megakaryocytes but not in endothelial cells or monocytes.[21] The ability to distinguish between megakaryocytes and other marrow cells is demonstrated in Figs 1 and 2 where the mean fluorescence level of the megakaryocytes was more than 50-fold that of the control cells. Using bidimensional plots of fluorescence *v* FSC, the frequency of megakaryocytes (about 2%) enables localization and selection of the population of interest by more accurate gate settings. The precision of sorting can then be evaluated in real time by sorting the large, highly fluorescent cells on slides and examining them by phase-contrast microscopy to ascertain that these cells are morphologically recognizable megakaryocytes.

Sorting of small megakaryocytes requires higher resolution because it is based on fluorescence only and there is no sharp demarcation between small low-fluorescent megakaryocytes and other cells exhibiting low nonspecific fluorescence such as autofluorescence (Fig 1A). Use of the F(ab′) fragment improves the resolution by augmenting the difference in fluorescence intensity between megakaryocytes and control cells up to 180-fold (Fig 1B). By using bidimensional plots, small megakaryocytes were sorted according to the FL1 level of the total megakaryocytic population and to the FSC levels corresponding to the size up to 20 μm in diameter

(Fig 2, upper left quadrant). To verify the lineage association of these small, highly fluorescent cells, we examined the expression of GPIb by an immunoenzymatic staining technique. Approximately 75% of the small GPIIb/IIIa-positive cells also stained for GPIb. Based on data that GPIIb/IIIa appears or is detectable earlier in the differentiation sequence than GPIb, and on our previous data assessing the specificity of our anti-GPIIb/IIIa monoclonal antibodies,[21,25] we conclude that these small cells expressing high levels of GPIIb/IIIa represent early cells in the megakaryocytic lineage that have yet to express the GPIb epitope.

As shown by us[21] and others,[11] the majority (70%) of small megakaryocytes are found at densities >1.050 g/mL. The choice of cells of density <1.050 g/mL in this study was dictated by the need for megakaryocyte-enriched marrow to establish the sorting method. Studies requiring greater numbers of small cells could be performed by increasing the Percoll density in the preliminary enrichment step. It is possible, however, to eliminate the enrichment procedure if sorting time is not a limitation.

The size range of megakaryocytes (10 to 46 μm) is similar to that reported by others,[3,18,21] and the ploidy distribution is similar to that found in previous work[21] except for the higher proportion of 2N and 4N cells, probably as a result of using a different technique.

Human megakaryocytes have the capacity to grow in culture and to be biosynthetically active.[1,18] However, cultures of highly purified human megakaryocytes have not been examined. In the present selection method the isolated pure megakaryocytes were able to grow in medium supplemented with 10% plasma for at least three days and to show biosynthesis of proteins and DNA. An attempt to replace plasma by a defined medium was not fully successful, thereby indicating the inadequacy of the plasma substitute. Further studies will be required to determine whether this problem is trivial or related to the absence of a required growth factor(s). The low incorporation rate by the large cells suggests that mature megakaryocytes synthesize macromolecules at a lower rate than the small cells. However, it cannot be excluded that large cells were damaged during the isolation procedure to a greater extent than the small cells.[11] The incorporation rate was decreased by 30% to 50% when cultures were pulse-labeled after 20 hours, which reflects, at least in part, the decrease in cell viability as a function of time in culture. A similar phenomenon was observed by Greenberg et al using CCE and density centrifugation to purify rat megakaryocytes.[12]

As has been found for other marrow cells, megakaryocytic proliferation and maturation are controlled by hematopoietic growth factors.[19] Pure cultures of marrow-derived megakaryocytes provide the opportunity to study the direct effect of such factors on the maturation of these cells. In this study the effect of rGM-CSF was examined. The data showed that the small cells responded with a significant increase in thymidine and amino acid incorporation. The insignificant response of the large cells may reflect biologic nonresponsiveness of mature megakaryocytes or could be related to damage incurred during the isolation procedure. The response of the small cells became evident when the cells were preincubated for 20 hours with rGM-CSF. This delay may be due to a requirement for synthesis of a regulatory protein(s) before the onset of general protein synthesis or recovery of cellular responsiveness to GM-CSF because they were exposed to nonphysiological medium for several hours. It is conceivable that GM-CSF is stimulating the megakaryocyte colony–forming cell (CFU-MK) or possibly a myeloid progenitor cell is contaminating the cultures. Some investigators have suggested that CFU-MK express GPIIb/IIIa, which permits these cells to be sorted by our method.[26] Mitigating against these possibilities are (*a*) the lack of an increment in cell number during the culture period, (*b*) the infrequency of progenitor cells (at least in mice) at Percoll densities <1.050 g/mL,[13] and (*c*) more recent evidence suggesting that CFU-MK do not express GPIIb/IIIa.[27] Nonetheless, GM-CSF appears to promote the biosynthesis of macromolecules in nonproliferating, presumably endoreduplicating megakaryocytes. This conclusion is not entirely surprising because GM-CSF has been shown to promote proliferation of progenitor cells of other lineages including the CFU-MK as well as to influence the functions of mature cells in the granulocytic lineage.[28-30]

Based on these results and the known analytic potential of fluorescence-activated cell sorting, we conclude that the present method provides a useful means for the isolation and analysis of human megakaryocytes. This technique may facilitate the study of normal megakaryocytopoiesis in humans as well as the investigation of various clinical disorders of thrombocytopoiesis.

Augmentation of Neutrophil-Mediated Erythrocyte Lysis by Cells Derived In Vitro From Human Monocytes

By Franco Dallegri, Alberto Ballestrero, Guido Frumento, and Franco Patrone

Neutrophilic polymorphonuclear leukocytes (PMNs) were incubated with opsonized zymosan and lysed human erythrocytes (RBCs) as measured by a ^{51}Cr release method. Conversely, myeloperoxidase (MPO)-negative hydrogen peroxide (H_2O_2)-generating cells, derived in vitro from human monocytes (monocyte-derived cells (MDCs), were ineffective per se but capable of augmenting the lysis by PMNs. The lysis by PMNs and PMNs plus MDCs was inhibited by catalase, azide, taurine, and alanine, consistent with the requirement for hypochlorous acid (HOCl). As detected under conditions similar to those used for lytic assays, MDCs failed to produce HOCl but augmented the HOCl recovery from the PMN-RBC system. Moreover, when the extent of the lysis was plotted as a function of the HOCl recovery, a positive linear relationship was found. Although the actual size of the H_2O_2 extracellular pool could not be measured because of the inexistence of a reliable assay to probe our cytolytic model without perturbing the equilibrium of the system, the results presented suggest that MDCs enhance the PMN-mediated lysis by improving the HOCl production, presumably by supplying extra amounts of H_2O_2 to be handled by PMN MPO. In fact, the events mediated by MDCs could be reproduced by using an appropriate H_2O_2-generating enzymatic system (glucose–glucose oxidase). The present study provides direct evidence for the possibility of cooperation between MPO-positive and MPO-negative phagocytes in exerting functions (HOCl production and, in turn, cytolysis) possibly relevant to the outcome of inflammatory processes.

© ***1987 by Grune & Stratton, Inc.***

WHEN TRIGGERED by appropriate stimuli, either soluble (phorbol myristate acetate) or particulate (opsonized zymosan [OPZ], heat-aggregated IgG), neutrophils (neutrophilic polymorphonuclear leukocytes [PMNs]) have been shown to be capable of lysing a wide spectrum of eukaryotic target cells.[1-5] These in vitro systems of cytolysis have been used to understand the mechanisms by which PMNs may injure tissue cells at inflammatory sites. In the present paper, by the use of a previously characterized system constituted of OPZ-triggered PMNs and human erythrocytes (RBCs) as targets,[6] we provide evidence that the PMN cytolytic efficiency can be augmented by myeloperoxidase (MPO)-negative cells derived in vitro from human monocytes (MDCs) and per se incapable of mediating lysis. The results uncover a novel possible role for MPO-negative mononuclear phagocytes in interaction with PMNs during inflammatory processes.

MATERIALS AND METHODS

Preparation of PMNs. Heparinized venous blood (heparin, 10 U/mL, Liquemin, Roche, Milan, Italy) was obtained from healthy male volunteers. PMNs were isolated by dextran sedimentation and subsequent centrifugation on a Ficoll-Hypaque density gradient as previously described.[6] Contaminating erythrocytes were removed by hypotonic lysis.[6] The resulting PMNs were washed three times with Hanks' balanced salt solution lacking phenol red (HBSS, Flow Laboratories, Ltd, Irvine, Scotland) and resuspended in HBSS supplemented with 0.1 mg/mL bovine serum albumin (BSA, Calbiochem-Behring, San Diego) (BSA-HBSS). Final cell suspensions contained 97% or more PMNs and more than 98% viable cells as evaluated by the ethidium bromide–fluorescein diacetate test.[7]

Preparation of MDCs. Venous blood (350 mL) from healthy male volunteers was collected into 53 mL of anticoagulant citrate-phosphate-dextrose-adenine (CDPA) (Baxter, Trieste, Italy). The buffy coat, obtained two to three hours after venipuncture, was diluted with an equal volume of 0.9% NaCl, and 25 mL of the cell suspension was layered on 15 mL Ficoll-Hypaque (Nyegaard & Co, Oslo) in 50-mL polypropylene conical tubes (No. 25330, Corning Glass Works, Corning, NY). After centrifugation (400 g, 30 minutes, 22°C), the upper cell layer (mononuclear cells) was collected and spun down at 400 g for ten minutes at 22°C. The sedimented cells were washed three times with HBSS (200 g, ten minutes, 22°C) and resuspended in Fisher's medium (Flow) supplemented with 25% filtered horse serum (HS, Flow), 2 mmol/L glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin (HS-Fisher's medium[8]). The cells were then plated in 75-cm^2 tissue culture flasks (Sterilin, Ltd, Teddington, England) in thin suspension layers (2×10^7/mL, 5 mL). After incubation for two hours at 37°C in a humidified atmosphere of 95% air and 5% CO_2, nonadherent cells were removed by washing five times with prewarmed (37°C) HBSS and the adherent cells overlaid with 8 mL HS-Fisher's medium. The flasks were then returned to the CO_2 incubator. Three days later, the medium containing detached cells was decanted, and adherent cells were rinsed three times with prewarmed (37°C) HBSS. Adherent cells were then removed by pipetting after incubation (20 minutes, 4°C) with phosphate-buffered saline (PBS, pH 7.4) containing 0.2% EDTA (Sigma Chemical Co, St. Louis) and 5% heat-inactivated (30 minutes, 56°C) fetal calf serum (Flow).[9] The resulting cells were centrifuged (200 g, ten minutes, 4°C), washed three times with cold (4°C) HBSS, and resuspended in cold (4°C) BSA-HBSS. Only cell suspensions containing >90% α-naphthyl acetate esterase–positive cells, as determined by the method of Li et al,[10] were used. These cells, referred to as MDCs, were >97% viable as judged by the ethidium bromide–fluorescein diacetate test.[7]

Preparation of OPZ. OPZ was prepared by incubating a suspension containing 10 mg/mL boiled zymosan (Sigma) in PBS (pH 7.4) with an equal volume of fresh human serum for 30 minutes at 37°C. The particles were then washed three times with PBS and resuspended in BSA-HBSS at the appropriate concentration.

Measurement of RBC lysis. The RBC lysis was studied by a

^{51}Cr release method as previously described.[6] Briefly, RBCs were washed four times with HBSS and labeled (60 minutes, 37°C) with 100 to 200 μCi $Na_2[^{51}Cr]O_4$ (Radiochemical Centre, Amersham, England). The cells were then washed three times with HBSS and resuspended in BSA-HBSS. When required, RBCs were pretreated (60 minutes, 37°C) with 20 mmol/L 3-amino-1,2,4-triazole (AT, Sigma) plus 2 mmol/L L-ascorbic acid (Sigma) (RBC^{AT}) to inhibit catalase activity.[11] A quantity of 10^5 RBCs were mixed with PMNs, MDCs, or PMNs plus MDCs at appropriate concentrations. In some experiments, MDCs were replaced by glucose oxidase (GO, type II, Lot 111F-9605, Sigma) dissolved in HBSS (prepared without glucose) and mixed with the other components of the reaction to reach a final concentration of 5 mU/mL (incubation medium, BSA-HBSS with 1 mg/mL glucose). Incubations were initiated by the addition of OPZ (0.4 mg/mL) and followed by centrifugation of the samples at 50 g (five minutes, 22°C). Tests were performed in triplicate and in a final volume of 200 μL in round-bottomed microplates (Sterilin). After incubation for four hours at 37°C in a humidified atmosphere of 95% air and 5% CO_2, the ^{51}Cr release was determined in the cell-free supernatants. The percentage of cytolysis (percent ^{51}Cr release) was calculated according to the formula $(E - S)/(T - S) \times 100$, where E is the counts per minute released in the presence of effector cells, T is the counts per minute released after lysing target cells with 5% Triton X-100 (Sigma), S is the counts per minute spontaneously released by target cells in the absence of effector cells (in each case, <10%).

Measurement of H_2O_2 release. The hydrogen peroxide (H_2O_2) release was studied by a modification of the homovanillic acid (HVA)–horseradish peroxidase (HRP) method[12] as previously described.[11] Tests were performed in triplicate under experimental conditions similar to those used for cytolytic assays except that incubations were done in Falcon plastic tubes (12 × 75 mm, Falcon Labware, Oxnard, CA). Briefly, 5×10^5 PMNs were incubated (37°C) with and without 0.4 mg/mL OPZ in the presence of 200 μmol/L HVA (Sigma) plus 2 U/mL HRP (Sigma). When required, 2×10^6 RBC targets were added. Similar experiments were carried out with an appropriate number of MDCs both in presence and in absence of PMNs. The cells were sedimented by centrifugation (50 g, five minutes) at the beginning of the assay. The reactions, performed in a final volume of 2 mL, were stopped after 20 minutes with 0.25 mL of 0.1 mol/L glycine-NaOH buffer (pH 12) containing 25 mmol/L EDTA. The amount of H_2O_2 in the cell-free supernatants was determined fluorimetrically ($\lambda_{ex} = 312$ nm, $\lambda_{em} = 420$ nm) by using appropriate standards of H_2O_2. Preliminary experiments showed that the amount of H_2O_2 recovered from OPZ-triggered neutrophils incubated (20 minutes) as a pellet equals that recovered from OPZ-triggered neutrophils incubated as a pellet during the first five minutes of the assay period (20 minutes) and then resuspended and maintained in suspension.

Measurement of HOCl production. The generation of hypochlorous acid (HOCl) by OPZ-triggered PMNs was quantitated by the taurine trapping technique[13] as previously described.[11] The conditions of the assay were identical to those used for the H_2O_2 release except that the reactions were carried out in a final volume of 1 mL. Briefly, an appropriate number of PMNs was incubated (20 minutes, 37°C) with 0.4 mg/mL OPZ in the presence of 20 mmol/L taurine (Sigma). Tests were performed in the presence and in the absence of 2×10^6 RBC targets or 300 units catalase (bovine liver, Sigma; amount of enzyme chosen on the basis of preliminary experiments). Similar experiments were carried out with MDCs both in presence and in absence of PMNs. The cells were sedimented by centrifugation (50 g, five minutes) at the beginning of the assay. At the end of the incubation period (20 minutes), catalase (600 units, Sigma) was added to reduce any residual H_2O_2. The samples were then incubated (22°C, five minutes) with 100 nmol of 5-thio-2-nitrobenzoic acid (Nbs) prepared by reducing 5-5′-dithiobis (2-nitrobenzoic acid) (Sigma) as described by Aune and Thomas.[14] The amounts of Nbs oxidized were determined by measuring the absorbance at 412 nm of the cell-free supernatants ($\epsilon = 1.36 \times 10^4$ mol/L/cm). The quantities of HOCl trapped by taurine (yelding taurine chloramine) were calculated by taking into account that 1 mol taurine chloramine oxidizes 2 mol Nbs.[13] As for the H_2O_2 assay, the method of HOCl detection maintained its efficiency also when tests were carried out with cells incubated as a pellet for 20 minutes. Under the conditions described earlier, the uptake of taurine chloramine by RBCs, via the 4,4′-diisothiocyano-2,2′-disulfonic acid stilbene (DIDS)-inhibitable anion transport system,[15] did not affect the taurine chloramine recovery (the amounts of taurine chloramine recovered in the presence of RBCs equalled those recovered in the presence of RBCs pulsed (30 minutes) with 0.1 mmol/L DIDS (Sigma).[11]

Enzyme assays. The total cell content of MPO was measured after lysing the cells by sonication followed by freezing-thawing and solubilization with 0.5% hexadecyltrimethylammonium bromide (HTAB, Sigma).[16] The MPO activity released by cells incubated (one hour, 37°C) with 0.4 mg/mL OPZ was determined in HTAB-untreated cell-free supernatants. The MPO assay was done by an *O*-dianisidine method as previously described.[11] One unit of enzyme activity was defined as that oxidizing 1 μmol of *O*-dianisidine/min at 25°C (optical density, 550, $\epsilon = 11.3$ mmol/L/cm).

For determination of RBC catalase activity, the cells were lysed as described by Beutler,[17] and the enzyme activity was determined by recording the rate of decomposition of H_2O_2 at 230 nm ($\epsilon = 0.071$ mmol/L/cm).[17] The activity of "reagent" catalase (bovine liver, Sigma) was measured similarly. The results were expressed as nanomoles H_2O_2/min at 25°C or units (1 unit of enzyme activity was defined as that catalyzing the breakdown of 1 μmol H_2O_2/min at 25°C).

Special materials. Superoxide dismutase (SOD, type 1, bovine blood, Sigma), stored at −20°C at a concentration of 5 mg/mL in distilled water, was diluted in medium before use. Catalase (bovine liver, 40,000 U/mg protein), taurine, L-alanine, mannitol, and benzoate were purchased from Sigma. Sodium azide (NaN_3) and $(NH_4)_2SO_4$ were from Merck, Darmstadt, FRG. MPO, as a supernatant from the PMN granule fraction (MPO 4,800 mU/mL, 24.9 mg/mL protein), was prepared by using normal human PMNs and stored at −20°C.[18] Other reagent-grade compounds were used as obtained from commercial suppliers. In some experiments, BSA-HBSS medium was replaced with a Cl^--free, 0.1 mol/L phosphate buffer (pH 7.4) with 1.5 mmol/L $MgSO_4$ supplemented with 1 mg/mL glucose (Merck) and 0.1 mg/mL BSA (Calbiochem-Behring)(Cl^--free medium).

RESULTS

As depicted in Fig 1, OPZ-triggered PMNs lysed RBC targets, whereas MDCs were ineffective. When added to the PMN-RBC system (0.25×10^5 PMNs plus 10^5 RBCs, PMN:RBC ratio, 1:4), MDCs enhanced the lysis in a dose-dependent manner (Fig 2). As detailed in Table 1, the lysis in the complete PMN-MDC-RBC system (0.25×10^5 PMNs plus 0.25×10^5 MDCs plus 10^5 RBCs) was inhibited by adding catalase to destroy H_2O_2 (heat-inactivated catalase was ineffective), azide to inhibit MPO, and amino acids (alanine, taurine) to scavenge HOCl. Scavengers of superoxide anion (SOD) and hydroxyl radicals (mannitol, benzoate) were ineffective (Table 1). Similar results were obtained in the PMN-RBC system (Table 1), in agreement with our previous findings.[6,11] Moreover, the absence of Cl^- completely prevented lysis in the PMN-MDC-RBC system (percent ^{51}Cr release, 0.1 ± 0.8 and 36.0 ± 2.3 in the absence and

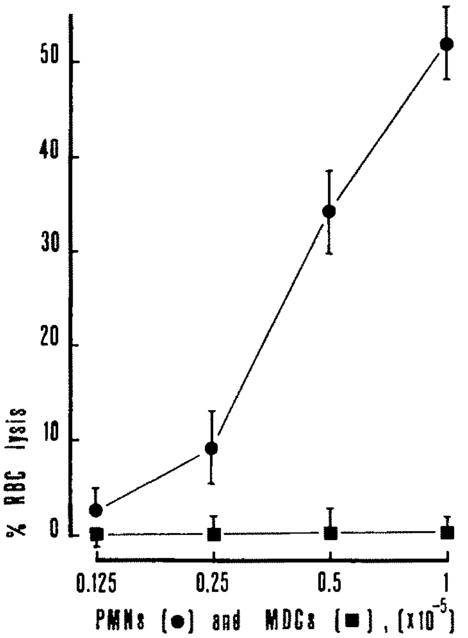

Fig 1. OPZ-triggered RBC lysis by PMNs or MDCs. The number of RBCs is 10^6/well. Each point represents x̄ ± 1 SD of at least three experiments.

in the presence of Cl^- respectively, x̄ ± 1 SD, n = 3). Similarly, Cl^- was required for RBC lysis by PMNs.[19] Finally, the addition of 20 mmol/L NH_4^+ caused >95% inhibition of the lysis in both the PMN-RBC and the PMN-MDC-RBC systems. These data suggest that amplification of PMN-mediated lysis by MDCs requires HOCl production via the MPO-H_2O_2-Cl^- system.

To gain further insight into the mechanism whereby MDCs enhance PMN-mediated lysis, we measured the recovery of H_2O_2 and HOCl generated by PMNs and MDCs under conditions similar to those used for cytolytic assays (cells incubated as a pellet). As shown in Table 2, both PMNs and MDCs, incubated with OPZ in absence of RBCs, released H_2O_2. Nevertheless, only PMNs produced HOCl (Table 2), consistent with the absence of detectable MPO activity in MDCs (MDC MPO content, undetectable; PMN MPO content, 157.2 ± 11.3 mU/10^6 PMNs, OPZ-triggered MPO release, 4.2 ± 0.6 mU/10^6 PMNs/1h, x̄ ± 1 SD, n = 4). When MDCs were added to PMNs in absence of RBCs, the H_2O_2 recovery increased, but the HOCl recovery did not change (Table 2). It seems therefore that the HOCl production cannot be further enhanced by the extra amount of H_2O_2 supplied by MDCs. This is in agreement with the incapacity of the H_2O_2-generating enzymatic system, glucose-GO, to increase the HOCl production by OPZ-triggered PMNs (HOCl recovery, 15.5 ± 2.6 and 15.9 ± 2.6 nmol/5 × 10^5 PMNs/20 min from PMNs incubated alone or with 5 mU/mL GO respectively; 5 mU/mL generated GO 2.3 ± 0.5 nmol/H_2O_2/min, x̄ ± 1 SD, n = 3). In ancillary experiments carried out with cells in suspension instead of centrifuged as a pellet, the HOCl production by OPZ-triggered PMNs could not be augmented by adding 5 mU/mL GO or 16 mU/mL MPO from the supernatant of the PMN granule fraction (92.8 ± 6.9, 92.8 ± 7.3, and 91.5 ± 9.2 nmol HOCl/10^6 PMNs/1 h from PMNs incubated alone, with GO, and with MPO respectively, x̄ ± 1 SD, n = 3).

When RBCs were added to PMNs to complete the system (PMN:RBC ratio, 1:4; number of RBCs 2 × 10^6; cells were incubated as a pellet) as in the cytolytic assays, a decreased

H_2O_2 and HOCl recovery (~50%) was found (Table 2). This reduction in HOCl generation results in a relative impairment of the HOCl-dependent PMN lytic efficiency.[6] As summarized in Table 2, MDCs increased the H_2O_2 and HOCl recovery from the PMN-RBC system. Moreover, when the extent of the lysis by PMNs and PMNs plus MDCs (Figs 1 and 2) was plotted as a function of the HOCl recovery detected under conditions similar to those used for cytolysis (identical cell ratios but with 2 × 10^6 RBCs instead of 10^5 RBCs used in lytic assays), a positive linear relationship was found (Fig 3). Together, these results suggest the possibility that MDCs amplify the lysis primarily by improving the HOCl production in the PMN-RBC system, possibly through an effective restoration of the PMN H_2O_2 extracellular pool depleted by RBC targets. Three additional findings are consistent with this possibility. First, the replacement of RBC targets with RBC^{AT} (RBC^{AT} had a >94% reduction in catalase activity; catalase activity of native RBCs 4,258 ± 112 nmol H_2O_2/min/10^6cells, $\bar{x} \pm 1$ SD, n = 6), incapable of efficiently consuming PMN-derived H_2O_2,[6] completely abrogated the MDC capacity to augment the PMN-mediated HOCl-dependent (not shown) lysis (percent increment, 1.1 ± 3.7, $\bar{x} \pm 1$ SD, n = 3) and the HOCl recovery from the system (percent increment, −0.02 ± 8.2, $\bar{x} \pm 1$ SD, n = 4). Second, enhancement of the HOCl production by MDCs in the PMN-RBC system (Table 2) could be reproduced by substituting catalase for RBCs in the system (Table 3) and choosing an amount of enzyme (300 units in 1 mL) that results in a reduction of the HOCl recovery from PMNs similar in magnitude to that observed in the presence of 2 × 10^6 RBCs (Tables 2 and 3). The requirement for 300 units catalase, ie, ~35 times the amount of catalase in 2 × 10^6 RBCs, is conceivably due to the fact that the enzyme is distributed throughout the assay volume (1 mL) whereas RBC catalase is confined to the cell pellet (the HOCl assays were carried out with cells as a pellet to simulate the conditions used for measuring the lysis). Third, the PMN-mediated RBC lysis was augmented by 5 mU/mL GO, per se virtually ineffective (Fig 4). The lysis was prevented by the MPO inhibitor azide as well as by the HOCl-trapping agent taurine (Fig 4). In addition, 5 mU/mL GO enhanced the recovery of HOCl from the PMN-RBC system by 46.9% + 5.2% ($\bar{x} \pm 1$ SD, n = 3), against an expected value of 55% (value calculated on the basis of the regression line from Fig 3 by using the extent of the RBC lysis by PMNs plus GO as known variables).

Table 3. Recovery of HOCl From OPZ-Triggered PMNs and/or MDCs in the Presence and in the Absence of Catalase

Assay Conditions*	HOCl Recovery†
PMNs	15.6 ± 1.9
MDCs	0

DISCUSSION

In our model system as reported elsewhere[6] and herein confirmed by probing cytolysis with chemical agents, the RBC lysis by PMNs requires HOCl production via the MPO-catalyzed oxidation of chloride ions by H_2O_2. Although the cytolysin or cytolysins actually operative remain to be identified,[11,20,21] the extent of the lysis strictly correlates with the amount of HOCl generated by PMNs, at least under our experimental conditions (the present paper and Dallegri et al[6]). Consistent with this view, MPO-negative MDCs incapable of generating HOCl did not cause lysis unless supplemented with MPO activity from a super-

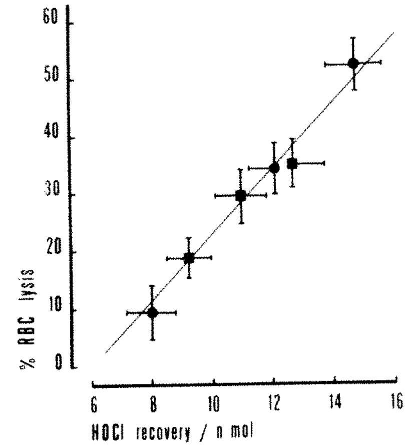

Fig 3. Positive linear relationship ($P < .01$) between the RBC lysis mediated by PMNs (●) and PMNs plus MDCs (■) (data from Figs 1 and 2) and the HOCl recovery (nmol/20 min) from PMNs (●) and PMNs plus MDCs (■) in presence of RBC targets (as for the lytic assays, the number of RBCs was kept constant, 2 × 10^6). Each point represents $\bar{x} \pm 1$ SD of at least three experiments. Regression line, y = 5.436 × −31.266.

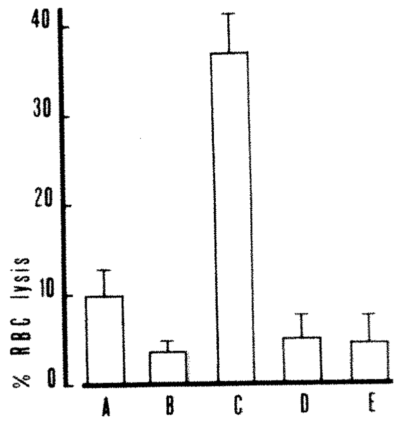

Fig 4. Effect of GO on the RBC lysis by OPZ-triggered PMNs. The ordinate shows the percent lysis by (A) 0.25 × 10^6 PMNs, (B) 5 mU/mL GO, (C) 0.25 × 10^6 PMNs plus 5 mU/mL GO, (D) 0.25 × 10^6 PMNs plus 5 mU/mL GO plus 1 mmol/L azide, and (E) 0.25 × 10^6 PMNs plus 5 mU/mL GO plus 20 mmol/L taurine. The number of RBCs is 10^6/well. Results are expressed as $\bar{x} \pm 1$ SD of three experiments.

natant of the PMN granule fraction (unpublished observations). Nevertheless, they efficiently augmented both HOCl recovery from the PMN-RBC lytic system and the HOCl-dependent lysis.

A series of interconnected events underlies the expression of the observed MDC "helper" activity. After the interaction between the PMN surface and OPZ, a plasmalemma-associated NADPH oxidase system is activated in the area of PMN-OPZ contact,[22] with consequent H_2O_2 production. The generated H_2O_2 is released directly into the extracellular fluid until the OPZ particle is completely engulfed. Part of this H_2O_2 can probably undergo backdiffusion into PMNs themselves.[23] At the luminal surface of the phagosomal membrane, which is derived from the plasmalemma, H_2O_2 production continues,[24] and the generated H_2O_2 can diffuse into PMN cytoplasm and outside the cell.[25] The net amount of H_2O_2 released extracellularly (extracellular H_2O_2 pool) represents that fraction of H_2O_2 synthesized and not used by PMN catabolic pathways in different subcellular compartments, including MPO within phagosomes[5,21] and the catalase and glutathione cycle within the cytosol.[26-28] Although discrepancies exist among different authors,[13,29] in our setting the extracellular H_2O_2 pool is likely to be transformed entirely into HOCl by the MPO released into the medium or absorbed to the PMN surface. In fact, HOCl production by OPZ-triggered PMNs could not be augmented by adding an appropriate surplus of MPO activity, which suggests that the H_2O_2 available for the chlorinating reaction is entirely used by the released MPO. Moreover, HOCl production could not be augmented by biochemical (GO) or cellular (MDCs) extra sources of H_2O_2, which suggests that the amount of MPO released functions at a maximum rate without a potential reserve of activity. Thus, it appears that OPZ-triggered PMNs produce a definite amount of HOCl by releasing MPO and H_2O_2 via a process so balanced that excesses of MPO and H_2O_2 are virtually absent or, if present, trivial at least under our conditions (pH, Cl^- concentration, temperature). Although the H_2O_2 released and transformed into HOCl represents a relatively small fraction of the total amount of H_2O_2 produced (Nauseef et al,[26] Test and Weiss,[27] and unpublished observations) and is generally assumed to be in dynamic equilibrium with the remainder (primarily dissipated by the PMN catabolic pathways mentioned earlier), it can be expected that the addition of extra H_2O_2-consuming pathways to the PMN microenvironment can perturb the equilibrium of the system so much that subsequent HOCl production is impaired. RBCs added to OPZ-triggered PMNs to make up a complete cytolytic system reduce the HOCl production by consuming H_2O_2 primarily via catalase (Dallegri et al,[6] Test and Weiss,[27] and the present paper). Such a consumption of H_2O_2, which results in a relative impairment of HOCl-dependent PMN lytic efficiency,[6] is likely to take place within RBC targets before lysis. In fact, the PMN-delivered lethal hit and the RBC catalase–mediated impairment of the lysis occur during the first 45 minutes of incubation when target cells are still "viable" (changes in the final extent of the lysis could not be detected when exogenous catalase was added to block the lytic pathway 45 minutes after the start of the incubation period, lysis at this time being virtually absent; unpublished observations). This is consistent with results obtained by other authors in a different system[30] and with the fact that H_2O_2, having a relatively low reactivity and no charge, can diffuse away from its sites of formation and across cell membranes easily.[31] Although attempts to directly measure the actual size of the extracellular H_2O_2 pool in our cytolytic system with cells as a pellet (without adding extra H_2O_2-consuming pathways, for instance, HRP) are presently hampered by the nonexistence of a reliable H_2O_2 assay, the results herein reported provide inferential evidence that the reduction of the PMN extracellular H_2O_2 pool by RBC catalase and the reconstitution of this pool by MDCs are crucial to MDC-mediated augmentation of PMN HOCl production and, in turn, lysis. This is suggested by different findings. First, neither HOCl recovery nor the extent of the lysis could be augmented by MDCs after inhibition of the RBC H_2O_2–consuming capacity, ie, using RBC^{AT} as targets. Second, enhancement of HOCl production by MDCs in the PMN-RBC system could be reproduced by substituting an appropriate amount of reagent catalase for RBCs in the system. Third, MDC-dependent enhancement of both HOCl recovery from the PMN-RBC system and PMN-mediated lysis could be reproduced by replacing MDCs with an appropriate H_2O_2-generating enzymatic system (GO, Fig 4) or H_2O_2-generating, granule-depleted PMN cytoplasts obtained as described by Roos et al[32] and unpublished observations). Fourth, the "final" events occurring in our system in the presence and in the absence of MDCs (amount of HOCl produced and extent of the lysis) strictly correlate (Fig 3). Thus, on the basis of these observations coupled with the evidence that MDCs are per se cytolytically ineffective and with the results obtained by probing the lytic systems with chemical agents, we conclude that (*a*) MDCs amplify the lysis by improving HOCl production, presumably via an effective restoration of the extracellular H_2O_2 pool generated by PMNs and depleted by RBCs; and (*b*) if present, the intervention of nonoxidative cytolytic factors, released by MDCs and capable of contributing to the lysis,[33] would be trivial at least under the present conditions. In addition, the involvement of PMN-directed cytokines released by MDCs and capable of increasing the HOCl production can be ruled out because MDCs did not affect the HOCl recovery from PMNs in absence of RBCs. Similarly, the possibility that MDCs may act by releasing NH_4^+, which favors NH_2Cl formation ($NH_4^+ + HOCl \rightarrow NH_2Cl + H_2O + H^+$),[34] can be ruled out because exogenous NH_4^+ inhibited the lysis in the PMN-RBC system thus suggesting that lytic levels of NH_2Cl cannot be reached in our conditions. Finally, because MDCs had no effect when added to the PMN-RBC^{AT} system, it is unlikely that they act by sensitizing RBC targets to the PMN-delivered, HOCl-mediated attack.

In conclusion, it has been reported that macrophages ingesting effete PMNs or granules from PMNs become capable of mediating MPO-dependent iodination.[35] Further, macrophages can use eosinophil peroxidase (EPO) to enhance their microbicidal or cytolytic activity.[36-38] These results have suggested a way by which MPO-negative and MPO-positive phagocytes can interact synergistically in exerting certain effector functions. Nevertheless, the aforementioned experiments were performed with cellular debris or purified cellular components (EPO, MPO). In the present study using two complete viable cellular systems, ie, PMNs and MPO-negative MDCs, we attained direct evidence for cooperation between two distinct populations of phagocytes in mediating cytolysis. Although speculative, the present use of MDCs as a model raises the possibility that macrophages at inflammatory sites may interact with neutrophils to increase the local HOCl production and, in turn, the injury of surrounding tissue cells. This might be only one of the events amplified by macrophages and relevant to the outcome of the inflammatory process. In fact, aside from the role in promoting cytolysis, phagocyte-derived HOCl and/or its chlorinated derivatives have recently been recognized to mediate a variety of biologic effects, either protective or harmful to the host,[21,39] ranging from the destruction of microorganisms[40] and modulation of lymphocyte function[41] to the inhibition of antiproteinase activities[42] and inactivation of chemotactic factors.[43]

Expression of Myelomonocytic Antigens on Chronic Lymphocytic Leukemia B Cells Correlates With Their Ability to Produce Interleukin 1

By Fortunato Morabito, Edgar F. Prasthofer, Nancy E. Dunlap, Carlo E. Grossi, and Arabella B. Tilden

We analyzed the expression of myelomonocytic-associated antigens on lymphocytes from B cell chronic lymphocytic leukemia (B-CLL) patients. Blood mononuclear cells were depleted of monocytes by one-step Percoll density gradient centrifugation and tested for antigen expression by fluorescent microscopy and flow cytometry. The reactivity of patient lymphocytes was as follows: 26 of 31 were positive for CD14 (Myr), 22 of 31 for a monocyte Fc receptor (MFC-1), 22 of 31 for CD11b (C3bi receptor), eight of 31 for CD15 (Leu-M1), five of 18 for CD13 (My 7), seven of 18 for My 9, and five of 30 for Mo 2. The B lymphocytes of B-CLL patients were also tested for the ability to produce interleukin 1 (IL-1) after depletion of monocytes and T lymphocytes. In 13 of 17 cases, B lymphocytes of patients produced IL-1 as detected in a mouse thymocyte proliferation assay and, in selected cases, a radioimmunoassay specific for IL-1_β. The 13 cases that produced IL-1 were also positive for the expression of one or more myelomonocytic-associated antigens, whereas the four cases that did not produce IL-1 lacked expression of these antigens. In conclusion, the malignant B cells of B-CLL patients frequently express a variety of antigens generally considered specific for myelomonocytic cells, and expression of these antigens is associated with the ability to produce IL-1.

THE CLONAL ORIGIN of B cell chronic lymphocytic leukemia (B-CLL) is well established,[1-4] and various degrees of B cell maturation have been consistently detected among clones from different patients as well as among cells of each individual clone.[5-8] Differences in the expression of some surface antigens and receptors exist between B-CLL cells and resting, mature peripheral blood B cells. Notably, B-CLL cells express the 67-kd glycoprotein CD5 recognized by the monoclonal antibodies Leu-1 and OKT1.[9-11] This marker is found on all T cells but is absent from most B cells from adult blood and tissues, with the exception of a minority of B cells localized in the follicles of lymphoid tissues.[12] In contrast, CD5 is frequently detected on fetal B cells and in the early phase of B cell reconstitution after bone marrow transplantation.[13,14] Altogether, these data suggest that the normal counterpart of B-CLL cells is an immature B cell. Other surface determinants unrelated to normal B cell lineage have been found on B-CLL cells such as antigens revealed by anti–T cell heteroantisera[15]; Leu-8–TQ1, an antigen previously thought to be restricted to cells of T lineage[16]; and sheep erythrocyte receptors, commonly, but not always related to antisheep erythrocyte activity of the monoclonal surface immunoglobulin.[17-20]

The finding of myeloid lineage markers on malignant lymphoblasts has been quite frequent in acute leukemia, which raises the issue of lineage infidelity or promiscuity.[21-28] In contrast, myeloid marker expression on malignant cells from chronic leukemia patients has not been described, with the exception of C3bi (CR3) receptors (CD11b), which have been detected on B-CLL cells[29] and, more commonly, on hairy cells.[30] In this respect, it is of note that CD11b is also found on cells with the T-helper[31] and T-suppressor[32] phenotypes and on a large proportion of natural killer (NK) cells.[33] B-CLL cells may share functional properties with myelomonocytic cells and NK cells, namely, the ability to produce and release interleukin 1 (IL-1).[34-37]

In this study we show that, in addition to CD11b, other myelomonocytic markers are frequently expressed on B-CLL cells and that the presence or absence of these markers correlates with their ability or inability to produce IL-1.

MATERIALS AND METHODS

Patient population. Thirty-one patients with B-CLL were diagnosed on the basis of clinical, morphological, and immunologic criteria. All patients had WBC counts ranging from 11 to 200 × $10^3/\mu L$ (85% to 95% lymphocytes). Hematologic data and surface marker analyses of the malignant cells are shown in Table 1. Eleven patients had not received treatment for their disease; the remainder had been treated discontinuously with chlorambucil and prednisone but were free of therapy for a month or longer before study. Blood samples for these studies were obtained after informed consent.

Phenotypic analysis of B-CLL cells. Peripheral blood mononuclear cells were separated on Ficoll-Hypaque (Pharmacia Fine Chemicals, Piscataway, NJ) and depleted of monocytes by one-step density gradient centrifugation on 50.6% Percoll (Pharmacia) in RPMI 1640.[38] This monocyte-depleted cell fraction was used for phenotypic analyses with monoclonal antibodies obtained from Becton Dickinson (Mountain View, CA) (Leu-1, Leu-5, Leu-M1, HLA-DR), Coulter Immunology (Hialeah, FL) (B1, B4, Mo1, Mo2, My4, My7, My9) and Ortho Pharmaceutical Corp (Raritan, NJ) (OKM1). The MFC-1 monoclonal antibody was produced in our laboratory. The specificities of these antibodies are shown in Table 2. Monoclonal antibody binding was assessed by indirect immunofluorescence using an affinity-purified, fluorescein isothio-

cyanate (FITC)-labeled goat antimouse immunoglobulin antiserum (Southern Biotechnology Associates, Birmingham, AL) as a secondary reagent. Nonspecific staining was assessed with irrelevant, FITC-conjugated mouse IgG1 and IgG2a antibodies (Becton Dickinson) and with the FITC-labeled secondary reagent alone. Before staining with monoclonal antibodies, the cells were incubated with aggregated Ig to block binding to Fc receptors. This procedure was followed with all monoclonal antibodies except MCF-1, which is specific for the 66 to 68-kd Fc receptor of IgG.[48] Two-color immunofluorescence was performed by using phycoerythyrin (PE)-conjugated My4 (Coulter) and FITC-conjugated Leu-16 (Becton Dickinson). Cell samples were analyzed by flow cytometry (FACS-Analyzer, Becton Dickinson) and by fluorescence microscopy.

patients were first depleted of monocytes by one-step Percoll gradients[38] and then depleted of T cells by rosetting with 2-aminoethylisothiouronium–treated sheep erythrocytes.[52] The resulting B-CLL cell suspensions consistently contained <1% T cells and <2% monocytes as determined by morphological and cytochemical criteria.[53]

As a control for IL-1 production, monocytes were isolated from the mononuclear cells of ten normal subjects by one-step Percoll gradients.[38] The B-CLL cell preparations and monocytes from healthy donors were cultured at 5×10^5 cells/mL in RPMI 1640 medium with 5% fetal calf serum (FCS) in round-bottomed culture tubes. Each cell suspension was cultured with culture medium alone, with 2 μg/mL lipopolysaccharide (LPS, *Escherichia coli*, Sigma Chemical Co., St Louis), and LPS with the addition of 1 μg/mL indomethacin (Sigma). After a 24-hour incubation at 37°C in a humidified atmosphere with 5% CO_2, culture supernatants were harvested after centrifugation and stored at −70°C until assay for IL-1 activity or prostaglandin E_2 (PGE_2) levels.

The IL-1 activity of supernatants was determined by a mouse thymocyte proliferation assay as described.[54] Thymic cell suspensions were obtained from 4- to 8-week-old C3H/HeJ mice, suspended in RPMI 1640 medium supplemented with 3% FCS and 2×10^{-5} mol/L 2-mercaptoethanol, and plated at 1.5×10^6 thymocytes/well in 96-well flat-bottomed plates. Dilutions of test supernatants were added to triplicate wells with and without the addition of a submitogenic concentration of phytohemagglutinin (PHA, Wellcome Reagents, Durham, NC) to reach a final volume of 200 μL/well. Cultures were incubated for 72 hours at 37°C and pulsed with 0.5 μCi/well of ^{3}H-thymidine (^{3}H-TdR) ten hours before harvesting on a multiple automated sample harvester. The ^{3}H-TdR uptake was determined by β-scintillation counting. IL-1 activity is reported as counts per minute of thymocyte cultures containing test supernatants and PHA minus the counts per minute of thymocyte cultures with test supernatants alone. Some supernatants were also analyzed for levels of IL-1_β by radioimmunoassay (RIA) (Cistron Biotechnology, Pine Brook, NJ).

Supernatants were analyzed for levels of PGE_2 by RIA as described previously.[55]

*Surface marker analyses were determined on monocyte-depleted peripheral blood lymphocytes by both FACS and immunofluorescence microscopy. Positivity (+) is indicated when >40% of cells were stained by the specific marker.

RESULTS

Thirty-one patients with B-CLL were studied and classified according to the Rai clinical staging system (Table 1). Although 52% of the patients had received prior treatment, we detected a high percentage of circulating monoclonal B lymphocytes in these cases, as shown by the expression of CD19, CD20, and HLA-DR determinants and the restriction to a single light-chain surface immunoglobulin. In some cases, immunoglobulin was undetectable on the cell surface. The B-CLL cells of 29 to 31 patients expressed CD5, the p67 antigen that is detected on a subpopulation of normal and neoplastic B lymphocytes.[9-11]

The expression of myelomonocytic-associated antigens on B-CLL lymphocytes was analyzed with a panel of monoclonal antibodies, the specificity of which is listed in Table 2. Lymphocytes from most of the patients expressed the CD14 antigen (My4), whereas the expression of CD13 (My7) and My9 deteminants was not as common (Table 3). The CD15 antigen recognized by Leu-M1 was also expressed on approximately 20% of patient cell samples. Finally, in 22 of 31 patients, the lymphocytes expressed C3bi or Fc receptors, not necessarily coincidentally, as shown by their reactivity with OKM1 or MFC-1 monoclonal antibodies. The FACS profiles of B-CLL cells stained for a B cell and a monocytic antigen from three representative patients are shown in Fig 1. The top and middle rows illustrate the equivalent CD19 and CD14 reactivity on lymphocyte preparations from two patients. The bottom row shows the FACS profiles of lymphocytes from a patient whose malignant cells lacked CD14. Several cases were studied by two-color immunofluorescence to directly demonstrate coexpression of the myelomonocytic marker (CD14) and the B cell marker (CD20) on the same population of cells. A representative contour plot is shown in Fig 2 where 80% of the lymphocytes were positve for both CD14 and CD20. The specificity of binding was assessed by incubating lymphocytes with irrelevant FITC-conjugated mouse IgG1 and IgG2a monoclonal antibodies and with FITC-conjugated goat antimouse immunoglobulin alone. In all cases, lymphocytes were negative for immunofluorescence after these treatments.

B lymphocytes from 17 B-CLL patients were tested for IL-1 production. Mononuclear cells from these patients were depleted of monocytes and T lymphocytes and cultured for 24 hours in the absence or presence of LPS and LPS with indomethacin (Table 4). Monocyte-enriched populations

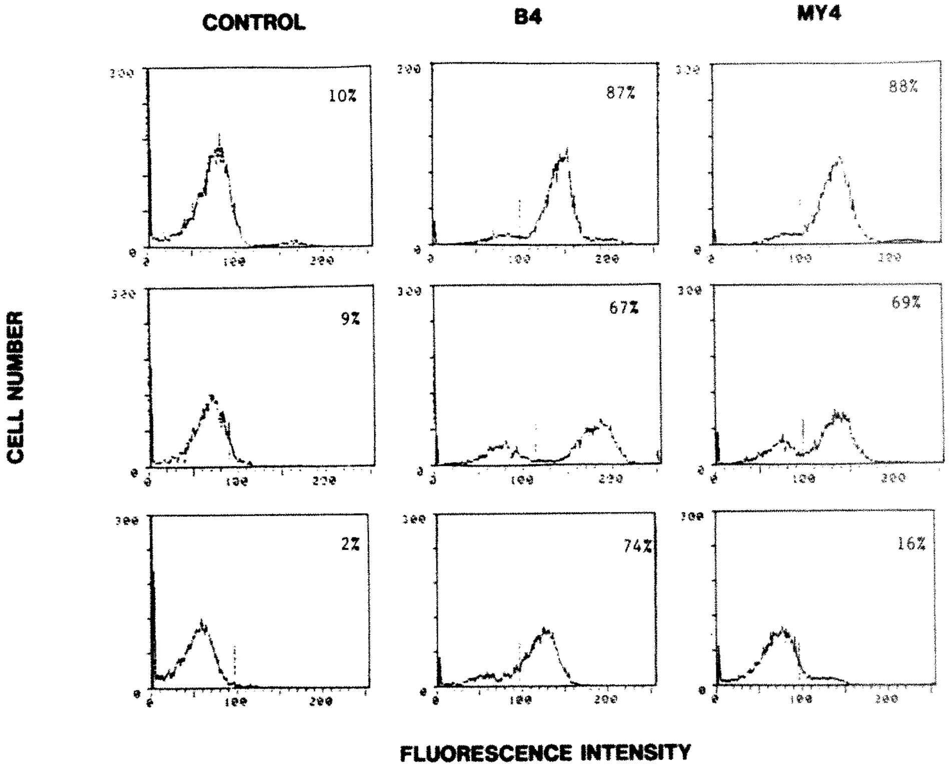

Fig 1. FACS-Analyzer profiles demonstrating expression of a B cell antigen (B4, CD19) and a monocytic antigen (My4, CD14) on B-CLL cells from three representative patients. In cases illustrated in the top and middle rows the distribution of cells coexpressing the two antigens is virtually identical. Cells from the patient illustrated in the bottom row express CD19 but not CD14.

from ten normal subjects were used as positive controls for IL-1 production. B lymphocytes from most of the patients studied spontaneously produced low levels of IL-1 as detected in a mouse thymocyte proliferation assay. LPS was able to enhance IL-1 production in all but four cases. We also assessed IL-1 activity in supernatants generated in the presence of both LPS and indomethacin, a prostaglandin synthetase inhibitor. Monocytes produce both IL-1 and PGE_2, and PGE_2 in culture supernatants can inhibit mouse thymocyte proliferation in the assay for IL-1 activity,[56] thus masking the actual levels of IL-1 produced by the cells as measured in this assay. Although the addition of indomethacin trebled the mean counts per minute of IL-1 activity in monocyte-LPS culture supernatants, it had little or no effect on IL-1 activity detectable in supernatants from most B-CLL lymphocyte cultures. Supernatants were also tested for PGE_2 levels by RIA (data not shown). Although monocyte culture supernatants generated with LPS had detectable levels of PGE_2 (usually 2 to 10 ng/mL), the addition of indomethacin reduced the amount of PGE_2 produced to <0.01 ng/mL. In contrast, LPS-stimulated B-CLL cell supernatants had <0.01 ng/mL PGE_2, with or without the addition of indomethacin.

Because the mouse thymocyte proliferation assay is not entirely specific for IL-1 but also can detect other mitogenic factors, we also tested for the presence of IL-1_β in a specific RIA. Culture supernatants from CD14+ B lymphocytes of six B-CLL patients were positive for IL-1 in both the mouse thymocyte proliferation assay and the IL-1_β-specific RIA.

We examined the relationship between myelomonocytic antigen expression and IL-1 production by LPS-stimulated B lymphocytes from B-CLL patients. Of the 17 cases studied for both parameters, four cases had little or no IL-1 production (<5,000 cpm) under any culture condition tested. These cases were also negative for all of the myelomonocytic antigens tested (CD14, CD13, My9) as well as for CD15, C3bi, and Fc receptor expression (Tables 3 and 4, patients no. 5, 7, 15, and 24). On the contrary, the 13 patients whose B lymphocytes produced moderate or high amounts of IL-1 activity as compared with monocytes were CD14 (My4)-positive and also randomly displayed other myelomonocytic markers. These associations are summarized in Table 5.

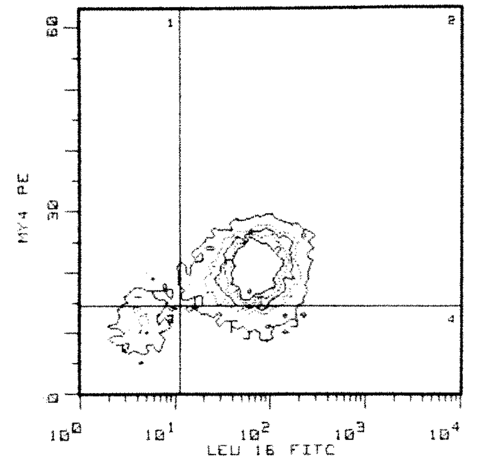

Fig 2. A FACS contour plot demonstrating coexpression of the B cell antigen CD20 (Leu-16) and the monocyte antigen CD14 (My4) on the same population. In this case 80% of the cells were positive for both antigens by two-color immunofluorescence, whereas 9% were positive for FITC-Leu-16 only and 3% were positive for PE-My4 only.

†Test supernatants were obtained from B-CLL cells or monocytes from healthy donors cultured in medium alone, with LPS, or with LPS and indomethacin as described in Materials and Methods.

DISCUSSION

In this study we have shown that, in a high percentage of cases, B-CLL cells bear surface C3bi receptors (CD11b) that are not found commonly on blood or tissue B cells. In addition they have a 66- to 68-kd Fc receptor for IgG similar to that of monocytes and express a variety of membrane antigens considered specific for myelomonocytic cells (most frequently My4/CD14) and not detected previously on malignant B cells.[46,47]

The presence of C3bi receptors on B-CLL cells is not completely unexpected because this determinant has been observed on hairy cells.[30] It is possible that, in addition to activated (hairy) B cells, CD11b is expressed on a small subset of blood or tissue B cells, possibly also CD5+. Sharing of similar Fc IgG receptors among cells of different lineages is also not unprecedented, as shown by the detection of CD16 on NK cells and granulocytes.[57] Also, some B cell lines, eg, SB, have been shown to have a low-density expression of the 66- to 68-kd monocyte Fc receptor on their surface.[58]

The variate but frequent expression of myelomonocytic lineage antigens on B-CLL cells provides another criterion to determine the phenotypic heterogeneity of the neoplastic cell clones in a disease characterized by a high degree of clinical uniformity. A correlation between expression of myelomonocytic markers and clinical stage of disease, white cell count, or previous treatment was not apparent. In contrast, an association was noted between the presence of these antigens and the ability of the cells to produce IL-1. Thus, aberrant antigens were, in these cases, good indicators of a functional characteristic of the neoplastic cells. B-CLL cells that were shown to be poor IL-1 producers (four of 17 cases) lacked all the myelomonocytic antigens tested as well as CD11b and the monocyte-associated 66- to 68-kd Fc receptor. The inability to produce IL-1 was unrelated to treatment because, in three of four cases, the patients had not received previous treatment and the monocytes were inefficient IL-1 producers in all four cases.

IL-1 production by normal peripheral blood B lymphocytes and B-CLL cells has been described previously.[34-37] Here we have shown that IL-1 production by B-CLL cells is increased after LPS stimulation and, in a few cases, further boosted by incubation with LPS and indomethacin. In three cases the addition of indomethacin produced a two- to threefold increase of IL-1 activity in the culture supernatants compared with that observed in the supernatants of cells incubated with LPS alone. This effect of indomethancin is probably not attributable to prostaglandin production by contaminating monocytes because the amount of PGE$_2$ pro-

Table 5. Relationship Between IL-1 Production and Myelomonocytic Markers on B Lymphocytes From 17 B-CLL Patients

IL-1 Activity*	Number of Cell Samples Reactive With Monoclonal Antibodies†							
	My4	My7	My9	Leu-M1	Mo2	Mo1	OKM1	MFC-1

*Mean counts per minute ± SD (range) of ^{3}HTdR uptake in thymocyte cultures containing 25% test supernatant (from LPS and indomethacin cultures) and PHA minus the counts per minute of cultures with test supernatant alone.

†Not all patients were studied with respect to My7 and My9 expression.

duced in cultures of both LPS and LPS+ indomethacin-stimulated B-CLL cells was very low. We have previously demonstrated that indomethacin can exert an immunomodulatory effect that is not related to the inhibition of prostaglandin synthesis.[55] Therefore it is possible that indomethacin exerted a direct effect on IL-1 production by B-CLL cells.

Neoplastic cells from lymphoid malignancies commonly express immunoglobulin and/or other surface antigens that allow lineage assignment and determination of the stage of maturation or activation.[4] However, mixed-lineage cell phenotypes (eg, lymphoid and myeloid) have been described in hematopoietic malignancies, particularly in acute lymphoblastic leukemia and in lymphoblastic crisis of acute myelogenous leukemia.[21-28] In several instances, this lineage infidelity is simply attributable to a lack of lineage specificity of the antigen tested, as is the case of CD15 (Leu-M1), a hapten that is expressed on myelomonocytic cells and on a variety of neoplastic cells of both hematopoietic and nonhematopoietic origin.[59-66] In other cases, a bona fide mixed phenotype can be determined, and this is reinforced by the finding of inappropriate gene rearrangements (eg, of Ig genes in malignant T lymphoblasts or of Ti_β genes in B cell malignancies).[67-74]

Several hypotheses have been proposed to explain these findings, and they are not mutually exclusive[28]: (*a*) the mixed-lineage phenotype may be a feature of early precursor cells, the extremely low frequency of which prevents identification in the normal; (*b*) the aberrant antigens may be transiently expressed during cell maturation and therefore escape recognition in the normally developing cell population; (*c*) a limited degree of cell promiscuity may precede lineage fidelity as a normal course of the differentiation events; and (*d*) the infidelity of gene expression may be a consequence of the neoplastic transformation. All these possibilities are related to early events during cell differentiation, and the malignant counterparts of early hematopoietic cells commonly produce an acute disease. This may explain the relatively rare finding of aberrant phenotypes in chronic leukemia compared with acute leukemia.

ACKNOWLEDGMENT

We are grateful to Jane Hamner for excellent secretarial assistance in the preparation of this manuscript.

Long-Term Monoclonal Reconstitution of Erythropoiesis in Genetically Anemic W/W^v Mice by Injection of 5-Fluorouracil–Treated Bone Marrow Cells of $Pgk\text{-}1^b/Pgk\text{-}1^a$ Mice

By Toru Nakano, Noriko Waki, Hidekazu Asai, and Yukihiko Kitamura

The spleen colony-forming assay does not represent the number of hematopoietic stem cells with extensive self-maintaining capacity because five to 50 spleen colony-forming units (CFU-S) are necessary to rescue a genetically anemic (WB X C57BL/6)F$_1$-W/W^v(WBB6F$_1$-W/W^v) mouse. We investigated which is more important for the reconstitution of erythropoiesis, the transplantation of multiple CFU-S or that of a single stem cell with extensive self-maintaining potential. The electrophoretic pattern of hemoglobin was used as a marker of reconstitution and that of phosphoglycerate kinase (PGK), an X chromosome–linked enzyme, as a tool for estimating the number of stem cells. For this purpose, we developed the C57BL/6 congeneic strain with the $Pgk\text{-}1^a$ gene. Bone marrow cells were harvested after injection of 5-fluorouracil from C57BL/6–$Pgk\text{-}1^b/Pgk\text{-}1^a$ female mice in which each stem cell had either A-type PGK or B-type PGK due to the random inactivation of one of two X chromosomes. When a relatively small number of bone marrow cells (ie, 10^3 or 3×10^3) were injected into 200-rad–irradiated WBB6F$_1$-W/W^v mice, the hemoglobin pattern changed from the recipient type (Hbb^d/Hbb^s) to the donor type (Hbb^s/Hbb^s) in seven of 150 mice for at least 8 weeks. Erythrocytes of all these WBB6F$_1$-W/W^v mice showed either A-type PGK alone or B-type PGK alone during the time of reconstitution, which suggests that a single stem cell with extensive self-maintaining potential may sustain the whole erythropoiesis of a mouse for at least 8 weeks.

© 1987 by Grune & Stratton, Inc.

THE HEMATOPOIETIC STEM CELL is characterized by extensive self-maintaining capacity and differentiation potential.[1,2] The hematopoietic cell that forms a macroscopic colony in the spleen of either lethally irradiated or genetically anemic W/W^v recipient mice (CFU-S) can differentiate into erythrocytes, granulocytes, megakaryocytes, macrophages,[2,3] and mast cells.[4,5] Therefore, the spleen colony method apparently represents the differentiation potential of the stem cell, but CFU-S are not necessarily considered to have extensive self-maintaining capacity.[6] The latter capacity has been estimated from the proportion of successfully reconstituted animals after transplantation of cell suspensions (presumably containing stem cells) into lethally irradiated or genetically anemic W/W^v recipient mice. For such a reconstitution assay, W/W^v mice are more suitable recipients than lethally irradiated mice because a considerable proportion of mice do not survive lethal irradiation and transplantation of a relatively small number of stem cells. On the other hand, histocompatible stem cells can be transferred to W/W^v mice without preceding lethal irradiation.[7-9]

Wiktor-Jedrzejczak et al[8] and Boggs et al[9] showed that five to 50 CFU-S were necessary to rescue the anemia of a W/W^v mouse. However, both groups of investigators did not determine which was more important, the quantity or the quality of stem cells. In other words, which was the more essential factor, the number of transplanted stem cells or the presence of a particular stem cell with extensive self-maintaining capacity in the injected cell suspension? To answer this question, we examined whether clonal reconstitution occurred after transplantation of a relatively small number of stem cells.

X chromosome–linked alloenzymes have been used as a marker to determine the number of stem cells from which blood cells originate.[10-13] Because of inactivation of one of the two X chromosomes in each somatic cell in females during embryogenesis, only one of two genes for the alloenzymes is active in any single somatic cells. Fialkow examined blood cells of women suffering from chronic myelocytic leukemia (CML) who were heterozygous for the X chromosome–linked gene for glucose-6-phosphate dehydrogenase (G6PD) and hence had two types of enzymatically different somatic cells.[10,11] Although both A- and B-type G6PD were found in normal tissues such as the skin of the CML patients, only a single-enzyme type was found in granulocytes, erythrocytes, and platelets of the patients, which suggests the clonal origin of CML. In mice, X chromosome–linked 3-phosphoglycerate kinase (PGK) alloenzymes can be used to investigate the clonal origin of blood cells.[12,13] In the present study, we developed the C57BL/6 congeneic strain with the $Pgk\text{-}1^a$ gene and used PGK heterozygous C57BL/6–$Pgk\text{-}1^b/Pgk\text{-}1^a$ female mice as donors of hematopoietic stem cells.

Because hematopoietic stem cells surviving a single injection of 5-fluorouracil (5FU) are reported to have more extensive proliferative potential than untreated stem cell populations,[14-16] we used bone marrow cells of 5FU-treated mice as a source of stem cells. When a relatively small number of bone marrow cells (ie, 10^3 or 3×10^3) from 5FU-treated female C57BL/6–$Pgk\text{-}1^b/Pgk\text{-}1^a$ mice were injected into 200-rad–irradiated (WB × C57BL/6)F$_1$-W/W^v (hereafter called WBB6F$_1$-W/W^v) mice, hemoglobin

pattern changed from the recipient type (*Hbb*^{d}/*Hbb*^{s}) to the donor type (*Hbb*^{s}/*Hbb*^{s}) for at least 8 weeks in seven of 150 mice. Erythrocytes of all these seven WBB6F$_1$-*W*/*W*^{v} mice showed either A-type PGK alone or B-type PGK alone, thereby suggesting that a single stem cell with extensive self-maintaining capacity may sustain the whole erythropoiesis of a mouse at least for 8 weeks.

MATERIALS AND METHODS

Mice. C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} and WBB6F$_1$-*W*/*W*^{v} mice were raised in our laboratory. The original stock of mice with the *Pgk-1*^{a} gene was introduced from Dr Vern M. Chapman, Roswell Park Memorial Institute, to the National Cancer Institute, Tokyo, by Dr Hiroshi Tanooka.[17,18] We obtained C3H mice with the *Pgk-1*^{a} gene from Dr Tanooka and introduced the *Pgk-1*^{a} gene to the C57BL/6 strain of our inbred colony by repeated backcrosses (11 backcrosses at the time of the present study). Because the original C57BL/6 strain has the usual-type PGK gene (*Pgk-1*^{b}), C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice were produced by mating C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{b} female mice with C57BL/6-*Pgk-1*^{a}/Y male mice. Resulting C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice were used as donors of bone marrow cells at 2 to 3 months of age. The A-type/B-type ratio of PGK in erythrocytes of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice is about 50/50.

Although the *W*^{v} mutant gene was derived from the Jackson Laboratory, Bar Harbor, ME, it is now maintained in our inbred C57BL/6 mouse colony.[19] The WB-*W*/+ strain, which was also obtained from the Jackson Laboratory, has been maintained by brother-sister mating. WBB6F$_1$-*W*/*W*^{v} mice that had been produced by a cross between WB-*W*/+ and C57BL/6-*W*^{v}/+ mice, were used as recipients at 4 months of age.

Hemoglobin of WBB6F$_1$-*W*/*W*^{v} mice (*Hbb*^{d}/*Hbb*^{s}) can be distinguished from that of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice (*Hbb*^{s}/*Hbb*^{s}) by electrophoresis.[20,21]

5FU treatment and bone marrow transplantation. 5FU (150 μg/g body weight) was injected intravenously to C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice; the mice were killed four days after the 5FU injection, and bone marrow cells were collected from at least five mice and suspended in Eagle's medium according to the method described previously.[22]

Recipient WBB6F$_1$-*W*/*W*^{v} mice were irradiated (200 rad) with a Shimadzu x-ray machine (180 kV and 20 mA, with a 2-mm Al filter, 50 rad/min) to facilitate the bone marrow reconstitution. Various numbers of bone marrow cells were injected through the lateral tail vein.

Assay of CFU-S. The method of Till and McCulloch[23] was used; the recipient WBB6F$_1$-*W*/*W*^{v} mice were killed eight or 14 days after the transplantation of bone marrow cells; spleens were removed and fixed in Bouin's solution, and colonies were counted with a dissection microscope (7×).

Sampling of blood. Mice were anesthetized with ether, and blood samples were obtained from the retroorbital sinus with heparinized microhematocrit tubes. Care was taken to remove small volumes (<50 μL) of blood to minimize possible hematologic stress. The microhematocrit tube was centrifuged, and the tube was cut beneath the level of the buffy coat; packed erythrocytes were divided into two parts; one part was used for examination of hemoglobin and another part for examination of PGK.

Examination of hemoglobin. Electrophoresis of hemoglobin was done after modification with cystamine according to the method described by Whitney[21]; the hemoglobin pattern was determined visually by using known mixtures as standards. By this method, hemoglobin of WBB6F$_1$-*W*/*W*^{v} mice (*Hbb*^{d}/*Hbb*^{s}) mixed with hemoglobin of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice (*Hbb*^{s}/*Hbb*^{s}) is detectable if the former contributes ≧5% of the total. We assumed that WBB6F$_1$-*W*/*W*^{v} recipient mice were reconstituted by bone marrow cells of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice only when the hemoglobin pattern of the former could not be distinguished from that of the latter. In other words, >95% of erythrocytes in the reconstituted WBB6F$_1$-*W*/*W*^{v} mice were derived from the bone marrow of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice.

Electrophoresis of PGK. Small pieces of filter paper were soaked with blood samples and placed in small plastic tubes; the tubes were kept at −80°C. The PGK pattern of erythrocytes was examined only when WBB6F$_1$-*W*/*W*^{v} recipient mice were assumed to be reconstituted by bone marrow cells of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice. After thawing, pieces of filter paper with blood samples were inserted into the gel plate. The electrophoresis was carried out on a gel plate (10 × 20 cm) of starch (Wako Chemical Co, Tokyo) for 17 hours at 5 V/cm and 4°C according to the method described by Tanooka and Tanaka.[18] The gel plates were then cut into two slices and PGK was detected as nonfluorescent spots due to conversion of NADH to NAD in the PGK assay system. The spot of A-type PGK was usually 6 cm from the origin, and that of B-type was 4 cm from the origin. According to the report of Reddy and Fialkow,[24] the relative activity of PGK alloenzymes was estimated visually by using known mixtures as standards. With this technique, a minor population in a mixture of blood is detectable if it contributes ≧5% of the total PGK activity.

The proportion of A-type PGK in serial blood samples was plotted as the deviation of individual samples from the percentage of A-type PGK in C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice according to Burton et al.[12] Therefore, +50% indicated that only A-type PGK was present, 0% that A-type PGK and B-type PGK were equally mixed, and −50% that only B-type PGK was present.

Limiting-dilution analysis. The principle of the method has been described by Porter and Berry,[25] Breivik,[26] and Boggs et al,[9] and briefly it was carried out as follows. Random samples from a homogeneous cell population were assayed for the presence or absence of stem cells. Such cells should be distributed among samples in a Poisson fashion. The finite probability that a sample will not contain a stem cell is defiend by $P_{(0)} = e^{-\phi x}$ where ϕ is the fraction of stem cells in the sample of x cells. P is the proportion of samples devoid of stem cells and estimates $P_{(0)}$. The concentration of stem cells in the sample can then be expressed as $\phi = -\ln P/x$.

RESULTS

First, we confirmed the effect of 5FU treatment in the present experimental condition; bone marrow cells from 5FU-treated and control C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice were injected into 200-rad–irradiated WBB6F$_1$-*W*/*W*^{v} mice. The recipient mice were divided into two groups; one group of mice was killed on day 8 and the other group on day 14. The 5FU treatment decreased the number of bone marrow cells from about 25 × 10^{6}/femur to about 2 × 10^{6}/femur but increased the day 14 to day 8 ratio of spleen colonies as reported by Hodgson and Bradley[14] and van Zant[16] (Table 1). Because hematopoietic stem cells that form day 14 colonies are considered to have more extensive proliferative potential than those that form day 8 colonies,[6] we used bone marrow cells of 5FU-treated mice throughout the present study.

Because we injected as few as 10^{3} 5FU-treated bone marrow cells in the next experiment, we confirmed the number of CFU-S in such a small number of 5FU-treated bone marrow cells of C57BL/6-*Pgk-1*^{b}/*Pgk-1*^{a} mice. As shown in Table 1, 10 × 10^{3} cells contained ~2.2 day 14 CFU-S and 2 × 10^{3} cells, ~0.4 day 14 CFU-S.

*Bone marrow cells were obtained from C57BL/6–*Pgk-1^b/Pgk-1^a* mice that had been injected with 5FU (150 μg/g body weight) four days before sacrifice.

†The number of recipients is shown in parenthesis.

Various numbers of bone marrow cells from 5FU-treated C57BL/6–*Pgk-1^b/Pgk-1^a* mice were injected into 200-rad–irradiated WBB6F$_1$-*W/W^v* mice; the hemoglobin pattern of the recipients was examined at 4-week intervals. When the hemoglobin pattern of WBB6F$_1$-*W/W^v* recipient mice (*Hbb^d/Hbb^s*) changed to pure *Hbb^s/Hbb^s*, the PGK pattern of erythrocytes was also examined.

In total, 303 WBB6F$_1$-*W/W^v* mice survived at least 16 weeks after bone marrow transplantation; in eight WBB6F$_1$-*W/W^v* mice, a pure *Hbb^s/Hbb^s* hemoglobin pattern was detected only at one observation time (transient reconstitution in Table 2, Fig 1), whereas pure *Hbb^s/Hbb^s* pattern was maintained at least during 8 weeks (ie, three observation times) in 48 WBB6F$_1$-*W/W^v* mice (long-term reconstitution in Table 2, Fig 2).

In 8 WBB6F$_1$-*W/W^v* recipient mice that showed transient reconstitution, erythrocytes of five mice showed either A-type PGK or B-type PGK, whereas erythrocytes of the remaining three mice showed AB-type PGK at the time of transient reconstitution. When transient reconstitution was lost (ie, hemoglobin pattern returned to *Hbb^d/Hbb^s*), the PGK pattern of erythrocytes also returned to type B in all aforementioned eight WBB6F$_1$-*W/W^v* mice.

WBB6F$_1$-*W/W^v* mice that were reconstituted by bone marrow cells of C57BL/6–*Pgk-1^b/Pgk-1^a* mice for a long term were divided into three groups by using the PGK pattern of erythrocytes as a criterion. In group 1, erythrocytes showed either A- or B-type PGK throughout the time of reconstitution. The reconstitution continued until the end of the observation period (40 weeks) or death in six of seven mice that belonged to group 1 (Fig 2A). In the remaining one WBB6F$_1$-*W/W^v* mouse, the hemoglobin pattern came back to *Hbb^d/Hbb^s* 28 weeks after bone marrow transplantation (Fig 2B). In group 2, erythrocytes showed AB-type PGK when the change of hemoglobin pattern to pure *Hbb^s/Hbb^s* was first detected. Then, the PGK pattern changed to either type A or B (Fig 2C). In group 3, erythrocytes showed AB-type PGK throughout the time of reconstitution (Fig 2D). In some mice of group 3, the type A–to–type B ratio of PGK was not always constant but fluctuated from time to time (Fig 2D). The distribution of WBB6F$_1$-*W/W^v* recipient mice among the aforementioned three groups was apparently influenced by the number of injected bone marrow cells (Table 3). All WBB6F$_1$-*W/W^v* mice that received 10^3 or 3 × 10^3 bone marrow cells from 5FU-treated C57BL/6–*Pgk-1^b/Pgk-1^a* mice belonged to group 1, whereas all WBB6F$_1$-*W/W^v* mice that received ≧50 × 10^3 cells belonged to groups 2 or 3.

We calculated the concentration of stem cells that may reconstitute the whole erythropoiesis of WBB6F$_1$-*W/W^v* mice for a long term by using limiting-dilution analysis. From data shown in Table 2, we calculated the proportion of

Table 2. Number of WBB6F$_1$-*W/W^v* Mice (*Hbb^d/Hbb^s*) in Which a Transient or Long-term Change of Hemoglobin Pattern Was Observed After Injection of Various Numbers of Bone Marrow Cells From 5FU-Treated C57BL/6–*Pgk-1^b/Pgk-1^a* Mice (*Hbb^s/Hbb^s*)

No. of Cells (× 10^3)	No. of Mice	No. of Mice in Which Hemoglobin Pattern Changed (%) Transient	Long-term	Total
1	65	0 (0)	3 (5)	3 (5)

75	30	0 (0)	11 (37)	11 (37)
100	21	0 (0)	11 (52)	11 (52)

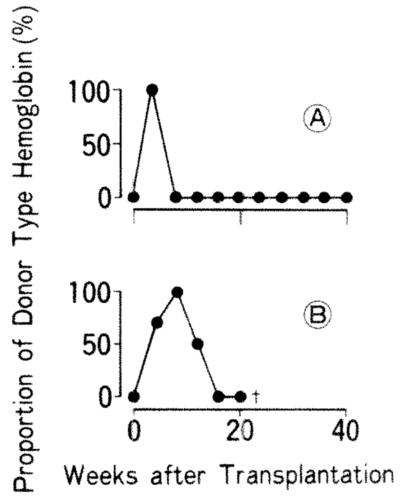

Fig 1. Typical cases of transient reconstitution. Electrophoretic pattern of hemoglobin of WBB6F$_1$-*W/W^v* mice (*Hbb^d/Hbb^s*) changed to the donor type (*Hbb^s/Hbb^s*) at 4 weeks (A) or 8 weeks (B) after the injection of bone marrow cells from 5FU-treated C57BL/6–*Pgk-1^b/Pgk-1^a* mice; 10 × 10^3 cells were injected in A and 3 × 10^3 cells in B.

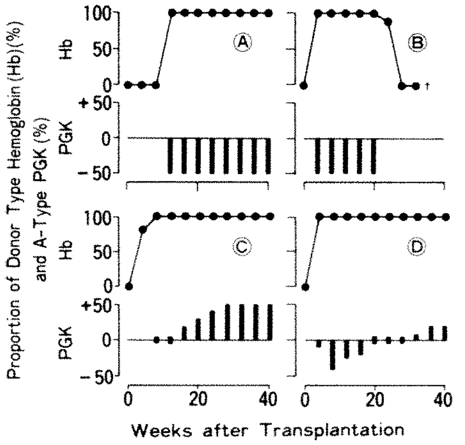

Fig 2. Typical cases of long-term reconstitution. Proportions of donor-type hemoglobin and A-type PGK are shown. The data of the proportion of A-type PGK for each mouse are plotted as the deviation of individual samples from the percentage of A-type PGK in C57BL/6–*Pgk-1*^{b}/*Pgk-1*^{a} mice according to Burton et al.[12] Therefore, +50% indicates that only A-type PGK is present, 0% that A-type PGK and B-type PGK were equally mixed, and −50% that only B-type PGK is present. (A) The WBB6F$_1$-*W*/*W*^{v} mouse was injected with 10^3 bone marrow cells from 5FU-treated C57BL/6–*Pgk-1*^{b}/*Pgk-1*^{a} mice. Erythrocytes showed B-type PGK alone throughout the observation periods (group 1). (B) The reconstitution ended at 28 weeks after the injection of 3 × 10^3 cells (group 1). (C) Erythrocytes showed both A-type and B-type PGK when hemoglobin first changed to the donor type at 8 weeks after the injection of 75 × 10^3 bone marrow cells. The PGK pattern changed to type A (group 2). (D) The WBB6F$_1$-*W*/*W*^{v} mouse received 50 × 10^3 bone marrow cells. Although erythrocytes showed both A-type and B-type PGK throughout the observation period, the proportion of A-type PGK fluctuated gradually (group 3).

WBB6F$_1$-*W*/*W*^{v} mice in which long-term complete reconstitution of erythropoiesis did not occur after bone marrow transplantation (proportion of unsuccessful transplantation), and plotted this against the number of injected cells (Fig 3). A straight line was obtained ($P < .01$ by χ^2 test) that intercepted the ordinate at 0.96. Therefore, the proportion of unsuccessful transplantations may be used to estimate the fraction of stem cells in 5FU-treated bone marrow cells. The slope of the line in Fig 3 is the estimate of the fraction of stem cells. Calculation of its 95% confidence limits was carried out according to the method described by Porter and Berry[25] and Breivik.[26] The concentration of such a stem cell that may reconstitute the whole erythropoiesis for a long term was 0.7 (95% confidence limits, 0.6 to 0.9) per 10^5 5FU-treated bone marrow cells.

Table 3. PGK Type of Erythrocytes in WBB6F$_1$-*W*/*W*^{v} Mice (*Hbb*^{d}/*Hbb*^{s}) in Which the Hemoglobin Pattern Changed to the Donor Type (*Hbb*^{s}/*Hbb*^{s}) for at Least 8 Weeks

No. of Bone Marrow Cells Injected (× 10^3)	No. of Mice at the Following PGK Type			
	Throughout A or Throughout B	AB to A or AB to B	Throughout AB	Total
1	3	0	0	3
3	4	0	0	4
10	0	0	2	2
30	1	0	5	6
50	0	6	5	11
75	0	6	5	11
100	0	4	7	11

This is the same experiment as shown in Table 2.

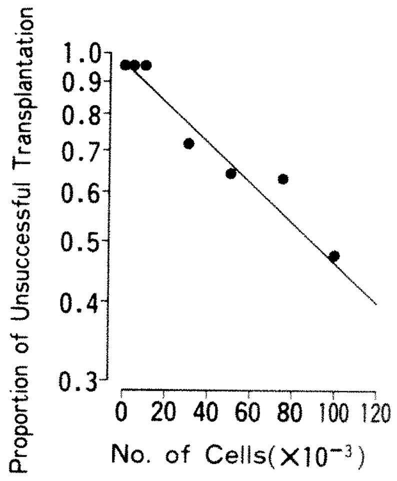

Fig 3. Proportion of WBB6F$_1$-*W*/*W*^{v} mice in which the hemoglobin pattern changed to the donor type for at least 8 weeks after the injection of various numbers of bone marrow cells from 5FU-treated C57BL/6–*Pgk-1*^{b}/*Pgk-1*^{a} mice. The logarithmic regression line is described by the equation $\ln P = -0.69 \times 10^{-5} x - 0.04$. The slope of this line gives an estimate of the fraction of stem cells with extensive self-maintaining potential among injected bone marrow cells.

DISCUSSION

When bone marrow cells of 5FU-treated C57BL/6–*Pgk-1*^{b}/*Pgk-1*^{a} mice were injected into 200-rad–irradiated WBB6F$_1$-*W*/*W*^{v} mice, the donor-type hemoglobin pattern (*Hbb*^{d}/*Hbb*^{s}) was detectable either transiently or for a long term (at least 8 weeks). Although the proportion of WBB6F$_1$-*W*/*W*^{v} mice with the long-term reconstitution increased in parallel with the number of injected bone marrow cells, transient reconstitution did not occur when ≧75 × 10^3 bone marrow cells were injected. Transient reconstitution probably results from lodgment and differentiation of stem cell(s) with limited proliferative potential, whereas the long-term reconstitution may be attributable to the successful transplantation of stem cell(s) with extensive proliferative potential. When comparably large numbers of bone marrow cells were injected, the probability that both types of stem cells were successfully transplanted might increase. In such cases, transient and long-term reconstitutions occurred at the same time and were recognized as long-term reconstitution.

The PGK pattern of erythrocytes in long-term reconstituted WBB6F$_1$-*W*/*W*^{v} mice was influenced by the number of injected bone marrow cells. The proportion of reconstituted mice with double enzyme patterns increased in parallel with the number of cells. When each WBB6F$_1$-*W*/*W*^{v} mouse received 10^3 or 3 × 10^3 bone marrow cells, erythrocytes of all seven long-term reconstituted WBB6F$_1$-*W*/*W*^{v} mice showed either an A-type or B-type PGK pattern (group 1 of Fig 2). The result appears to indicate that a single stem cell with extensive proliferative potential reconstitutes the whole erythropoiesis of these seven WBB6F$_1$-W/W^v mice for at least 8 weeks due to the following reason. In a population of stem cells consisting of equal numbers of A- and B-type cells, the probability that proliferation of *n* cells occurs in A-type cells only or in B-type cells only is $(1/2^n) \times 2$, ie, $1/2^{n-1}$. Consequently, the 100% (7/7) incidence of single-enzyme reconstitution cannot be explained in the case of $n \geqq 2$.

Estimation by limiting-dilution analysis also supports the possibility of monoclonal reconstitution. Because 10^3 bone marrow cells were injected into 65 WBB6F$_1$-W/W^v mice and 3×10^3 cells into 85 WBB6F$_1$-W/W^v mice, in total, 3.2×10^5 cells were injected into 150 WBB6F$_1$-W/W^v mice. The concentration of stem cells with an extensive proliferative potential was $0.7/10^5$ bone marrow cells, which indicated ~5 such stem cells in 3.2×10^5 bone marrow cells. When ~5 stem cells are injected into 150 WBB6F$_1$-W/W^v mice, the possibility that two stem cells are injected into a single WBB6F$_1$-W/W^v mouse should be low.

When calculated by using the concentration of day 14 CFU-S shown in Table 1, 3.2×10^5 bone marrow cells from 5FU-treated C57BL/6-$Pgk\text{-}1^b/Pgk\text{-}1^a$ mice have the capacity to produce about 64 to 81 day 14 spleen colonies in 200-rad–irradiated WBB6F$_1$-W/W^v mice. If a single day 14 CFU-S had been able to reconstitute the whole erythropoiesis of a WBB6F$_1$-W/W^v mouse, about a half of 150 WBB6F$_1$-W/W^v mice injected with 10^3 or 3×10^3 bone marrow cells would have shown a pure Hbb^s/Hbb^s hemoglobin pattern. In fact, three WBB6F$_1$-W/W^v mice showed a pure Hbb^s/Hbb^s pattern transiently and seven WBB6F$_1$-W/W^v mice for a long term. Therefore, most of the stem cells that produce a day 14 spleen colony do not appear to have the potential to reconstitute the whole erythropoiesis of a WBB6F$_1$-W/W^v mouse even transiently. This is consistent with the results of Wiktor-Jedrzejczak et al,[8] Boggs et al,[9] and Visser et al[27] that the CFU-S assay does not represent the number of stem cells with extensive proliferative potential.

Wiktor-Jedrzejczak et al,[8] Boggs et al,[9] and Visser et al[27] used bone marrow cells from nontreated syngeneic donors, whereas we harvested bone marrow cells from 5FU-treated donors of the parental strain origin. The number of bone marrow cells necessary to reconstitute a WBB6F$_1$-W/W^v mouse was smaller in their experiments than in our present experiment. Although 5FU treatment significantly increased the day 14–to–day 8 ratio of colonies, it does not appear to increase the proportion of stem cells with extensive proliferative potential. However, because we used C57BL/6-$Pgk\text{-}1^b/Pgk\text{-}1^a$ mice rather than syngeneic +/+ mice as donors, there is a possibility that the hybrid resistance reported by Harrison et al[20] in the present strain combination may reduce the efficiency of the stem cells of C57BL/6 strain origin.

Long-term reconstitution occurred in 33 of 82 WBB6F$_1$-W/W^v mice after transplantation of 50×10^3 to 100×10^3 bone marrow cells from 5FU-treated C57BL/6-$Pgk\text{-}1^b/Pgk\text{-}1^a$ mice. In all these 33 WBB6F$_1$-W/W^v mice, the PGK pattern of erythrocytes was of the AB type when the hemoglobin pattern first changed to the Hbb^s/Hbb^s type. The PGK pattern changed from a double-enzyme pattern to a single-enzyme pattern in 16 of 33 WBB6F$_1$-W/W^v mice (group 2 of Fig 2), but the double-enzyme pattern remained in 17 WBB6F$_1$-W/W^v mice (group 3 of Fig 2).

There are two possible explanations for group 2. (*a*) The reconstitution may result from the lodgment and differentiation of both a stem cell(s) with limited proliferative potential and a single stem cell with extensive proliferative potential. A stem cell with extensive proliferative potential continued the proliferation and differentiation after the expiration of stem cell(s) with limited proliferative potential. (*b*) The reconstitution may be initiated by lodgment and differentiation of two or more stem cells with extensive proliferative potential. However, subsequent emergence of a single monoclonal population occurred. Probably, stem cells belonging to the other clone(s) may remain in the hematopoietic tissues, but their differentiation was suppressed by unknown mechanisms. Determination of PGK patterns of CFU-S and in vitro colony-forming cells from such hematopoietic tissues may prove or disprove the possibilities.

In group 3, long-term reconstitution appears to be attributable to the lodgment of ≧2 stem cells with extensive proliferative potential. Even when the AB-type PGK pattern remained throughout the observation period, the type A–to–type B PGK ratio fluctuated in some WBB6F$_1$-W/W^v recipients. This is consistent with the recent result of Lemischka et al[28] and may be explained by the concept of clonal succession proposed by Kay.[29]

To investigate the fate of a single stem cell, Abramson et al[30] induced chromosomal abberations by x-irradiation, and Dick et al,[31] Lemischka et al,[28] and Keller et al[32] marked the stem cells with the integration sites of retrovirus. These markers are very useful because of the huge numbers of variations. However, when these markers are used, it seems difficult to exclude the influences of irradiation or retrovirus infection. Moreover, clones that failed to bear abnormal chromosomes or retrovirus and clones of the recipient origin are not detectable. These difficulties may be overcome with the present system in which electrophoretic patterns of hemoglobin and PGK are used as markers. Furthermore, vast numbers of recipient mice can be investigated frequently because it is much easier to examine patterns of hemoglobin and PGK than to examine chromosomal aberrations or integration sites of retrovirus. The present system is especially useful as a model of monoclonal reconstitution because a lot of information about human stem cell disorders such as CML, polycythemia vera, and agnogenic myeloid metaplasia has been accumulated by using another X chromosome–linked enzyme, G6PD, as a marker.[10]

Analysis of the Erythroid Phenotype of HEL Cells: Clonal Variation and the Effect of Inducers

By Th. Papayannopoulou, B. Nakamoto, S. Kurachi, and R. Nelson

The erythroid phenotype of HEL cells, before and after the addition of a variety of inducers, was assessed at the cellular and biochemical level. Among 14 inducers used, δ-aminolevulinic acid (δ-ALA) was identified as the most optimal inducer of heme and globin synthesis in HEL cells. The relative synthesis of globin chains produced by HEL cells, mainly γ and α chains with traces of ϵ and ζ chains, was not influenced by the majority of the inducers used. However, δ-ALA and bromodeoxyuridine did increase the relative synthesis of α and ϵ chains respectively. Subcloning experiments revealed heterogeneity in the constitutive expression of α globin; however, the latter was inducible in all clones by either hemin or δ-ALA. One rare clone of HEL cells was found to produce, in contrast to parental cells, significant amounts of ϵ globin. This clone differed from K562 cells by the absence of any ζ globin expression, thus demonstrating the independent regulation of the two embryonic chains, ϵ and ζ. Changes in the expression of several surface markers specific for erythroid cells were found to accompany the globin accumulation in these cells, and some of these changes appeared to be inducer specific. Thus, the unique globin and nonglobin phenotypic properties of HEL cells and their subclones make them valuable cellular models complementary to the existing K562 cells for studying regulatory aspects of erythroid-specific proteins.

ESTABLISHED ERYTHROLEUKEMIA cell lines capable of constitutive and induced globin expression are valuable tools for the investigation of cellular and molecular mechanisms regulating globin expression and erythroid differentiation. We have previously described the establishment of a human erythroleukemia line, the HEL cells,[1] which, like K562 cells,[2] are capable of human globin expression. Detailed characterization of the surface antigenic profile of HEL cells[3] disclosed that these cells display several erythroid-specific surface markers and, in addition, features of other nonerythroid cell lineages (ie, platelet/megakaryocytic lineage) that have been the subject of several recent studies.[4-12] However, only preliminary data have been presented to date on the erythroid phenotype of HEL cells.[1] In the present study, we report detailed biochemical characterization of globin produced by HEL cells before and after induction by several inducing agents. Furthermore, through the availability of antiglobin chain–specific monoclonal antibodies (MoAbs) we were able to study, at the cellular level in both HEL and K562 cells, the distribution of the various globins at basal conditions and its modulation by the inducers. The augmentation in globin expression was attended by certain coordinate changes in the surface erythroid phenotype of HEL cells, as assessed through the use of monoclonal antibodies with erythroid specificity. The present analysis and comparative studies with K562 cells indicate that these two lines, by virtue of their unique characteristics and their composite phenotype, complement each other as models to be exploited for studies on the regulation of globin expression.

MATERIALS AND METHODS

Cell Lines and Culture Methods

HEL cells have been in continuous culture in our laboratory since their establishment in 1980. Three different sublines of K562 cells were used for comparison: clone C-16, obtained from Dr M. Fukuda[13]; K562 cells from Dr J. Hansen (K562-H); and K562(S) cells from Dr G. Rovera.[14] Both K562 and HEL cells were maintained in RPMI 1640 medium supplemented with 10% fetal calf serum, pyruvate, and antibiotics in a humidified 5% CO_2 incubator. Cells were split and transferred into fresh medium at biweekly intervals. All cultures were tested periodically to ensure the absence of mycoplasma. To obtain cell doubling time in suspension cultures, daily cell counts in a hemocytometer were done. To derive clones from HEL or K562 cells, two systems of cloning were used: the limited-dilution method in microtiter wells or cloning in methylcellulose (MC) semisolid media and subcloning of individual clones initially lifted from MC plates. Cloning of HEL and K562 cells was also carried out in plasma clot cultures, but these cultures were used primarily for either benzidine staining or immunofluorescence staining of colonies (see the following sections).

Induction

During log-phase growth (about 2 × 10^5/cells/mL), a given inducer (Table1) was added at various doses to the culture media, and aliquots of cells were taken for testing at several intervals after the addition of inducer. The effect of various inducers on heme synthesis was assessed by benzidine staining and total hemoglobin determination, whereas the effect on globin was evaluated by globin chain analysis and by anti-globin immunofluorescence labeling. The effect on surface markers was evaluated by surface immunofluorescence labeling using antibodies with known specificities.

Benzidine Staining

For evaluation of heme or hemoglobin induction in HEL or K562 cells, benzidine staining was used in either cell suspension[15] or in fixed cytocentrifuge smears. For the latter, an adaptation of the method described by McLeod et al[16] was used.

Hemoglobin Analysis

Hemoglobin determination in lysates of induced and uninduced cells was carried out by a spectrophotometric method,[17] whereas separation of the hemoglobin species present was achieved by isoelectric focusing in polyacrylamide gels as described[18] with slight modifications. Hemoglobin bands were visualized by benzidine staining. For definitive identification of hemoglobin bands in our gels, we isolated their constituent chains (see the next section) in globin chain isoelectric focusing gels by using sliced bands from hemoglobin gels.

Globin Chain Analysis

For globin chain separation, lysates from ^{3}H-leucine–labeled cells (for an eight-12-hour period) were subjected to isoelectric focusing

according to a method described by Rhighetti et al[19] and as adapted by us.[20] Before isoelectric focusing, globin was purified through haptoglobin binding.[21] Under our conditions of isoelectric focusing, all human chains (ϵ, ζ, γ, β, α) can be distinctly separated from each other. After isofocusing, the gels were fixed, treated with En^{3}Hance (DuPont, Boston), dried, and subjected to fluorography and densitometry as described.[20]

Immunofluorescence With Antiglobin Chain Antibodies

Cytocentrifuge smears prepared from uninduced and induced cells were fixed in methanol and reacted with antiglobin chain antibodies[22] in an indirect immunofluorescence assay using antimouse IgG (F(ab')$_2$) conjugated to fluorescein isothiocyanate (FITC) as a second antibody. Two MoAbs, one against γ chains and one specific for β chains, were used in a 1:1,000 dilution of ascites fluid. A polyclonal antibody monospecific for ζ chains was also used. This antibody was made by using Hb Portland as an immunogen, and it was kindly provided to us by Dr D. Chui.[23]

Surface Immunofluorescence

Several previously characterized MoAbs were used in an indirect immunofluorescence assay for evaluating the membrane reactivity of induced v uninduced cells. These antibodies include antiglycophorin A (R-10 and F-11),[3] EP-1 and EP-2,[24] anti-i (Den), anti-I (Ma),[25] anti-H (BE2 and *Ulex europaeus* I),[25] and antitransferrin receptor antibodies OKT9[26] and BE/25[27] as well as a recent series of antierythroid MoAbs generated by us.[28] Labeled cells were viewed under a Zeiss epifluorescence microscope through the appropriate filters, or they were subjected to fluorometric analysis in a fluorescence-activated cell sorter (Ortho system 50H Cytofluorograf with a 2150 computer, Westwood, MA).

Subcloning

Subcloning of HEL cells was done in MC media. Single colonies grown in MC were subcloned at least twice to ensure a single-cell origin of the clones. Subcloning of K562 cells was carried out by the limited-dilution method. After cloning, the isolated clones were expanded in suspension cultures, and they were induced and evaluated for globin expression and benzidine positivity, as indicated for parental cells.

Commitment Assay

To test whether a brief exposure to inducers leads to an irreversible decision for terminal differentiation in the absence of the inducer, a two-step commitment assay was performed as described previously for K562 cells[29] or MEL cells.[30] Briefly, after a one-day exposure of HEL and K562 cells to an optimal concentration of an inducer, the cells were washed to remove the inducer, counted, and plated (at 1,000 to 3,000 cells/mL) in Iscove's modified Dulbecco's medium (IMDM) or RPMI 1640, 30% fetal calf serum (FCS), and 0.8% MC. Colony number as well as the proportion of benzidine-positive colonies[30] was determined at day 5 postplating.

RESULTS

Induction of Heme Synthesis

Uninduced HEL cells showed only occasional benzidine-positive cells (Table 1), and hemoglobin levels in these cells were between 0.2 and 0.4 pg hemoglobin/cell. The effect of the various inducers on benzidine postivity is shown in Table 1. The addition of δ-aminolevulinic acid (δ-ALA) to growing HEL cells yielded the most optimum induction, as assessed by benzidine positivity and hemoglobin analysis; up to one third of the cells became benzidine-positive, and the total hemoglobin content increased from three- to tenfold, ie, from 0.4 to 3 to 4 pg hemoglobin/cell. Most of the other inducers caused a slight increase in benzidine positivity and, in contrast to δ-ALA, had an early adverse effect on the proliferation and viability of HEL cells. The metalloporphyrins (Zn-protoporphyrin-IX, Co-protoporphyrin IX, or protoporphyrin-IX) were very toxic to HEL cells, which resulted in significant cell death during the first three or four days in culture. Hemin solutions and hemolysates, however, were much less toxic. It is notable, however, that HEL cells are far more sensitive than K562 cells to the toxic effects of hemin. The effect of hemin on new heme synthesis could not be assessed with confidence when using the wet benzidine stain because of nonspecific positivity, presumably due to the uptake of exogenous hemin. Among the various HEL clones tested, including an earlier passage of HEL cells (HEL-92), there was no significant variability in benzidine positivity, either before or after induction. However, one clone, HEL-R, showed significant levels of benzidine positivity, especially after induction (Table 2) and, in that respect, differed from the other parental HEL cells or subclones tested.

Apart from the presence of the specific inducer, the level and type of serum used seemed to influence the level of induction. The induction potentiating property of the sera tested was as follows: 20% FCS > 10% FCS > newborn bovine serum > human serum > horse serum.

Induction of Globin Synthesis

It was previously shown that the main globin species produced by uninduced HEL cells is Bart's hemoglobin (Fig 1). Only traces of hemoglobin fractions comigrating with embryonic hemoglobins (Gower I, Gower II) or with hemoglobin F were present. This phenotype was confirmed by determining the chain composition of the major hemoglobin fractions in two-dimensional gels. This type of analysis disclosed that the fraction migrating in the position of hemoglobin Portland is composed not of γ and ζ chains but of a mixture of acetylated and nonacetylated Gγ and Aγ chains (Fig 1). Furthermore, as expected from hemoglobin analysis, globin chain isofocusing of ^{3}H-leucine–labeled lysates showed either trace or undetectable levels of ϵ and ζ chains and a variable amount of α chains. Although the major globin species are γ chains, the proportion of Gγ to Aγ is not as in fetuses because there is an excess of Aγ chains instead of Gγ. The pattern of globin chain synthesis in HEL cells contrasts with the one present in K562 cells in which there is predominance of Gγ chains and abundant synthesis of embryonic globin chains (Figs 3-5).

At a cellular level, a small but significant proportion of uninduced HEL cells was labeled with anti-γ chain monoclonal antibody, whereas only rare cells were found to be positive with a polyclonal and monospecific antibody for ζ chains (Fig 2A). In no instance were β-positive cells seen. An antibody to ϵ chains was not available to assess the cellular distribution of ϵ globin. The effect of the various inducers on globin synthesis is shown in Table 1 and Figs 3 to 5. γ chain

positivity by immunofluorescence was used as a screening of globin induction with all inducers, and labeling of cell lysates with ^{3}H-leucine was carried out only in the most potent inducers identified by the screening assay. The majority of the inducers appeared to somewhat augment γ globin synthesis. However, only few of them appeared to influence the specific globin pattern of HEL cells. Thus, hemin and δ-ALA consistently increased the proportion of α-chains, as described previously for K562 cells,[31] whereas 5-azacytidine and BrDU increased the relative expression of ϵ chains. The effect on ϵ globin was mostly evident in a subclone of K562 cells, C-16, which does not synthesize significant levels of ϵ chains in the uninduced state (Fig 3). Also, the addition of BrDU and sodium butyrate increase the relative synthesis of ϵ globin in HEL-92, whereas δ-ALA did not (Fig 5 and data not shown). Of interest, the addition of BrDU in HEL cells but not in K562 cells induced the appearance of a significant proportion of adherent, elongated cells (data not shown). Because of the demonstrated cellular heterogeneity in ζ globin and a presumed similar heterogeneity in ϵ globin expression, subcloning of HEL cells was carried out in the hope of obtaining globin phenotypes that differed significantly from the parental cells. Among a total of 20 clones tested in detail, the only variation was the one concerning the α chains (data not shown). However, one HEL clone obtained from parental HEL cells repeatedly treated for mycoplasma contamination was found to be distinctly different from the parental population. This subclone, designated HEL-R, is characterized by a high level of ϵ chain expression and higher levels of α chain expression compared

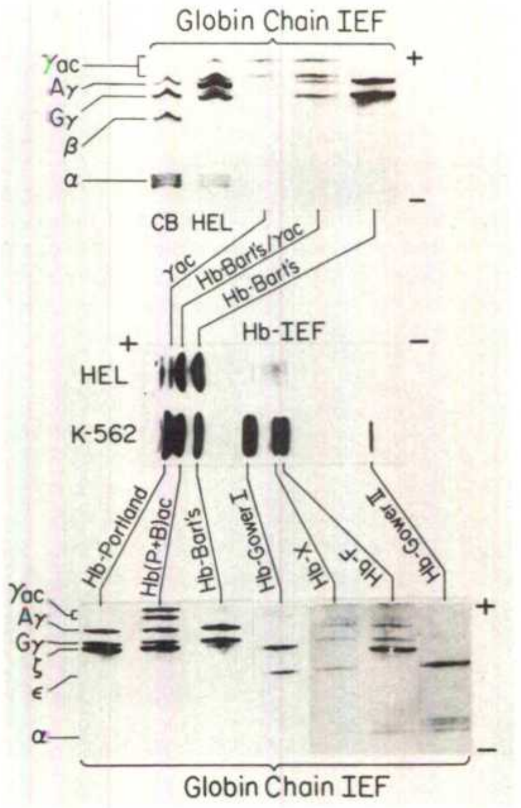

Fig 1. Hemoglobin (Hb) and globin chain isoelectric focusing of K562 (K562-H) and HEL lysates (^{3}H-leucine labeled). Individual hemoglobin species separated in hemoglobin isoelectric focusing gels (Hb-IEF) were sliced and run in noxidet P40-urea gels to analyze their constituent globin chains (globin chain IEF gels). Major Hb bands from HEL cells are Bart's and Bart's acetylated (B-ac), which migrates in the position of Hb Portland. Embryonic globins (Gower I, Gower II, Hb-X) as well as Hb F are minor bands in this HEL subline (severely α chain deficient), although there were considerably more in HEL-R. Hb-IEF, first-dimension Hb gels stained with benzidine; globin chain IEF, second-dimension gels showing radiolabeled globin chain bands; CB, Cord blood lysate; γac, acetylated γ chains.

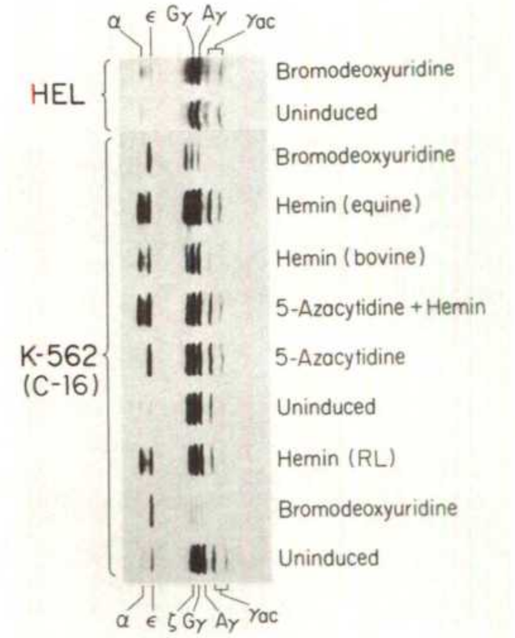

Fig 3. Effect of various inducers on the relative expression of globin chains in K562 (C-16) and HEL cells. Note the increase in α chains by hemin and the relative increase in ϵ chains by 5-azacytidine and BrDU. (Hemin [RL] is hemin crystallized by Dr R. Labbe', University of Washington.)

with parental cells (Fig 5). However, ζ chain is virtually absent, and this feature as well as the increased proportion of Aγ over Gγ chains distinguishes this subclone from K562 cells (Fig 5). In addition to the high levels of ϵ globin production, this clone was characterized by high constitutive levels of heme and total globin synthesis (ie, higher basal levels of γ globin and benzidine-positive cells) and by its high inducibility by the same inducers used for parental cells (Table 2).

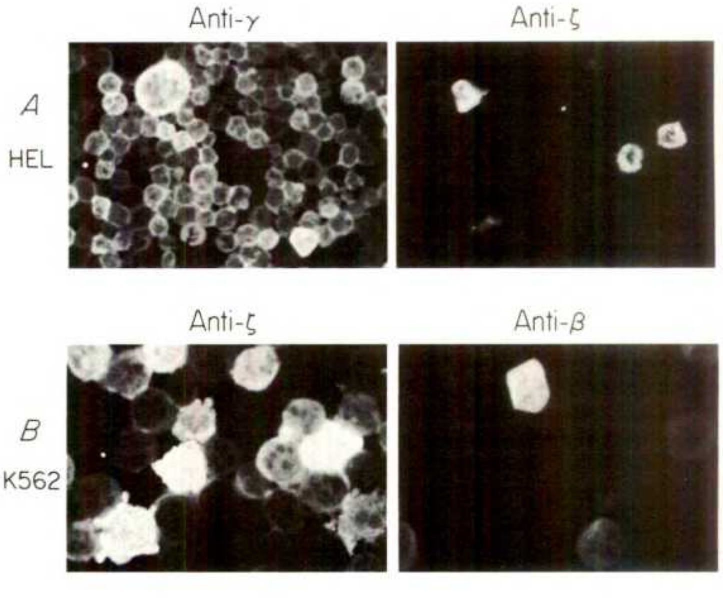

Fig 2. (A) Immunofluorescent labeling of δ-ALA-induced HEL cells by monoclonal anti-γ chain antibody conjugated to FITC and by monospecific anti-ζ antibody plus antirabbit IgG-FITC. Preparations are of similar cellular densities and photographed at the same magnification (×312). Note the high proportion of γ+ cells and the very low proportion of ζ+ cells within this HEL population. (B) Immunofluorescent labeling of δ-ALA-induced K562 (C-16) cells with anti-ζ antibody and with monoclonal anti-βδ antibody conjugated to FITC. Although γ globin can be detected in the great majority of induced K562 (C-16) cells (see Table 2), a smaller proportion of cells is ζ-positive, and rare cells are βδ-positive. This positivity is attributable to the presence of δ rather than β chains (see text).

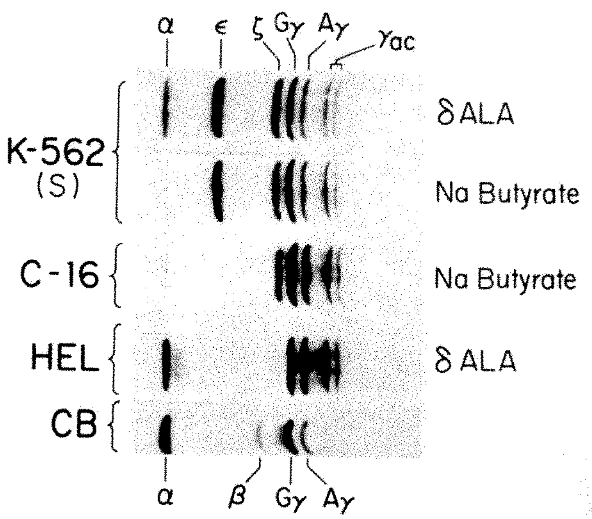

Fig 4. Globin chain isofocusing of ^{3}H-leucine-labeled K562(S) and K562 (C-16) cells induced by δ-ALA and sodium butyrate and of HEL cells induced by δ-ALA. Note the difference in ε chain expression between K562(S) and C-16 induced by the same inducer (butyrate) and the α chain increase by δ-ALA in both K562 and HEL (compare with uninduced cells in Fig 3).

Commitment to Terminal Maturation

The presence of γ globin-positive cells among the uninduced HEL cells and the rare benzidine-positive cells suggests that a certain proportion of HEL cells tends to accumulate higher hemoglobin as if they spontaneously undergo terminal maturation. To test whether spontaneous commitment to terminal maturation can also be observed or enhanced under conditions of clonal growth, we evaluated the number of benzidine-positive clones in a clonal assay. HEL cells were cloned in MC media, and colonies were evaluated six to ten days postplating. The morphology of colonies generated from HEL cells was characteristic and differed from the ones observed in K562 cells cultured for comparison. K562 cells produce compact and round colonies, but only one third of HEL colonies were of this type, the rest being diffused or scattered and reminiscent in morphology of human granulocytic-macrophage colonies. Subcloning of compact colonies tended to generate mostly compact colonies, and the same was true for noncompact colonies (data not shown). Spontaneous maturation was assessed by the appearance of a red color and by benzidine positivity of colonies in situ. There were no fully hemoglobinized (red) colonies from HEL cells, but colonies with benzidine-positive cells were up to 4%. In K562 plates, there were rare, small colonies with a reddish color and many more colonies with benzidine positivity. Colonies with apparent spontaneous maturation (any appearance of reddish color) were plucked from MC plates and labeled with tritiated leucine, and their lysates were used for globin chain isoelectric focusing. The globin phenotype of these spontaneously maturing HEL or K562 colonies was similar to the ones obtained in subclones (see the previous section). Of note, no β chains were again present in any of these spontaneously maturing colonies. To test whether commitment to terminal differentiation/maturation can be influenced by inducers, selective inducers were tested in a commitment assay as described before.[29] In preliminary experiments, we have determined that 24-hour exposure to the inducer followed by plating in MC in the absence of the inducer and by evaluation of colonies at day 5 are adequate conditions to detect any influence in commitment decision. Parallel experiments with K562 cells under these conditions were also carried out. The data obtained are shown in Table 3. An increase in the uniformly benzidine-positive colonies and in the mixed benzidine-positive colonies in K562 cells by these inducers was confirmed with these experiments. However, in HEL cells, at best, partial commitment by the same inducers, as judged by the assay used, could be observed. Of interest, virtually all benzidine-positive colonies in HEL cells were of the mixed type, which indicated that only part of the progeny becomes terminally committed.

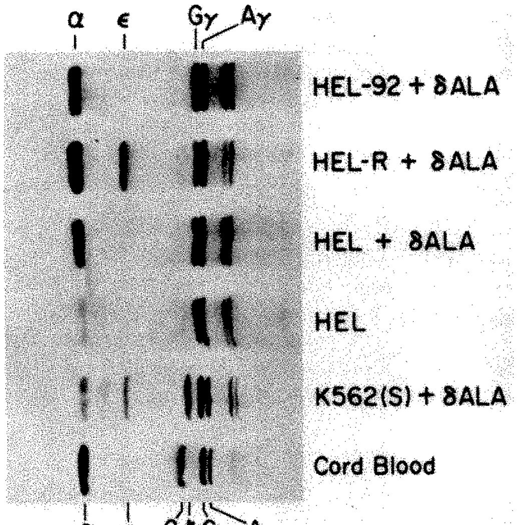

Fig 5. Isoelectric focusing of uninduced and induced ^{3}H-leucine-labeled cell lysates from HEL and HEL-R. The features that distinguish this clone from the parental line are the presence of high levels of ε chain, the increased levels of α chains, and its higher overall heme and globin inducibility.

Induction of Erythroid Surface Antigens

A detailed characterization of the membrane antigenic profile of HEL cells and its comparison with K562 cells has been previously presented.[3] It was also shown previously that treatment of HEL cells with 12-0-tetradecanoylphorbol-

Table 3. Induction of Commitment to Terminal Maturation

	Benzidine+ Colonies (%) After a 24-h Exposure to

*Mean of two replicate MC plates counted on day 5 postplating.

13-acetate (TPA) reduced the abundance of some of the erythroid markers (ie, glycophorin, globin) while, at the same time, the cells changed their behavior and became noninducible.[4] In this study, we examined whether globin induction in HEL cells was accompanied by changes in their surface erythroid antigens.

Glycophorin. Uninduced and δ-ALA–induced HEL cells were treated with two MoAbs against glycophorin, R-10, and F-11 and then with antimouse $F(ab')_2$-IgG (or IgM) conjugated to FITC and subjected to analysis (Fig 6). Before induction, as previously noted,[3] virtually all cells were positive with R-10. However, induction by δ-ALA resulted in a rightward shift of the profile toward greater intensity of fluorescence. Although this shift was reproducible, the magnitude of the change was not great. In contrast to findings with R-10, a significant change was observed with antibody F-11. The latter, although highly reactive with normal erythroblasts,[3] shows a very low intensity of fluorescence in uninduced cells; however, after induction, a significant shift toward higher fluorescence intensity is found (Fig 6). Similar changes were produced with hemin induction, but the changes were greater and more reproducible with δ-ALA induction.

iI-antigens. HEL cells expressed i antigen, and only an occasional cell reacted with anti I serum.[5] The behavior of iI antigenic expression was tested after induction of HEL cells with hemin, δ-ALA, sodium butyrate, and BrDU. The last two inducers were chosen because of their reported influence on I antigen expression in K562 cells.[32] Hemin and δ-ALA caused only minor changes in I expression. However, BrDU and butyrate increased the expression of I antigen (Fig 7). Because these two agents, ie, sodium butyrate and BrDU, cause a significant reduction in the proliferation of the cells at the doses used, we examined whether changes in the proliferative status of the cells could be responsible for the effect. To control for proliferation inhibition, we cultured HEL cells in media containing antitransferrin for six days. Such cells, as independent experiments showed, failed to proliferate, but they remained viable for that period of time. As seen in Fig 7, antitransferrin-treated HEL cells showed an increased expression of I antigen. Therefore, it is very likely that, at least in part, the increase in I antigen expression after sodium butyrate and BrDU is due to changes in their proliferative status, although a direct induction, especially by BrDU (Fig 7), cannot be entirely excluded. The interpretation of these changes is somewhat supported by the information that anti-I–positive K562 cells (separated by a cell sorter) showed an increased doubling time compared with anti-I–negative cells (data not shown). In addition, it is of interest that another unrelated antigen, BB-2, which is dramatically increased with butyrate treatments, is also enhanced upon the cessation of proliferation of HEL cells by the addition of antitransferrin or TPA.[4]

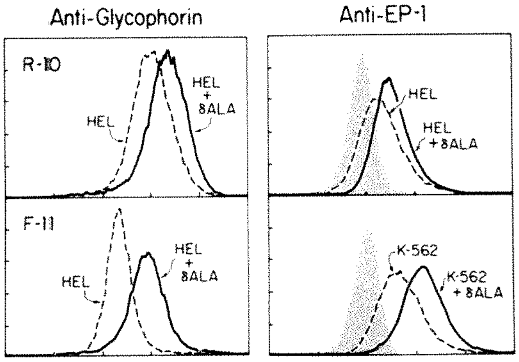

Fig 6. **HEL cells labeled with antiglycophorin MoAbs (R-10 and F-11) before and after induction by δ-ALA. Before induction significant reactivity with MoAb R-10 and much less so with F-11 was observed. After induction, however, reactivity with both MoAbs, especially with F-11, was increased, as indicated by a rightward shift in fluorescence intensity. Enhancement of expression of Ep-1 antigen in HEL and K562 cells after δ-ALA induction. Dotted peaks are negative control samples labeled with an irrelevant first antibody of the same idiotype as Ep-1 and with the same second antibody (x-axis, relative cell number; y-axis, fluorescence intensity).**

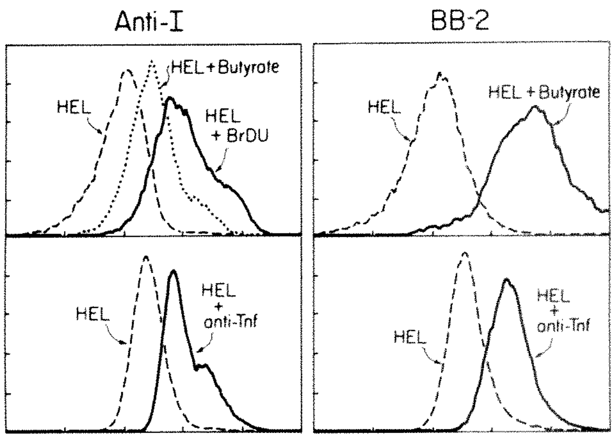

Fig 7. **Enhancement of expression of I antigen in HEL cells after induction by butyrate and BrDU. Both inducers yielded a weak induction of HEL cells, and the isolated I antigen increase is partly attributable to cessation of cell proliferation as indicated by control nondividing cells (HEL cells with antitransferrin) and by parallel changes in another antigen (present in all myeloid and B lymphoid cells) detected by antibody BB-2 (x- and y-axes are as in Fig 6).**

H antigen. The great majority of HEL cells are positively labeled with anti-H MoAb BE2[25] and with the lectin *Ulex europaeus* I. No significant changes were observed with induction.

Other erythroid surface antigens. We have recently described the characterization of two antierythroid-specific antibodies (anti–EP-1 and anti–EP-2) raised through the use of normal erythroid cells as immunogens.[24] Using these antibodies in K562 cells, we observed that their reactivity is increased after globin induction.[24] Similar experiments with δ-ALA–induced HEL cells have shown that this enhancement can also be observed in HEL cells after induction (Fig 6). Furthermore, we have tested the reactivity of induced HEL cells with a set of four new antierythroid monoclonals.[28] Augmentation in reactivity was again observed during the first three days of induction (data not shown).

Transferrin receptor. The increase in transferrin-bound iron in the developing erythroid cell correlates with the stages of the most active hemoglobin synthesis. We have examined the reactivity of uninduced and induced HEL or K562 cells with two antitransferrin receptor antibodies (OKT9 and BE/25). The data indicate that some increase in the expression or the density of transferrin receptors occurs after δ-ALA induction of either K562 or HEL cells. Because the cells' proliferation rate (doubling times) early on is similar to that of control cells, the increase in antitransferrin receptor reactivity may reflect an increase in the traffic of iron into the cells during induction.

DISCUSSION

Analysis of the basal and inducible erythroid phenotype of HEL cells performed in this study disclosed several points of interest. Among several inducers used, the effectiveness of δ-ALA was surprising. Augmentation in hemoglobin synthesis after δ-ALA addition was observed in the absence of any initial effects on the proliferative capacity and cell viability. Other inducers showed fewer effects on the augmentation of hemoglobin synthesis, and this was accompanied by more toxicity (cessation of proliferation and cell viability). It was of interest that δ-ALA was also a potent inducer in K562 cells. This remarkable responsiveness of these two human cell lines to δ-ALA addition may indicate that in both lines early steps in heme biosynthesis are rate limiting. Furthermore, because δ-ALA is not among the potent inducers of murine erythroleukemia cells,[33,34] biochemical differences within the heme synthetic pathway between the human and murine lines[35] may underlie these effects.

Studies on the cellular distribution of globin chains and the subcloning experiments suggested that, in contrast to the widespread expression of γ globin, expression of embryonic globins (ζ and ε) is restricted to a subpopulation of cells. This population, however, does not seem to synthesize exclusively embryonic globins and seems to overlap with cells expressing γ globin. The numerical relationships of γ-positive cells (over 90%) and ζ-positive cells (≃25%) in K562 cells, the double (γ and ζ) labeling experiments in the same cells (data not shown), and the significant production of ε globin by a population virtually all positive in γ globin—HEL-R and K562(S)—support this notion. This is of interest in view of previous evidence which, based on globin biosynthetic studies, showed that ζ globin expression is confined only to the embryonic cell population during normal development.[36] Subsequent studies, however, indicated that cells coexpressing fetal (γ) and embryonic (ε and ζ) globin do exist during the transitional period of embryonic to fetal erythropoiesis.[37,38] Thus, coexpression of fetal and embryonic globins in HEL-R and K562 cells may not be necessarily aberrant but a reflection of earlier developmental phenotypes realized through their leukemic transformation. Furthermore, the globin phenotype of HEL-R expressing high levels of ε in the virtual absence of ζ globin suggests that the two embryonic globins are independently regulated and provides a cellular model for further understanding of control mechanisms.

Expression of adult globins is virtually absent in both HEL and K562 cells although, in one study, a small number of δ and β mRNA copies were detected[39] and, in another, an unsubstantiated claim about hemoglobin A synthesis is made.[40] The small number of β-positive cells found in K562 cells in the present study is of interest. These cells were detected only by a MoAb reacting both with β and δ chains,[22] and they were not found in subsequent studies in which an anti-β chain antibody that does not crossreact with δ chains was used (kindly provided by Dr Jensen).[41] The presence of δ globin but not β globin, as implied by these studies, and the readily detected δ mRNA by previous studies[39,42] seem to suggest that either the factors for δ expression are different from those required for β expression[43] or that *cis* inhibition of β globin may be operative in these cells.

Induction of hemoglobin synthesis was, with few exceptions, not accompanied by changes in the specific types of globin. Some consistent trends, however, were noted (ie, preferential increase in α or ε chains), and these were shared by both HEL and K562 cells. Previously noted variations in the proportion of various hemoglobins or globins in K562 cells[40,44] can be easily reconciled by the findings presented here, ie, the heterogeneity in α and ε production by individual clones and the fact that some of the inducers favor the production of some chains over the rest.

Although globin is augmented after induction of HEL and K562 cells, a well-coordinated expression of the terminal maturation protein program, as it occurs in murine erythroleukemic cells, does not take place. Thus, minimum or no changes in nonglobin proteins have been pointed out in previous studies of K562 cells,[45] and the overall protein profile of induced cells does not resemble the protein profile of normal nucleated erythroid cells.[6] Nevertheless, despite the absence of a coordinated expression of the entire erythroid maturation program upon induction, a few nonglobin changes were noted, and these most likely are indicative of an attempt for further maturation; thus, glycophorin attains a form presumably more enriched in carbohydrate groups (Fig 6A), and the expression of some erythroid-specific antigens, recognized by MoAbs, is enhanced (Fig 6B). In addition, an increase in I antigen expression was noted with two inducers, BrDU and butyrate (Fig 7), as previous studies with K562 cells have pointed out.[32] It is of interest that, in our studies, increased I expression was also correlated with decreased proliferative activity and a decreased number of divisions in both HEL and K562 cells. However, the relevance of this finding to physiological increments in I antigen expression during erythroblast maturation[46] is unclear.

ACKNOWLEDGMENT

We are grateful to Dr David Chui for his gift of anti-ζ antibody and to Dr R.H. Jensen for anti-β monoclonal antibody. We also thank Drs M. Fukuda, G. Rovera, and J. Hansen for the original donation of various K562 lines and Doreen Loomans for skillful secretarial assistance.

Human Granulocyte-Macrophage Progenitors and Their Sensitivity to Cytotoxins: Analysis by Limiting Dilution

By Kathryn E. Barber, Philip S. Crosier, Steven Gillis, and James D. Watson

Limiting dilution analysis of granulocyte-macrophage progenitor cells was performed by using adherent and T cell-depleted normal human bone marrow and the recombinant human growth factors, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Estimated frequencies for progenitor cells responding to G-CSF were one in 489 for colonies scored at day 7, and one in 1,015 for day 14 colonies. For GM-CSF the frequencies were one in 1,407 (day 7) and one in 574 (day 14). The effects of tumor necrosis factor (TNF) and lymphotoxin (LT) on the frequency of progenitors responding to either G-CSF or GM-CSF was determined. Both TNF and LT inhibited the response of cells to G-CSF, and in these cultures the frequency of progenitor cells that responded to G-CSF was reduced to less than one in 100,000 cells. In contrast, the frequency of cells able to form colonies in cultures stimulated with GM-CSF was unaltered by either cytotoxin. This differential sensitivity to cytotoxins suggests that either G-CSF and GM-CSF are acting on separate granulocyte progenitor populations or that TNF and LT selectively influence the biochemical pathways associated with the activation of receptors for G-CSF.

© 1987 by Grune & Stratton, Inc.

THE CYTOTOXINS tumor necrosis factor (TNF) and lymphotoxin (LT) are capable of exerting a number of effects on hematopoiesis in vitro.[1-7] Although TNF and LT are distinct molecular species with different antigenic determinants, there are clear similarities in both structure and biologic properties. The cDNA molecules for human TNF and LT have been isolated and expressed.[8-10] The recombinant products share 28% amino acid homology and 46% nucleotide homology, with areas of homology grouped predominantly in two regions of the molecules.[8] These homologous regions are likely to be important in specific receptor binding, and there is evidence that TNF and LT bind to the same cell surface receptor.[11]

We have recently reported that the suppressive effects of these molecules on granulocyte-macrophage progenitor cells are variable and dependent upon the growth factor used to stimulate granulocyte-macrophage colony formation. Colonies formed after stimulation with granulocyte colony-stimulating factor (G-CSF) are more sensitive to the suppressive effects of TNF and LT than are colonies formed after stimulation with granulocyte-macrophage colony-stimulating factor (GM-CSF).[12] This observation suggests that progenitors responsive to G-CSF are more sensitive to cytotoxin-induced inhibition than are those progenitors responsive to GM-CSF. To determine the frequency of human bone marrow progenitors sensitive to the effects of TNF or LT a limiting dilution analysis was performed. Cultures were stimulated with either recombinant human G-CSF or recombinant human GM-CSF. We report a striking difference between the number of progenitors responsive to G-CSF when no cytotoxin is present and the number capable of proliferative response to G-CSF in the presence of either TNF or LT. This is in marked contrast to cultures stimulated with GM-CSF where neither TNF nor LT influenced the progenitor cell frequency. These findings are important in determining the mode of action of each of these hematopoietic growth factors.

MATERIALS AND METHODS

G-CSF, GM-CSF, TNF, and LT. Recombinant human G-CSF (specific activity, 10^7 U/mg) and recombinant human GM-CSF (specific activity, 3.7×10^7 U/mg) were supplied by Immunex Corp, Seattle. Recombinant human TNF (specific activity, 5.02×10^7 U/mg) and recombinant human LT (specific activity, 1.2×10^8 U/mg) were generous gifts from Genentech Inc, South San Francisco.

Human bone marrow. Human bone marrow was obtained by aspiration from a panel of healthy volunteers. This procedure had hospital ethical committee approval. The marrow was prepared for use in limiting dilution assays by dilution in Iscove's modified Dulbecco's medium (IMDM; GIBCO, Grand Island, NY) supplemented with asparagine, benzylpenicillin, and streptomycin sulfate, which was followed by separation on Ficoll-Hypaque (density, 1.077 g/mL; Sigma Chemical Co, St Louis). Adherent cells were depleted by incubating the marrow cells in culture medium with 7.5% fetal calf serum (FCS, GIBCO) for 60 minutes at 37°C in 36 × 12-mm polystyrene dishes (10^7 cells/2 mL). Depletion of T cells was achieved by panning where nonadherent cells were incubated with optimal concentrations of Leu-1 and Leu-5 (Becton Dickinson, Mountain View, CA), UCHT1 (P. Beverley), and OKT4 and OKT8 (Ortho Pharmaceutical Corp, Raritan, NJ) for 20 minutes at 4°C; washed; resuspended at 2×10^7 cells/3 mL; and incubated for 70 minutes at 4°C on 100 × 15-mm polystyrene dishes coated with goat antibody to mouse immunoglobulin (Tago Diagnostics, Inc, Burlingame, CA). The nonadherent cells were recovered by swirling the plates and gently washing five times. The number of T cells contaminating the final preparation was assessed by incubation with goat antimouse IgG-fluorescein isothiocyanate (FITC) (Tago) for 20 minutes at 4°C then analysis by FACS 440 (Becton Dickinson). The number of T cells was always $<1\%$.

Limiting dilution assays. Limiting dilution assays were performed in 96-well microtitre plates (Nunc, Kamstrup, Denmark). Bone marrow cells were suspended in IMDM containing 0.3% agar,

(Difco, Detroit), 20% FCS (vol/vol preselected batch; Gibco), and appropriate concentrations of growth factors and/or cytotoxins. G-CSF and GM-CSF were added at final concentrations of 100 U/mL, which are saturating for growth. TNF and LT were added at final concentrations of 100 U/mL, doses that have been shown to cause suppression of granulocyte-macrophage colony formation.[12] Cell concentrations ranged from 2.5×10^2/mL to 5×10^5/mL. Aliquots of 200 μL were plated in 24 microwells for each cell concentration. Cultures were incubated at 37°C in a humidified atmosphere of 5% CO_2 in air for 14 days. The number of wells containing one or more colonies (aggregates of 40 or more cells) were assessed at days 7 and 14.

Calculation of progenitor frequencies. Microcultures were scored as positive if they contained one or more colony. The percentage of nonresponding cultures was plotted against the responder cell number. The frequency of responding cells was calculated from experiments in which eight to 11 different doses of bone marrow cells were cultured by the reiterative, maximum-likelihood method.[13]

RESULTS

Frequency of granulocyte-macrophage progenitors resistant to the effects of cytotoxins. The effects of TNF and LT on the frequency of progenitor cells that responded to G-CSF and GM-CSF were examined. In these limiting dilution experiments cultures were stimulated with either G-CSF or GM-CSF, and for each growth factor, cultures contained either no cytotoxin, TNF, or LT. Cultures were scored at days 7 and 14. Progenitor cell frequencies were calculated for each combination of growth factor and cytotoxin at both time points.

The data presented in Fig 1 are from an experiment where adherent and T cell–depleted bone marrow was stimulated with either G-CSF (panels A and B) or GM-CSF (panels C and D). Panels A and C show the results of assays scored at day 7 and panels B and D, the results of assays scored at day 14. Estimates of progenitor frequency were calculated by maximum-likelihood determinations for each growth factor/cytotoxin combination and are presented in the legend. Similar results were obtained in two limiting dilution experiments performed on bone marrow mononuclear cells that had not been further fractionated and in an additional experiment performed on adherent and T cell–depleted bone marrow. From these experiments mean estimated precursor frequencies were calculated (Table 1). Both TNF and LT inhibited the response of cells to G-CSF such that the frequency of progenitor cells responding to G-CSF was reduced from one in 489 on day 7 and one in 1,015 on day 14 to less than one in 100,000 for both populations of cells. In contrast, neither TNF nor LT significantly altered the frequency of progenitors that responded to GM-CSF.

Colonies in microcultures stimulated by GM-CSF had the

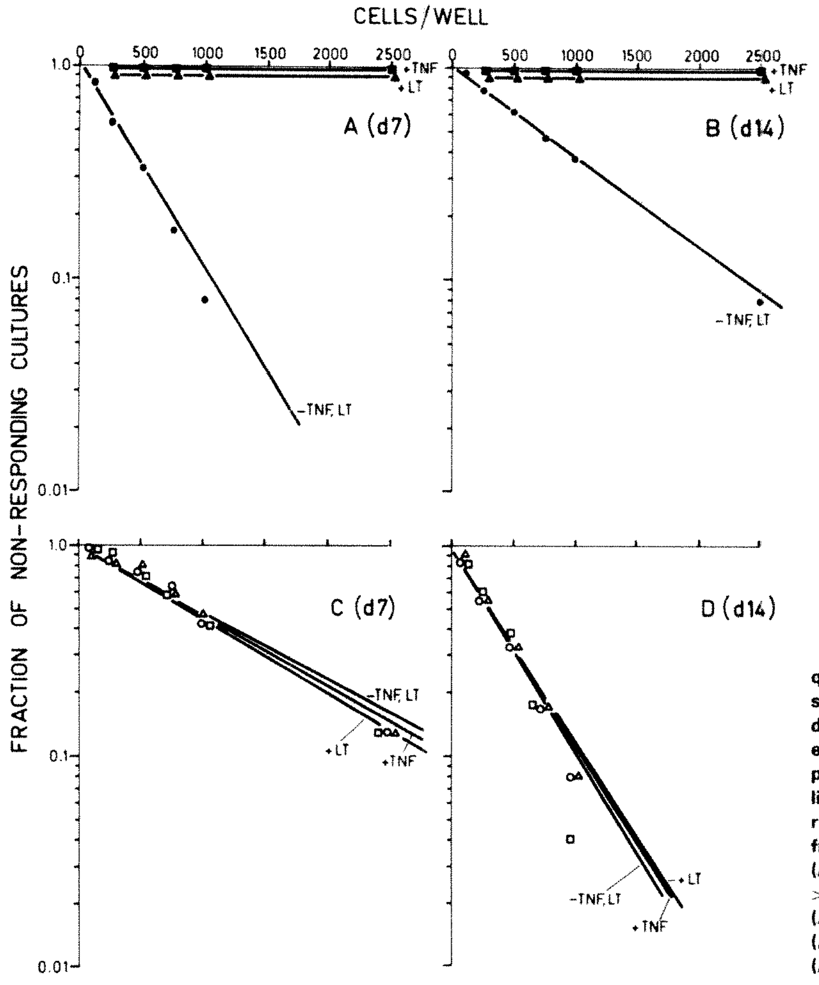

Fig 1. Effect of cytotoxins on progenitor frequencies for day 7 (A, C) and day 14 (B, D) colonies stimulated by G-CSF (A, B) or GM-CSF (C, D). The data shown are from one of four reproducible experiments. The lines were drawn such that the precursor frequency, calculated from maximum-likelihood determination, corresponded to a nonresponding culture fraction of 0.37. Reciprocals of frequency estimates were as follows: ●, d7, 453 (*P* = .74); d14, 1,020 (*P* = .99). ■▲, d7 and d14, >100,000. ○, d7, 1,361 (*P* = .93); d14, 452 (*P* = .93). □, d7, 1,355 (*P* = .90); d14, 460 (*P* = .74). △, d7, 1,313 (*P* = .99); d14, 461 (*P* = .77).

Table 1. Progenitor Frequencies in Human Bone Marrow

	Progenitor Cell Frequency	
Stimulus/Cytotoxin	Day 7	Day 14
G-CSF	1:489 ± 36	1:1,015 ± 41
G-CSF + TNF	<1:100,000	<1:100,000
G-CSF + LT		
GM-CSF	1:1,407 ± 124	1:574 ± 105
GM-CSF + TNF	1:1,375 ± 28	1:510 ± 71
GM-CSF + LT	1:1,437 ± 175	1:526 ± 91

Mean estimated progenitor frequencies for day 7 and day 14 colonies stimulated by G-CSF or GM-CSF in the absence or presence of cytotoxins. Means ± SD from three bone marrow samples are shown.

morphological appearances of pure granulocyte, pure macrophage, mixed granulocyte-macrophage, and eosinophil colonies. The relative proportions of these colony types were unaltered by either TNF or LT. The rare colony present in cultures stimulated by G-CSF in the presence of either TNF or LT was granulocytic in morphology.

DISCUSSION

The experiments described have given frequency estimates for late (day 7) and early (day 14) progenitor cells in adherent and T cell–depleted human bone marrow that are capable of proliferation in response to stimulation with either recombinant human G-CSF or recombinant human GM-CSF. These were one in 489 (day 7) and one in 1,015 (day 14) for G-CSF and one in 1,407 (day 7) and one in 574 (day 14) for GM-CSF. These frequencies are similar to those described for clonogenic cells in human bone marrow where light-density marrow cells were cultured with partially purified native G-CSF or GM-CSF.[14] The linearity of the plots and demonstration that the y-axis is intercepted at value 0 for both growth factors suggests that the effects of G-CSF and GM-CSF on progenitor cells are direct rather than indirect (mediated by accessory cells).

This study demonstrates the striking difference in sensitivity to cytotoxins of progenitor cells responsive to either G-CSF or GM-CSF. Clonogenic cells that proliferate after stimulation with GM-CSF are resistant to the suppressive effects of TNF (100 U/mL) and LT (100 U/mL), with no significant alteration in the frequency of responding marrow cells. A small suppressive effect in cultures stimulated with GM-CSF is noted when TNF or LT is added in doses of 1,000 U/mL.[12] In contrast, less than one in 100,000 cells are resistant to the effects of TNF or LT when cultures are stimulated with G-CSF.

A feature of the hematopoietic system is the overlapping functional properties of hematopoietic growth factors and apparent redundancy in the control of blood cell production. This is particularly so for G-CSF and GM-CSF, both of which stimulate the formation of granulocyte colonies and activate mature granulocyte function.[15,16] The mechanisms for the differential effect observed in the experiments described in this paper are therefore of considerable interest. One interpretation of the results is that the two growth factors, G-CSF and GM-CSF, act on largely separate populations of clonogenic cells that are different in their responses to the cytotoxins TNF and LT. Cells that proliferate in response to G-CSF are responsive to the effects of TNF and LT, whereas those cells capable of proliferation after stimulation with GM-CSF are relatively unresponsive to the cytotoxins. This mechanism, implicating separate progenitor populations, could result from differences in the expression of receptors for TNF and LT between the two cell pools. The observation that progenitors giving rise to both day 7 and day 14 colonies in response to G-CSF are both extremely sensitive to cytotoxins and, by contrast, that both sets of progenitors responsive to GM-CSF are resistant suggests that the effect is not due to cytotoxins acting on a more mature cell of the same granulocyte-macrophage progenitor pool that has increased responsiveness to G-CSF as compared with GM-CSF. Additional evidence supporting this is that cell clusters (aggregates of three to 39 cells) are less sensitive to the suppressive effects of the cytotoxins than are cell colonies.[12]

TNF and LT show considerable homology in amino acid sequence, bind to the same cell surface receptor, and share a number of biologic properties.[8-11] One possibility that might account for their difference in activity in the presence of G-CSF and GM-CSF may lie in effects on biochemical pathways associated with cell surface receptors for these two growth factors. There is only limited data on the structure of receptors for colony-stimulating factors and the intracellular pathways they might influence. The receptor for macrophage colony–stimulating factor possesses protein tyrosine kinase activity.[17] It is unclear whether G-CSF and GM-CSF receptors have an intrinsic protein kinase activity. Although the murine G-CSF receptor appears to have a molecular weight (mol wt) of approximately 150,000 daltons[18] and is large enough to include an intracellular protein kinase domain, the murine GM-CSF receptor has an estimated mol wt of only 50,000 to 70,000 daltons.[19,20] The intracellular domain of such a receptor may be too small to include a protein kinase component. It is possible that differences in the intracellular signaling systems activated after the binding of G-CSF and GM-CSF to their specific receptors may result in different interactions with TNF and LT. GM-CSF may be capable of antagonizing some or all of the effects of TNF and LT by acting at a postreceptor level. If the cytotoxins were to selectively influence the biochemical pathways associated with activation of receptors for G-CSF, it would not be possible to determine, from these experiments, whether G-CSF and GM-CSF were acting on the same, different, or overlapping populations of progenitor cells. There is experimental evidence from clone transfer studies that G-CSF and GM-CSF are capable of stimulating the same clone, though these experiments were conducted by using partially purified growth factors and require validation with fully purified molecules.[14] There are at least two potential mechanisms for a selective effect of TNF and LT on biochemical pathways activated after binding of G-CSF to its receptor. The effects could be either directly inhibitory or mediated by the induction of differentiation. The cytotoxins are capable of inducing cellular differentiation,[6,7] and G-CSF has been shown to be a powerful inducer of myeloid differentiation in vitro.[16,21] It is possible that TNF and LT, in synergy with G-CSF, have induced a rapid differentiation of progenitor cells at the expense of proliferation, with cell aggregates not reaching colony size or extinction of colonies before day 7.

Further investigation of the differential sensitivity of the granulocyte-macrophage system to the effect of cytotoxins may be helpful in further determining the roles of G-CSF and GM-CSF in regulating myeloid cell production.

Proteoglycan Synthesis in Two Murine Bone Marrow Stromal Cell Lines

By Suzanne L. Kirby and Stuart A. Bentley

There is evidence indicating that stromal proteoglycans are an important functional component of the hematopoietic microenvironment. Proteoglycan synthesis was therefore investigated in the MS3-2A and D2XRII hematopoietic stromal cell lines. These lines differ in their capacity to support hematopoiesis in vitro, D2XRII supporting in vitro hematopoiesis, whereas MS3-2A does not. Cells were labeled with ^{35}S-sulfate as precursor, and 4 mol/L guanidine HCl extracts of cells and media were analyzed by ion-exchange chromatography, cesium chloride density gradient centrifugation, and molecular sieve chromatography. Proteoglycans were further examined by enzymatic and chemical digestions. MS3-2A cells produced at least three proteoglycan species. Two chondroitin/dermatan sulfate (CS/DS) proteoglycans, K_{av} = 0.40 and K_{av} = 0.68 on Sepharose CL-2B, were present primarily in the medium. The respective glycosaminoglycan molecular weight (mol wt) values were 38 kd and 40 kd. A heparan sulfate (HS) proteoglycan of K_{av} = 0.58 and glycosaminoglycan mol wt 36 kd was present primarily in the cell layer extract. D2XRII cells synthesized two HS proteoglycans. The larger (K_{av} = 0.45; glycosaminoglycan mol wt, 30 kd) was of low density on gradient centrifugation and more prominent in the cell layer extracts, whereas the smaller (K_{av} = 0.68; glycosaminoglycan mol wt, 38 kd) was dense and present mainly in the culture medium. A single CS/DS proteoglycan species of K_{av} 0.78 and average glycosaminoglycan of mol wt 18 kd was present in roughly equal amounts in the medium and in the cell layer. MS3-2A and D2XRII thus appear phenotypically distinct with respect to proteoglycan synthesis. These differences are discussed in relation to the microenvironmental function of bone marrow stromal elements.

© 1987 by Grune & Stratton, Inc.

HEMATOPOIETIC STEM CELL function in vivo is dependent on close-range interaction with a complex cellular microenvironment.[1,2] The technique of long-term bone marrow culture[3] has provided a valuable in vitro model for study of the hematopoietic microenvironment at both the cellular and the molecular level. A variety of cellular phenotypes have been implicated as potential mediators of hematopoietic microenvironmental function,[4-9] and a variety of hematopoietic growth regulators have been demonstrated.[10-13]

There is evidence indicating that extracellular matrix components play a significant role in supporting hematopoiesis in long-term bone marrow culture. Proteoglycans are important components of extracellular matrices[14] and appear to have growth regulatory functions in a number of systems.[15] Proteoglycans are complex macromolecules consisting of a central protein core to which is attached a variable number of glycosaminoglycan side chains. Glycosaminoglycans are polysaccharides consisting of repeated disaccharide subunits that in turn consist of an amino sugar linked to a carboxylate, a sulfate ester, or both.[14] Chondroitin sulfate (CS) was found to be the major glycosaminoglycan in the medium and heparan sulfate (HS), the major glycosaminoglycan in the cell layer of murine long-term bone marrow cultures.[16] Perturbation of proteoglycan synthesis in murine long-term bone marrow culture by addition to the culture medium of *p*-nitrophenyl-β-D-xyloside[17] was shown to have profound effects on hematopoietic function[18] and lead to a fivefold increase in granulocyte/macrophage progenitors (CFU-G/M) and a tenfold increase in pluripotential hematopoietic stem cells (CFU-S). These changes were associated with increased levels of CS in the medium.[18]

Only a single major study has addressed the question of intact proteoglycan synthesis in long-term bone marrow culture.[19] Essentially similar patterns of proteoglycan synthesis were demonstrated in the cell layer and the medium, both of which were shown to contain at least three species of CS/dermatan sulfate (CS/DS) proteoglycans. CS and DS are closely related glycosaminoglycans, with glucuronic acid/*N*-acetyl galactosamine disaccharide subunits differing only in the degree of epimerization of glucuronic acid to iduronic acid. HS proteoglycan accounted for approximately 10% of the labeled material. Intact long-term bone marrow cultures contain a variety of cellular phenotypes, both stromal and hematopoietic, many of which have been shown to synthesize proteoglycans. It is not therefore possible to ascribe the synthesis of particular proteoglycan species to particular classes of cells.

An alternative approach for the investigation of stromal proteoglycan synthesis is the study of stromal cell lines derived from long-term bone marrow cultures. In the present study, we investigated two such stromal cell lines, namely, MS3-2A[20,21] and D2XRII,[22,23] the major properties of which are summarized in Table 1. These cell lines differ in one essential respect: D2XRII cells are microenvironmentally competent and support long-term in vitro hematopoiesis when cocultivated with hematopoietic progenitor cells.[23] MS3-2A cells are not microenvironmentally competent but appear to function as preosteoblasts responding to 1:3-dihydroxyvitamin D stimulation with greatly increased levels of alkaline phosphatase activity.[24]

MATERIALS AND METHODS

Materials. Guanidine HCl (practical grade), cesium chloride (optical grade), Sephadex G-50, diethyl aminoethyl (DEAE)-

Sephacel, Sepharose (CL-2B, CL-4B, and CL-6B), 6-aminohexanoic acid, benzamidine HCl, *N*-ethylmaleimide (NEM), phenylmethylsulfonyl fluoride (PMSF), CS (whale cartilage), chondroitinase ABC (*Proteus vulgaris*), and chondroitinase AC (*Arthrobacter aurescens*) were purchased from Sigma Chemical Co, St Louis; heparitinase (*Flavobacterium heparinum*) from ICN Immunobiologicals, Lisle, IL; sodium ^{35}S-sulfate from ICN Radiochemicals, Irvine, CA; Safety-Solve scintillation cocktail from Research Products International Corp, Mount Prospect, IL; fetal calf serum and sulfate-free RPMI 1640 medium from GIBCO, Grand Island, NY; L-glutamine, 1000× penicillin/streptomycin, HEPES, RPMI 1640, and medium 199 from the Tissue Culture Facility, University of North Carolina at Chapel Hill.

Cell culture techniques. The MS3-2A cell line was generously provided by Dr T.M. Dexter, Manchester, England. The D2XRII cell line was generously provided by Dr J.S. Greenberger, Worcester, MA. Cultures were maintained in 25-cm^2 tissue culture flasks at 34°C in a humidified atmosphere of 5% CO_2, 95% air. MS3-2A cells were cultured in medium 199, supplemented with 15% fetal calf serum, 1% 200 mmol/L L-glutamine, and penicillin/streptomycin 1000×. D2XRII cells were grown in RPMI 1640 containing 10% fetal calf serum, 1% 1 mol/L HEPES, 1% 200 mmol/L L-glutamine, and 1000× penicillin/streptomycin, under similar conditions. The cells reached confluence in four to five days and were subcultured by trypsinization, with a split ratio of 1:5.

Radioisotope labeling. Labeling was initiated as the cell cultures approached confluence by adding fresh medium containing either 50 μCi/mL or 200 μCi/mL sodium ^{35}S-sulfate as precursor. Sulfate-free RPMI 1640 was used in the labeling experiments.

Isolation of proteoglycans. After labeling, the cells were removed from the bottom of the flask with a cell scraper and the contents transferred to a centrifuge tube. The medium and cells were centrifuged at 1,000 g for 15 minutes at 5°C. The medium was decanted, and 0.53 g/mL solid guanidine HCl, 10 μL/mL 100× NEM, and 10 μL/mL 100× PMSF were added to make the solution 4 mmol/L in guanidine HCl, 10 mmol/L in NEM, and 1 mmol/L in PMSF. Cell pellets were extracted at room temperature with 4 mmol/L guanidine HCl, 0.1 mol/L 6-aminohexanoic acid, 10 mmol/L NEM, 1 mmol/L PMSF, 5 mmol/L benzamidine HCl, 50 mmol/L sodium EDTA, 50 mmol/L sodium acetate, and 0.5% Triton X-100, pH 5.8, 1 mL/25-cm^2 flask culture. The cell extracts and media were stored at −20°C for subsequent analysis. Unincorporated isotope was removed from the medium fractions and cell extracts by Sephadex G-50 chromatography (bed volume of 8 mL for each 1.5-mL sample). Columns were eluted with 8 mol/L urea, 0.05 mol/L sodium acetate, 0.15 mol/L sodium chloride, and 0.5% Triton X-100 for subsequent ion-exchange chromatography. Recoveries of macromolecular material were >85%, and separation from unincorporated material was complete.

Column chromatography. Sephadex G-50–excluded fractions in 8 mol/L urea, 0.15 mol/L sodium chloride, 0.5 mol/L sodium acetate, and 0.5% Triton X-100 were applied to DEAE-Sephacel columns (1.6 × 4 cm) equilibrated with the same 8 mol/L urea buffer. After sample application, the columns were washed with approximately 20 mL 8 mol/L urea buffer and then eluted with a linear NaCl gradient (0.15 to 1.0 mol/L) using a total volume of 100 mL. ^{35}S-labeled peaks were pooled and then concentrated on DEAE-Sephacel columns of 1.5-mL bed volume.[25] Recoveries of ^{35}S-labeled material were >80%.

Analytic columns of Sepharose CL-2B and CL-4B (1.6 × 100 cm) were prepared in and eluted with 4 mol/L guanidine HCl, 0.05 mol/L Tris, 0.05 mol/L sodium acetate, and 0.2% Triton X-100, pH 7.0, at a flow rate of 12 mL/h. Analytic columns of Sepharose CL-6B (1.6 × 100 cm) were prepared in and eluted with 0.1 mol/L sodium acetate and 0.1 mol/L Tris, pH 7.3 (flow rate, 12 mL/h). The void and total column volumes were marked with blue dextran and free ^{35}S-sulfate, respectively. Recoveries of labeled macromolecules were >80%.

Isopyknic cesium chloride centrifugation. Solid cesium chloride, 0.5 g/g, was added to medium and cellular proteoglycan fractions in 4 mol/L guanidine HCl buffer after ion-exchange chromatography and concentration to give an initial density of 1.40 g/mL. Dissociative density gradients were formed by using a Beckman 60 SW rotor at 37,000 rpm at 10°C for 48 hours in a Beckman L8-70 ultracentrifuge (Beckman Instruments, Inc., Fullerton, CA). Fifteen 0.25-mL fractions were collected after piercing the bottom of the tube. These fractions were pooled into four approximately equal fractions, designated D1 through D4 from bottom to top, for subsequent gel-filtration chromatography.

Chemical analyses. Alkaline borohydride treatment was performed in 0.05 mol/L sodium hydroxide and 1 mol/L sodium borohydride at 45°C for 24 hours, which resulted in β-elimination of glycosaminoglycan chains from the protein core.[26] Excess borohydride was destroyed by neutralization with glacial acetic acid. Nitrous acid treatment was performed at room temperature in 0.18 mol/L acetic acid with 0.24 mol/L sodium nitrite for 80 minutes.[27] The reaction was stopped by the addition of an equal volume of 2 mol/L ammonium sulfamate.

Enzymatic treatments. Samples were digested for four hours at 37°C with chondroitinase ABC (0.05 to 0.1 U/mg carrier) and chondroitinase AC (0.25U/mg carrier) in a 0.1 mol/L Tris, 0.1 mol/L sodium acetate buffer, pH 7.3.[28] Enzyme concentrations were adjusted for the content of CS carrier. Heparitinase digestion was carried out in a 0.1 mol/L Tris, 0.1 mol/L sodium acetate, and 0.005 mol/L calcium acetate buffer, pH 7.0, containing 0.5 mg/mL ovalbumin, 1 mmol/L PMSF, and 0.1 U/mL heparitinase.[29] Digestion was continued for three hours at 37°C and fresh enzyme added for one additional hour.

RESULTS

Kinetics of macromolecular incorporation of label. The accumulation of ^{35}S-labeled macromolecules in the media was linear for up to 96 hours but tended to plateau in the cell layer extracts (Fig 1). Preliminary gel-filtration chromatography indicated that proteoglycan synthesis was qualitatively stable for 96 hours, although there was progressive accumulation of smaller molecules, presumably proteoglycan degradation products, during the later stages of the observation period (data not shown). A 48-hour labeling period gave maximum incorporation of isotope with acceptable levels of proteoglycan degradation and was therefore considered optimal for subsequent experiments. At the 48-hour time point, the ratio of macromolecular ^{35}S activity in the media to that in the cell layer extracts was approximately 2:1.

Analysis of culture media proteoglycans. DEAE-

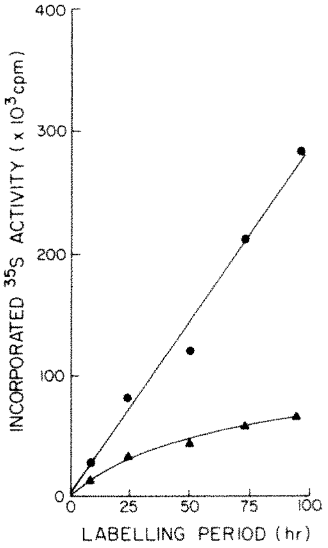

Fig 1. Accumulation of ^{35}S-labeled macromolecules in the medium (●) and cell layer (▲) of MS3-2A cultures. Virtually identical results were obtained in D2XRII cultures.

Table 2. Analysis of CsCl Density Gradient Fractions From MS3-2A and D2XRII Culture Medium

Fraction	Density (g/L)	Percent of Total Gradient Activity	CS/DS Proteoglycan Percent of Fraction	CS/DS Proteoglycan K_{av}	HS Proteoglycan Fraction (%)	HS Proteoglycan K_{av}
MS3-2A D1	1.59	25	46	0.36, 0.70	47	0.62
MS3-2A D2	1.48	34	64	0.42, 0.69	28	0.60
MS3-2A D3	1.39	28	73	0.38, 0.67	37	0.62
MS3-2A D4	1.33	13	62	0.60	43	0.69
D2XRII D1	1.58	22	20	0.85	80	0.66
D2XRII D2	1.48	33	40	0.82	60	0.69
D2XRII D3	1.39	24	65	0.78	30	0.62
D2XRII D4/I	1.31	9	42	0.64	66	0.55
D2XRII D4/II	1.31	12	70	0.80	20	*

CS/DS proteoglycans were quantitated as chondroitinase ABC-sensitive activity and HS proteoglycans, as heparitinase-sensitive activity.

*Scanty residual material with no clearly defined peak.

Sephacel chromatography of macromolecular material from both MS3-2A and D2XRII culture media revealed single, broad ^{35}S-labeled peaks eluting between 0.40 and 0.65 mol/L NaCl (data not shown). Pooled material from these peaks was further analyzed by CsCl density gradient centrifugation. Sepharose CL-2B chromatograms of the gradient fractions from the MS3-2A culture medium are illustrated in Fig 2A. All the gradient fractions contained proteoglycans of K_{av} 0.65 to 0.70 in substantial quantities, with a tendency to decreasing hydrodynamic size with decreasing density. The D1 to D3 fractions also contained proteoglycans of K_{av} 0.35 to 0.45, whereas the D4 fractions contained an incompletely resolved peak of intermediate hydrodynamic size. Sepharose CL-2B chromatograms of the gradient fractions from the D2XRII culture medium are illustrated in Fig 2B. All D2XRII medium fractions contained a major labeled peak in the range 0.65 to 0.75 K_{av}, whereas the medium D4 fraction also contained a clearly defined second peak of K_{av} 0.55.

The percentages of ^{35}S-labeled material in each culture medium fraction sensitive to chondroitinase ABC and heparitinase digestion and eluting at Vt (total column volume) on subsequent Sepharose CL-2B chromatography are shown in Table 2 together with K_{av} values for the resistant material. Digestion data indicate that all MS3-2A medium fractions contained a polydisperse CS/DS proteoglycan of K_{av}, 0.68 that accounted for 45% of the total radioactivity recovered from the gradient. The intermediate-density fractions (mainly D2 and D3) also contained a larger CS/DS proteoglycan (K_{av}, 0.35 to 0.45) that accounted for 20% of the recovered activity. In addition, all fractions contained a polydisperse HS proteoglycan (K_{av}, 0.61) that accounted for 35% of the activity recovered from the gradient. Digestion data for D2XRII culture medium indicate that the major peaks in all fractions (K_{av}, 0.65 to 0.75) contained varying

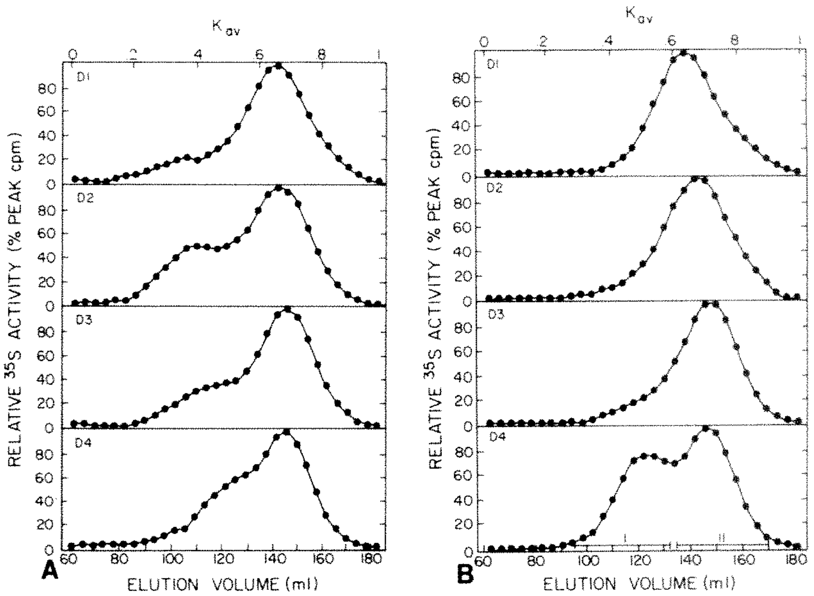

Fig 2. Sepharose CL-2B chromatograms of CsCl gradient fractions from MS3-2A and D2XRII culture media. All MS3-2A gradient fractions (A) contained proteoglycans of K_{av} 0.65 to 0.70 in substantial quantities. The D1 to D3 fractions also contained proteoglycans of K_{av} 0.35 to 0.45, whereas the D4 fraction contained an incompletely resolved peak of intermediate hydrodynamic size. All D2XRII medium fractions (B) contained a major labeled peak in the range 0.65 to 0.75 K_{av}. In addition, the D4 fraction contained a clearly defined second peak of K_{av} 0.55 (B).

proportions of a dense HS proteoglycan of K_{av} 0.67 and a somewhat less dense polydisperse CS/DS proteoglycan (K_{av} 0.78). These proteoglycans accounted, respectively, for 45% and 49% of the total activity recovered from the gradient. Analysis of the D4 gradient fraction also revealed the presence of a larger, low-density HS proteoglycan (K_{av}, 0.55) that accounted for approximately 6% of the total recovered radioactivity.

Proteoglycans from MS3-2A and D2XRII culture medium were digested with chondroitinase ABC or heparitinase and the resistant material separated on Sepharose CL-2B. The resulting peaks (see Fig 2) were pooled, concentrated by ultrafiltration, and subjected to alkaline borohydride treatment for subsequent glycosaminoglycan analysis. The Sepharose CL-6B elution profile for MS3-2A culture medium HS glycosaminoglycan showed a single peak of K_{av} 0.37 that corresponded to a molecular weight (mol wt) of 36 kd. The elution profile for D2XRII medium HS glycosaminoglycan showed a single peak of K_{av} 0.36 that corresponded to a mol wt of 38 kd. Both peaks were fully susceptible to nitrous acid digestion, which confirmed that the chondroitinase ABC–resistant material in both original samples was HS proteoglycan. The larger, low-density HS proteoglycan was purified separately from the D2XRII medium D4 fraction and subjected to alkaline borohydride treatment. A subsequent Sepharose CL-6B chromatogram showed a single included peak of K_{av} 0.35 that corresponded to a glycosaminoglycan mol wt of 40 kd. The elution profiles of glycosaminoglycans isolated from the two MS3-2A medium CS/DS proteoglycans were virtually identical to each other and showed single included peaks of K_{av} 0.36 that corresponded to a glycosaminoglycan mol wt of 38 kd. Glycosaminoglycan chains from the D2XRII medium CS/DS proteoglycan were considerably smaller and gave a single included peak of K_{av} 0.47 that corresponded to a mol wt of 22 kd.

Analysis of cell layer extract proteoglycans. DEAE-Sephacel elution profiles of macromolecular material obtained from MS3-2A and D2XRII cell layer extracts showed single, broad ^{35}S-labeled peaks eluting between 0.40 mol/L and 0.65 mol/L NaCl (data not shown). Pooled material from these peaks was further analyzed by CsCl density gradient centrifugation. Sepharose CL-2B chromatograms of the gradient fractions from MS3-2A cell layer extract are illustrated in Fig 3A. Chromatograms of all fractions showed peaks of K_{av} 0.55 to 0.60. Fractions D1 to D3 contained a small amount of a proteoglycan species of similar hydrodynamic size to that seen in the equivalent medium fractions (K_{av}, 0.35 to 0.45). Fraction D1 also contained an incompletely resolved peak of K_{av} 0.73. Sepharose CL-2B chromatograms of the CsCl gradient fractions from D2XRII cell layer extract are illustrated in Fig 3B. The D1 to D3 fractions each showed two major peaks of K_{av} 0.55 to 0.60 and K_{av} 0.78, respectively. The K_{av} 0.78 peak predominated in fraction D1, whereas the K_{av} 0.55 to 0.60 peak predominated in fraction D3. The D4 fraction showed peaks of K_{av} 0.45 and 0.62.

The percentages of ^{35}S-labeled material in each cell layer extract fraction sensitive to chondroitinase ABC and heparitinase digestion and eluting at Vt on subsequent Sepharose CL-2B chromatography are shown in Table 3 together with K_{av} values for the resistant material. Digestion data for the MS3-2A cell layer extract indicate that all fractions contained a HS proteoglycan of K_{av} 0.55 to 0.60, although the majority of this proteoglycan was present in the low-density fractions (D3 and D4). HS proteoglycan accounted for approximately 45% of the total radioactivity recovered from the gradient. The K_{av} 0.35 to 0.45 material in gradient fractions D1 to D3 was a large CS/DS proteoglycan similar to that found in MS3-2A culture medium, and this accounted for approximately 10% of the total recovered radioactivity. Fractions D2 to D4 contained a CS/DS proteoglycan of K_{av} 0.65 to 0.70 that accounted for about 35% of total recovered radioactivity. The K_{av} 0.73 peak in gradient fraction D1 was fully sensitive to chondroitinase ABC digestion and accounted for 10% of the total recovered radioactivity. On Sepharose CL-6B chromatography before and after alkaline borohydride treatment, the observed K_{av} values were 0.36 and 0.44, respectively. This suggests that the material in

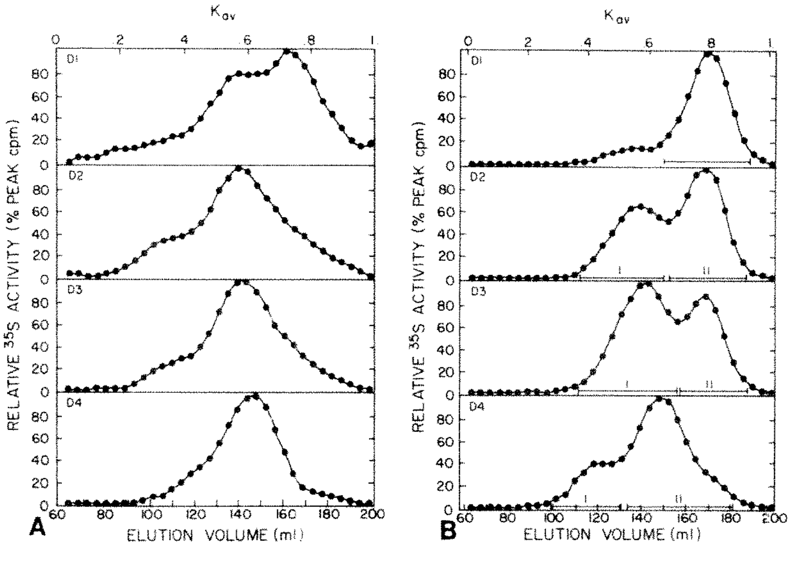

Fig 3. Sepharose CL-2B chromatograms of CsCl gradient fractions from MS3-2A and D2XRII cell layer extracts. MS3-2A cell layer (A) fractions D1 to D3 contained proteoglycans in the range of K_{av} 0.35 to 0.45. All fractions contained peaks of K_{av} 0.55 to 0.60. Fraction D1 also contained an incompletely resolved peak of K_{av} 0.73. The D2XRII cell layer (B) D1 to D3 fractions each showed two major peaks of K_{av} 0.55 to 0.60 and K_{av} 0.78, respectively, the K_{av} 0.78 peak predominating in fraction D1 and the K_{av} 0.55 to 0.60 peak, in fraction D3. The D4 fraction showed peaks of K_{av} 0.45 and 0.62.

Table 3. Analysis of CsCl Density Gradient Fractions From MS3-2A and D2XRII Cell Layer Extracts

Fraction	Density (g/L)	Percent of Total Gradient Activity	CS/DS Proteoglycan		HS Proteoglycan	
			Percent of Fraction	K_{av}	Fraction (%)	K_{av}
MS3-2A D1	1.60	30	76	0.35, 0.75	35	0.56

Table 4. Summary of Major Characteristics of Proteoglycans Identified in MS3-2A and D2XRII Culture Media

Designation	Source (Medium)	Percent of Source PG	K_{av} CL-2B	Density	GAG	GAG mol wt (kd)
MS3-M-DS1	MS3-2A	19	0.35-0.40	Int	DS	38
MS3-M-DS2	MS3-2A	45	0.68	Poly	DS	40
D2X-M-DS	D2XRII	49	0.78	Int	DS	22
MS3-M-HS	MS3-2A	36	0.61	Poly	HS	36
D2X-M-HS1	D2XRII	45	0.67	High	HS	38
D2X-M-HS2	D2XRII	6	0.55	Low	HS	40

Abbreviations: PG, proteoglycan; GAG, glycosaminoglycan; Int, intermediate; Poly, polydisperse.

question was a small CS/DS proteoglycan rather than a free glycosaminoglycan and that the corresponding glycosaminoglycan mol wt was 26 kd.

Digestion data for the D2XRII cell layer extract indicate the presence of an intermediate- to low-density HS proteoglycan of K_{av} 0.58 that accounted for 34% of the ^{35}S activity recovered from the gradient. The D4 fraction also contained a low-density HS proteoglycan of K_{av} 0.45 that appeared distinct from the K_{av} 0.58 material. This accounted for approximately 8% of the recovered activity. An intermediate- to high-density CS/DS proteoglycan of K_{av} 0.78 accounted for approximately 58% of the total activity recovered from the gradient.

Cell layer proteoglycans were digested with chondroitinase ABC or heparitinase and the resistant material separated on Sepharose 2B-CL. The resulting peaks (see Fig 3) were pooled, concentrated by ultrafiltration, and subjected to alkaline borohydride treatment for subsequent glycosaminoglycan analysis. The Sepharose CL-6B elution profile for MS3-2A cell layer HS glycosaminoglycan showed a single peak of K_{av} 0.37 that corresponded to a mol wt of 36 kd. This material was fully susceptible to subsequent nitrous acid digestion. The MS3-2A cell layer HS glycosaminoglycan was thus equal in size to the MS3-2A medium HS glycosaminoglycan, although the intact cell layer proteoglycan was somewhat larger and more buoyant. The elution profiles of glycosaminoglycans isolated from the two MS3-2A cell layer CS/DS proteoglycans were virtually identical to each other and showed single included peaks of K_{av} 0.36 that corresponded to a glycosaminoglycan mol wt of 38 kd. These results were in turn identical to those obtained for the corresponding proteoglycans isolated from MS3-2A medium.

The elution profile for D2XRII cell layer HS glycosaminoglycan showed a single peak of K_{av} 0.41 that corresponded to a mol wt of 30 kd. This material was fully susceptible to subsequent nitrous acid digestion. The larger, low-density HS proteoglycan was purified from the D2XRII cell layer D4 fraction and subjected to alkaline borohydride treatment. A subsequent Sepharose CL-6B chromatogram also showed a single included peak of K_{av} 0.41 that corresponded to a glycosaminoglycan mol wt of 30 kd. The elution profile of glycosaminoglycan isolated from the D2XRII cell layer CS/DS proteoglycan showed a single included peak of K_{av} 0.52, that corresponded to a glycosaminoglycan mol wt of 15 kd.

DISCUSSION

The major characteristics of the proteoglycans identified in MS3-2A and D2XRII culture media are summarized in Table 4. MS3-2A secreted two clearly identifiable CS/DS proteoglycans differing in size and buoyant density. In contrast, D2XRII cells produced only a single CS/DS proteoglycan that was smaller and more dense than the corresponding MS3-2A proteoglycan (MS3-M-DS2), with smaller glycosaminoglycan side chains. D2XRII cells secreted relatively more HS proteoglycan into the culture medium than did MS3-2A cells. In further contrast, the D2XRII medium HS proteoglycans were readily resolved into a small, high-density species (D2X-M-HS1) and a larger, low-density species (D2X-M-HS2), whereas only a single, polydisperse HS proteoglycan was identifiable in MS3-2A culture medium.

The major characteristics of the proteoglycans identified in MS3-2A and D2XRII cell layer extracts are summarized in Table 5. The D2XRII cell layer contained only a single CS/DS proteoglycan, closely resembling that identified in the culture medium. In contrast, three CS/DS proteoglycans were identified in the MS3-2A cell layer. Two of these (MS3-C-DS1 and MS3-C-DS2) were similar to correspond-

Table 5. Summary of Major Characteristics of Proteoglycans Identified in MS3-2A and D2XRII Cell Layer Extracts

Designation	Source (Cell)	Percent of Source PG	K_{av} CL-2B	Density	GAG	GAG mol wt (kd)
MS3-C-DS1	MS2-2A	10	0.35-0.40	Int	DS	38
MS3-C-DS2	MS3-2A	25	0.65-0.70	Poly	DS	40
MS3-C-DS3	MS3-2A	10	0.73	High	DS	26
D2X-C-DS	D2XRII	58	0.78	High	DS	15
MS3-C-HS	MS3-2A	55	0.55-0.60	Low	HS	36
D2X-C-HS1	D2XRII	34	0.58	Int	HS	30
D2X-C-HS2	D2XRII	8	0.45	Low	HS	30

ing proteoglycans in the culture medium (MS3-M-DS1 and MS3-M-DS2), whereas a third CS/DS proteoglycan (MS3-C-DS3) more closely resembled the D2XRII cell layer CS/DS proteoglycan. Both cell layers contained low-density HS proteoglycans. The D2XRII cell layer HS proteoglycans were further resolved into intermediate- and low-density fractions (D2X-C-HS1 and D2X-C-HS2). It is uncertain whether these represent distinct proteoglycan species or polydispersity of a single species.

The present studies have demonstrated substantial differences between the patterns of proteoglycan synthesis in MS3-2A and D2XRII cells. The proteoglycan synthesis pattern of MS3-2A cells had much in common with that observed in a variety of fibroblast cell lines. Vogel and Peterson,[30] studying proteoglycan synthesis in IMR-90 human embryonic lung fibroblasts, identified two CS/DS proteoglycans in the medium of K_{av} 0.29 and K_{av} 0.68 on Sepharose CL-2B. The major proteoglycan species found in the cell layer was a low-density HS proteoglycan of K_{av} 0.40 on Sepharose CL-2B. Carlstedt et al[31,32] found a large, glucuronic acid–rich DS proteoglycan and a smaller, iduronic acid–rich DS proteoglycan to be the major species in the culture medium from embryonic skin fibroblasts. The cells contained mainly HS proteoglycan, a DS proteoglycan similar to the large DS proteoglycan from the medium and free DS chains. The proteoglycan synthesis pattern of D2XRII cells more closely resembled that observed in endothelial cells. Bovine aortic endothelial cells have been shown to synthesize a large buoyant HS proteoglycan, a smaller dense HS proteoglycan of K_{av} 0.43 on Sepharose CL-4B, and a CS/DS proteoglycan of K_{av} 0.45.[33]

It is tempting to associate differences in proteoglycan synthesis with functional differences between these cell lines. MS3-2A cells appear to represent a fibroblast-like phenotype with the potential to develop into osteoblasts.[24] The osteoblastic potential of so-called bone marrow fibroblasts is well documented,[34] and it has further been demonstrated that these cells do not provide a microenvironment supportive of hematopoiesis in long-term bone marrow culture.[5] Because the proteoglycan synthesis pattern of D2XRII cells has more in common with the endothelial cell phenotype, the present findings are in accordance with the current consensus that the hematopoietic microenvironment in long-term bone marrow culture is provided by an endothelial-like cell.

Hematopoietically active human long-term bone marrow cultures were shown to produce three species of CS/DS proteoglycan on the basis of hydrodynamic size, with similar heterogeneity in the medium and the cell layer.[19] A large, glucuronic acid–rich species eluted in the void volume of a Sepharose CL-4B column. The remaining CS/DS proteoglycan appeared to consist of an intermediate-sized glucuronic acid–rich fraction excluded from a Sepharose CL-6B column and a smaller species, K_{av} 0.39 on Sepharose CL-6B, richer in iduronic acid. HS proteoglycan accounted for only 10% of the labeled material in this culture system. It was suggested that this pattern of proteoglycan synthesis resembled that of smooth muscle cells, which have previously been proposed as potential contributors to hematopoietic microenvironmental function.[9] Smooth muscle cells have been shown to produce two CS/DS proteoglycans, including a large, glucuronic acid–rich species of K_{av} 0.30 on Sepharose CL-2B and a smaller, iduronic acid–rich species of K_{av} 0.69, with only small quantities of HS proteoglycan.[35] Thus smooth muscle cells, in terms of proteoglycan synthesis, more closely resemble MS3-2A cells, which are incompetent microenvironmentally, than D2XRII cells. Although the presence of smooth musclelike cells in long-term bone marrow cultures is certainly a possibility, it is probable that the observed proteoglycan heterogeneity reflected the presence of multiple stromal and hematopoietic phenotypes. Synthesis of proteoglycan, especially CS proteoglycan, has been demonstrated in lymphocytes,[36,37] monocytes,[37,38] neutrophils,[39,40] eosinophils,[41] and basophils.[42] Proteoglycans derived from hematopoietic elements may thus represent a substantial proportion of total proteoglycan synthesis in hematopoietically active long-term bone marrow cultures.

There is compelling evidence that proteoglycans contribute significantly to the functional hematopoietic microenvironment.[18] To evaluate this contribution, it will be necessary to identify and characterize the specific proteoglycans involved. Proteoglycans are extremely complex structures and are therefore polydisperse. There is thus considerable overlap between different species with respect to chemical and physical properties, and resolution of individual proteoglycans is difficult, even in pure culture systems. In a heterogeneous system such as long-term bone marrow culture, such resolution is virtually impossible. The study of microenvironmentally competent stromal cell lines offers a potentially valuable alternative.

Hematopoetic Precursors Respond to a Unique B Lymphocyte–Derived Factor In Vivo

By Eero Niskanen, Janet Gorman, and Peter C. Isakson

In this study we detected a factor that stimulates the proliferation of bone marrow–derived hematopoietic precursors in diffusion chambers implanted in mice. This factor, called diffusible colony-stimulating factor (D-CSF), was found in medium conditioned in the presence of spleen and peripheral blood cells from mice with B cell leukemia (BCL$_1$). After the administration of D-CSF, the number of colonies formed in the plasma clot inside the chamber (CFU-DG) was increased, as were the number of hematopoietic precursors (CFU-MIX, CFU-S, CFU-C, and BFU-E) as judged by a subculture of diffusion chamber contents. Depletion of macrophages and T cells from the spleen cell suspension did not decrease the production of D-CSF, thereby indicating that it was derived from B cells. Neoplastic BCL$_1$ cells appear to be the source because D-CSF could not be detected in medium conditioned with normal B cells. BCL$_1$-conditioned medium (CM) did not enhance CFU-MIX, BFU-E, and CFU-C colony formation in vitro, which suggested that D-CSF is different from multi-CSF, EPA, or CSF. The addition of BCL$_1$ CM to multi-CSF–, erythroid potentiating activity (EPA), and CSF (EL-4CM)-containing cultures had no effect on CFU-MIX, BFU-E, and CFU-C colony formation, thus indicating the absence of a synergistic or inhibitory activity. On the other hand, EL-4 CM, which stimulates CFU-MIX, BFU-E, and CFU-C in vitro, had no effect on CFU-DG in vivo. Biochemical characterization of BCL$_1$ CM revealed that D-CSF is relatively heat stable and loses its bioactivity with protease treatments. It binds to lentil-lectin, according to gel-filtration chromatography has a relative molecular weight of approximately 43,000, and on reverse-phase high-performance liquid chromatography elutes with acetonitrile. These data also indicate that transformed B cells may serve as a source for hematopoietic regulators that act on hematopoietic precursors in vivo.

© 1987 by Grune & Stratton, Inc.

THE FORMATION OF COLONIES in semisolid cultures in vitro has been established as a standard probe to detect hematopoietic activities. Based on morphological assessment, cytokines have been identified that induce single cells to give rise to progeny consisting of erythroid, granulocytic, monocytic, megakaryocytic, or mixed populations of cells.[1-8] Whether hematopoietic cell proliferation in vivo is modulated by the same substances has been difficult to determine, except for the role of erythropoietin on red cell production. The existence of other physiological hematopoietic regulators active in vivo has been implied by enhanced granulocytic colony formation from bone marrow in diffusion chambers implanted in mice that are rendered cytopenic with cytotoxic agents or total body irradiation.[9,10] The murine bone marrow cells (CFU-DG) that give rise to these colonies can also give rise to multipotential precursor cells (12-day CFU-S),[11] which suggests that the diffusion chamber system detects activities early in hematopoietic differentiation.

Previously, we have discovered that two neoplastic human T cell lines (Mo and HUT 102) elaborate an activity that we call diffusible colony-stimulating factor (D-CSF), which enhances granulocytic colony formation from human marrow in diffusion chambers in mice. This activity can be separated from those activities that stimulate multipotential (CFU-MIX) and unipotential (BFU-E, CFU-C) precursors in vitro.[12,13] The unresponsiveness of murine hematopoietic cells to the human factor has limited further in vivo characterization of D-CSF and indicates species specificity. This obstacle is now removed by identification of murine B cell line leukemia, BCL$_1$, as a source of D-CSF.

MATERIALS AND METHODS

Cell preparation. The BCL$_1$ cell line is monoclonal and bears abundant surface IgM$_1$.[14,15] It is maintained by intravenous passage of 2×10^6 peripheral blood cells obtained from BCL$_1$-bearing BALB/c mice (Cumberland View Farms, Clinton, TN).

BCL$_1$ conditioned medium. The BCL$_1$ spleen cells and peripheral blood cells were obtained from BALB/c mice inoculated with BCL$_1$ cells 4 to 6 weeks earlier. After separation on a Ficoll-Hypaque gradient, macrophages were removed by adherence (30 minutes, four times) to glass and T cells by anti-Thy 1.2 antibody (Immunology Associates, Westchester, PA) plus baby rabbit complement. After these treatments, the preparations contained less than 0.3% macrophages and T cells as judged by nonspecific esterase stain and fluorescence microscopy, respectively. Purity of the BCL$_1$ cells was also assessed by fluorescence microscopy after staining with rhodamine-conjugated polyvalent Ig goat antimouse immunoglobulins. Pure populations of normal B cells were obtained similarly from the spleens of normal BALB/c mice. Then the cells were incubated in 75-cm^2 plastic flasks (Corning Glass Works, Corning, NY) at 37°C and 10% CO_2 in RPMI 1640 medium with or without 10% fetal calf serum (FCS) for six days at 2×10^6 cells/mL. In the absence of serum the cultures were supplemented with 1% Nutridoma (Boehringer Mannheim Biochemicals, Indianapolis) and 10 mM HEPES buffer (GIBCO, Grand Island, NY). During the culture period, cell viability remained high (>90%), and there was no net increase in cell number, which indicated a relatively quiescent cell population. Reverse transcriptase assay of BCL$_1$ conditioned medium (CM) did not demonstrate any increased activity, which suggested that viruses or virus-derived particles were not responsible for the hematopoietic effects. Endotoxin was removed from selected preparations by using the limulus amebocyte lysate absorption technique.[16]

EL-4 CM. EL-4 CM was obtained by culture of EL-4 cells (10^6/mL) in 2% FCS and RPMI 1640 with 10 nmol/L phorbol myristate acetate for two to three days. The CM was concentrated tenfold by a Millipore CS-30 apparatus and then dialyzed extensively against phosphate-buffered saline (PBS). This CM contained high levels of interleukin 3 (IL-3), IL-2, GM-CSF, and B cell stimulating factor (BSF-1).[17]

CFU-DG assay. The number of CFU-DG was determined by the plasma clot diffusion chamber technique.[18] Diffusion chambers were prepared by gluing Millipore filters (Millipore Corp, Bedford, MA; pore size, 0.22 uμ) onto both sides of a plastic ring. Each chamber was filled with 0.1 mL murine bone marrow cell suspension (concentration 1×10^6 cells/mL). After sealing, two chambers were implanted into the peritoneal cavity of each mouse. Preparations to be assessed were given either intraperitoneally (0.5 mL/d) or by osmotic minipumps (Alza Corp, Palo Alto, CA), which were implanted in the peritoneal cavity. At the end of the culture, six to eight chambers per group were removed from the hosts. The clot that had formed inside the chamber was fixed in 5% glutaraldehyde and stained with benzidine-hematoxylin, dried, and made transparent by dipping in immersion oil. On microscopic examination, cell aggregates containing more than 19 granulocytic cells or more than seven erythroid cells were counted as colonies. Based on a dilution curve, the amount of protein giving rise to one colony over control was considered 1 unit.

CFU-C assay. The double-layer agar technique was used to assay CFU-C.[19] Bone marrow cells (1×10^5/plate) were placed in the upper layer, and the agent to be assayed for stimulating activity was placed in the lower layer. In assays for inhibitory activity, bone marrow cells and compounds to be assayed were placed in the same single layer. Triplicate cultures were incubated in 5.0% CO_2, and the colonies were counted after seven days.

BFU-E assay. Cells were cultured in Petri dishes, by using the methylcellulose technique of Iscove et al.[20] Human urinary erythropoietin was obtained from Toyobo, Inc (Osaka, Japan). Duplicate plates were incubated at 37°C in a humidified atmosphere of 7% CO_2 in air. On day 8, aggregates of 40 cells or more were counted as BFU-E.

CFU-MIX assay. A technique first described by Fauser and Messner[21] and modified by Ash et al[22] was used to assay CFU-MIX. Cells were cultured in 35-mm Petri dishes with 5% CM from EL-4 cell line, 1 unit of human erythropoietin (Toyobo), 30% FCS, Iscove's 10^{-5} modified Dulbecco's medium, 5×10^{-5} mol/L 2-mercaptoethanol (Sigma Chemical Co, St Louis), and 0.9% methylcellulose as a viscous support. After 14 days of incubation at 37°C in a humid atmosphere containing 5% CO_2, cultures were examined for the presence of mixed colonies. Mixed colonies were identified by their composition of translucent and hemoglobinized cells. Heterogenous morphology was verified on slides prepared from individual colonies and stained with Wright's stain.

CFU-S assay. CFU-S were assessed by the method described by Till and McCulloch.[23] Host mice were pretreated with 850-R total body irradiation. Each mouse received 0.25 mL of cell suspension (concentration, 3.2×10^5 cells/mL). They were killed 12 days later, and their spleens were removed and fixed in Bouin's solution for colony count.

Culture of hematopoietic cells in diffusion chambers in mice. The diffusion chamber technique used in this study has been described in detail elsewhere.[18] Diffusion chambers were filled with 1×10^5 normal murine bone marrow cells and implanted intraperitoneally in mice. The hosts were injected intraperitoneally daily with 0.5 mL of media to be tested. After four days of implantation, six chambers per group were removed and placed in McCoy's medium containing 0.5% pronase (Calbiochem, La Jolla, CA) and 5% Ficoll (Sigma) to dissolve the clot formed inside the chambers. After agitation for 80 minutes at room temperature, the chambers were opened sterilely, and the contents were removed for determination of CFU-S, CFU-MIX, BFU-E, and CFU-C concentrations per chamber.

Enzyme treatments. BCL$_1$ CM was treated with trypsin (1.8 U/mL in 0.1 mol/L Tris-HCL for 20 minutes, Sigma), chymotrypsin (0.13 U/mL in 0.1 mol/L Tris-HCL for 20 minutes, Sigma), pronase (0.14 U/mL in PBS for 20 minutes, Calbiochem), or neuraminidase (8 U/mL in 1 mol/L sodium acetate for 90 minutes, Sigma).

Purification of D-CSF. BCL$_1$ CM was concentrated tenfold by a mini-ultrasart ultrafiltration module (Sartorius, Göttingen, West Germany) and dialyzed against PBS. This material was applied to a column (2.5 × 6 cm) of lentil-lectin Sepharose 4B (Pharmacia Fine Chemicals, Piscataway, NJ) that had been equilibrated with PBS. Then 10 vols of buffer was used to wash the column, and 35 mL of 0.2 mol/L methyl-D-mannoside in PBS was used to elute D-CSF. The resulting preparation was again concentrated tenfold, applied to an Ultrogel AcA44 column (1.5 × 90 cm; LKB, Gaithersberg, MD), and equilibrated with PBS as the running buffer. The column was calibrated by using ovalbumin (43 kd) and chymotrypsinogen (25 kd). The flow rate was 6 mL/h, and 3-mL fractions were collected. Fractions with the highest D-CSF activity were combined and applied directly to the high-performance liquid chromatography (HPLC) column without additional manipulation. Reverse-phase HPLC was performed on a Beckman apparatus (Beckman Instruments, Inc, Fullerton, CA) by using a Brownlee C-8 column (4.5 × 100 mm; Brownlee, Santa Clara, CA) with a starting solvent of 10% acetonitrile and 0.1% trifluoroacetic acid in water. The column was eluted with increasing concentrations of acetonitrile in 0.1% trifluoracetic acid by using the following gradient: 10% to 30% acetonitrile over 20 minutes and then 30% to 60% over 60 minutes. The flow rate was 1.5 mL/min. UV absorbance was monitored at 214 nm, and protein peaks were collected by a FRAC-100 fraction collector (Pharmacia), evaporated to dryness, and resuspended in a small volume of PBS.

Protein determination. The protein concentration was measured by the Bradford method.[24]

RESULTS

Effect of BCL$_1$ on granulopoiesis in vivo. BALB/c mice inoculated with BCL$_1$ demonstrate, in accordance with an earlier study (Muirhead, personal communication), an increase in the granulocyte count (Fig 1); the hematocrit value and platelet count remained unchanged up to 5 weeks. To determine whether the granulocytosis might be caused by an activity stimulating colony formation inside diffusion chambers, we implanted diffusion chambers containing 1×10^5 normal bone marrow cells in both normal and BCL$_1$ tumor-bearing mice. As judged by the number of colonies containing granulocytes (Table 1), the mice inoculated with leukemic B cells 4 weeks earlier provided an environment that enhanced proliferation and differentiation of CFU-DG compared with controls ($P < .01$). The number of erythroid colonies (CFU-DE) stayed unchanged (Table 1), which implied the absence of an effect on erythroid differentiation.

Effect of BCL$_1$ CM on CFU-DG. To determine whether BCL$_1$ cells themselves were producing a humoral factor acting on CFU-DG, we assayed CM obtained from in vitro cultures of BCL$_1$ cells from the spleen and peripheral blood of leukemic mice. These CM contained an activity that stimulated CFU-DG ($P < .01$) but not CFU-DE (Table 2).

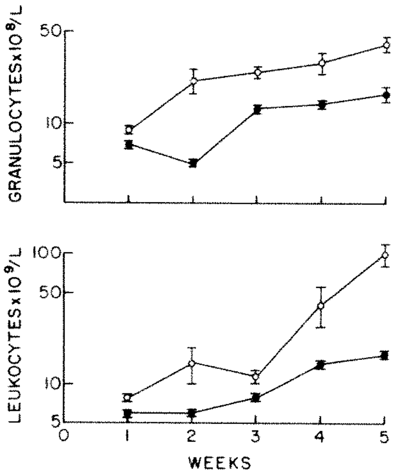

Fig 1. The number of leukocytes and granulocytes in normal BALB/c mice (●——●) and mice carrying the BCL_1 tumor (○——○) was determined weekly.

*Each point represents 18 to 24 observations from at least three different experiments.

†T cells and macrophages were removed from the cell preparation.

‡Concentration of the preparation tenfold did not have further effect on colony formation.

Treatment of BCL_1 CM with limulus amebocyte lysate did not reduce D-CSF activity (data not shown). In further experiments, T cells and macrophages were removed from spleen cell suspensions by using anti–Thy 1 plus complement and adherence to plastic, respectively; the effect of media conditioned in the presence of this purified B cell population was then assessed. As shown in Table 2, a dose-dependent increase in the number of the CFU-DG per chamber in treated mice could be observed. Medium conditioned in the presence of B lymphocytes from normal BALB/c mice failed to enhance colony formation (Table 2), thereby suggesting that neoplastic B cells were the source of D-CSF.

Effect of BCL_1 CM on CFU-MIX, BFU-E, and CFU-C in vitro. Because several T cell lines produce many hematopoietic activities detectable by in vitro culture[12,13] along with factors detectable by in vivo diffusion chamber culture, we evaluated BCL_1 CM for its action on other hematopoietic precursors. As shown in Table 3, even after a tenfold concentration, BCL_1 CM had no effect on either multipotential (CFU-MIX) or unipotential erythroid (BFU-E) and granulocyte-macrophage (CFU-GM) precursors in vitro. The same CM did not potentiate or inhibit the stimulatory effect on these precursors by EL-4 CM (Table 3). The addition of normal mouse serum to in vitro cultures containing BCL_1 CM had no effect on colony numbers (data not shown); neither did the addition of serum from mice treated with BCL_1 CM for three days contain any activity stimulating colony formation in agar (CFU-GM) or methylcellulose (BFU-E, CFU-MIX, data not shown). There was no difference between normal sera and sera from BCL_1 mice in stimulating colony formation in vitro (data not shown).

Effect of BCL_1 CM on CFU-MIX, CFU-S, BFU-E, and CFU-C in vivo. To determine whether BCL_1 CM had an effect on other precursor cells in in vivo cultures in addition to CFU-DG, the contents of diffusion chambers were harvested four days after implantation and subcultured in semisolid medium in vitro. As shown in Table 4, the number of CFU-S, CFU-MIX, BFU-E, and CFU-C was significantly increased, which implied that BCL_1 CM act either directly or indirectly via a more primitive cell on these precursors.

Biochemical characterization of BCL_1 CM. Biochemical characterization of D-CSF demonstrated that it is relatively heat stable (Fig 2) and resistant to neuraminidase treatment (Table 5). On the contrary, protease treatment of D-CSF abolished its bioactivity (Table 5). Table 6 summarizes a representative purification (one of three) of D-CSF from 10 L serum-free BCL_1 CM. Because many cytokines are glycoproteins, we passed BCL_1 CM over lentil-lectin agarose. Essentially all of the D-CSF activity was bound to this matrix and could be eluated with α-methyl-D-mannoside (data not shown). The lentil-lectin eluate was concentrated and fractionated by gel filtration on an Ultrogel AcA44 column. As shown in Fig 3, material with D-CSF activity was found in a pool of fractions near the ovalbumin standard (molecular weight [mol wt] 43,000). Finally, by using reverse-phase HPLC, D-CSF activity was recovered in a

fraction containing approximately 20 μg protein (Fig 4, Table 6).

Absence of adrenocorticotropic hormone in BCL_1 CM. Because some B cell lines are known to produce adrenocorticotropic hormone (ACTH)[25] and because the number of CFU-DG increases after methylprednisolone administration to the host mice,[26] the concentration of ACTH[25] was determined in BCL_1 CM. The failure to detect any increased levels of this hormone suggests that D-CSF is not identical to ACTH and that the stimulatory effect was not mediated by corticosteroids.

DISCUSSION

Results from this study suggest that the enhancement of CFU-DG colony formation in diffusion chambers implanted intraperitoneally in BCL_1 tumor-carrying mice (Table 1) was mediated by a humoral factor. It was most likely elaborated by tumor cells because an increase in the number of colonies could also be observed after the administration of medium conditioned in the presence of spleen and peripheral blood cells consisting mostly of malignant B cells (Table 2). Normal macrophages and lymphocytes present in the cell suspension were an unlikely source because removal of these

cells did not diminish the potency of the conditioned medium (Table 2). Additionally, medium conditioned in the presence of B cells from normal BALB/c mice failed to stimulate CFU-DG (Table 2), which suggested that nontransformed B cells do not produce D-CSF or that B cells must be activated to produce D-CSF.

The failure to stimulate BFU-E, CFU-C, and CFU-MIX colony formation in vitro by BCL_1 CM (Table 3) confirms our previous results indicating that D-CSF from human sources, like murine D-CSF, is different from erythroid-potentiating activity (EPA) GM-CSF, and multi-CSF. By boiling and using chromatographic techniques we were able to separate human T cell line (Mo and HUT 102)-derived D-CSF from EPA, CSF, and multi-CSF.[12,13,27] Unlike human GM-CSF, human D-CSF,[13] like murine CSF (Fig 2), was relatively heat stable, and on diethylaminoethyl–Sepharose chromatography it had less affinity for the matrix than EPA and multi-CSF.

The increase in the number of CFU-S, CFU-MIX, BFU-E, and CFU-C in the diffusion chambers in addition to enhanced CFU-DG colony formation suggests that production of these hematopoietic precursors, at least in in vivo culture, can be modulated by a stimulatory activity present in BCL_1 CM that is different from multi-CSF, EPA, and GM-CSF. The failure of colony-forming cells to respond in vitro to BCL_1 CM (Table 3) may indicate that expression of its stimulatory effect on hematopoietic progenitors requires the presence of compounds occurring in vivo but not the ingredients of in vitro cultures. The lack of stimulation after the addition of mouse serum to these cultures (data not shown) does not exclude this possibility because conditions inside the diffusion chambers in the peritoneal cavity are different. Alternatively, BCL_1 CM acts on CFU-DG indirectly via another growth factor. The inability to detect increased levels of GM-CSF, EPA, or multi-CSF in the serum of mice carrying BCL_1 or BCL_1 CM–treated mice may indicate that these factors are not involved in the modulation of CFU-DG growth. However, it is possible that D-CSF acts locally on cells that are different from CFU-DG and induces them to elaborate growth factors acting on CFU-DG.

Unchanged hematocrit values and platelet counts in mice receiving BCL_1 CM were not unexpected, despite the possibility that CFU-DG may be at least as primitive as multipotential 12-day CFU-S. It has been shown that when lithium is administered to mice, regardless of its stimulatory effect on CFU-DG[28] and CFU-S,[29] only peripheral blood granulocyte counts are higher. The data in the prior study[28] suggested that lithium, like BCL_1 tumor cells, stimulates CFU-DG colony formation through a humoral factor that is different from CSF detected by in vitro CFU-C assay.

Involvement of GM-CSF in the development of granulocytosis secondary to neoplasms has been suggested by several clinical and animals studies.[30-37] However, the possibility that other factors cause granulocytosis cannot be excluded. A recent report describes poor correlation between levels of GM-CSF derived from two mammary adenocarcinoma tumor lines and granulocyte levels in host mice.[38] The results of this study suggest that an increase in the granulocyte count was mediated by D-CSF.

Traditionally, B lymphocytes have been thought to secrete only immunoglobulin, but recent reports indicate that these cells can produce other biologically active molecules, including growth factors,[39,40] endorphins and ACTH,[25,40] and B cell differentiation factors.[41] Our data demonstrate that neoplastic B cells produce, in addition to immunoglobulin, molecules capable of directly or indirectly stimulating hematopoietic precursors in vivo. Initial biochemical purification demonstrates that D-CSF resembles other hematopoietic factors.[42] Its attachment to a lentil-lectin column and its elution with α-methyl-D-mannoside suggests that D-CSF is a glycoprotein. Its mol wt (43,000) (Fig 3) is in the same range as that of other colony-stimulating factors,[41] and like EPA[43] in reverse-phase HPLC, it elutes with acetonitrile (Fig 4). It probably does not have ACTH-like biological activity because the ACTH concentration in BCL_1 CM was not elevated. This concern was prompted by the aforementioned report[25] indicating the production of ACTH by B cells and by our earlier study[26] indicating that corticosteriods exert a stimulatory effect on CFU-DG. The possibility that D-CSF represents a component of murine leukemia viruses also seems remote because the reverse transcriptase assay was negative.

These findings provide further evidence that the hematopoietic factor detected by in vivo diffusion chamber assay is different from factors detectable by conventional in vitro assay.

Association of Hemoglobin H Disease With Hb J-Iran (β77 His → Asp): Impact on Subunit Assembly

By Samuel Rahbar and H. Franklin Bunn

A young Iranian female was found to be heterozygous for hemoglobin (Hb) J-Iran (β77 His → Asp) in combination with Hb H disease. The proportion of Hb J in the patient's hemolysate was suprisingly high: 65% Hb J, 30% Hb A. Thus, the interaction of a negatively charged β subunit variant of Hb with α-thalassemia leads to a marked increase in the relative amount of the variant Hb within red cells. This observation provides further support for an electrostatic model of Hb subunit assembly.

© 1987 by Grune & Stratton, Inc.

THE DISTRIBUTION of normal and variant hemoglobins (Hbs) in heterozygotes provides insight into the biosynthesis and assembly of the Hb tetramer. Because one β globin gene is inherited from each parent, an individual heterozygous for a β globin variant would be expected to have approximately equal levels of normal and abnormal Hbs. A few β variants such as E, the Lepores, Knossos, K-Woolwich, and Vicksburg are synthesized at a significantly lower rate than βA. In heterozygotes these variants constitute much less than half of the total Hb and are associated with a thalassemic phenotype. Low levels of the variant are also observed in heterozygotes for unstable Hbs such as Köln and Zürich. The variability in levels of most of the remaining stable variants appears to be due to differences in the rate of subunit assembly.[1]

Hb J-Iran (β77 His → Asp) is one of the many informative Hb variants that have been discovered in the ethnically diverse population of Iran.[2,3] Subsequently this variant was reported in Turkey[4] and in a Russian-Armenian family.[5] The concentration of this variant in heterozygotes was always found to be nearly equal to that of Hb A. In this report we describe a 14-year-old female who had Hb J-Iran in combination with Hb H disease. Surprisingly, electrophoresis on both cellulose acetate and on citrate agar revealed twice as much Hb J as Hb A. This observation provides additional insights into how the surface charge on mutant Hb affects subunit assembly.

METHODS

Routine hematologic data were obtained by standard techniques. Erythrocytes were examined for inclusion bodies after treatment with brilliant cresyl blue. Hb stability was assessed by incubations of hemolysates in isopropanol.[6] Hb electrophoresis was performed on cellulose acetate (Tris-EDTA-borate buffer, pH 8.6) and on acid citrate agar gel.[7] Globin chain electrophoresis was also performed at both acid and alkaline pH.[7] The proportions of different Hb fractions were determined after cellulose acetate electrophoresis and elution of unstained Hb bands as previously described.[8] In vitro globin chain synthesis and α/β synthetic ratios were measured by standard techniques.[9] Structural identification of the variant Hb was established by isolation of the abnormal subunit by urea-carboxymethylcellulose chromatography,[10] digestion with trypsin, separation of tryptic peptides on two-dimensional maps, and amino acid analysis of abnormal peptides.[11]

RESULTS

A 14-year-old Persian girl was referred for investigation of mild jaundice and anemia. On physical examination her spleen was found to be moderately enlarged. Two other siblings were also found to have mild anemia and splenomegaly. Erythrocytes from the proband and from two of her siblings displayed characteristic inclusion bodies of Hb H disease. The proportion of red cells containing inclusion bodies was much less in the proband than that found in her two siblings. Nevertheless the isopropanol stability test was positive in all three individuals. Hb electrophoresis on cellulose acetate at alkaline pH confirmed the presence of Hb H in the proband as well as in these two siblings. In addition to Hb H, the proband showed a fast-moving Hb band in the position of Hb J. The distribution of Hbs in the proband's hemolysate was 65% Hb J, 30% Hb A, 3% Hb H, and 2% Hb A_2. The α-to-β synthetic ratio in the proband was 0.2, consistent with three-gene deletion α-thalassemia. Three other siblings were also heterozygous for Hb J but lacked Hb H. The variant in their red cells composed about 50% of the total Hb. The marked difference in Hb distribution between the proband and her siblings was confirmed by citrate agar electrophoresis at pH 6.5 as well as by electrophoresis and chromatography of globin chains. Structural analysis of the variant demonstrated that it was Hb J-Iran (β77 His → Asp), a variant frequently found among Iranians.

DISCUSSION

This is the first description of the association of Hb H disease with a negatively charged β subunit variant. This severe form of α-thalassemia imposes a marked increase in the proportion of the variant Hb in the circulating red cells (Fig 1). Previously, the association of another negatively charged variant, Hb J-Baltimore (β16 Gly → Asp), with probable homozygous α-thalassemia-2 (α-/α-) was noted to cause a moderate increase of the variant within the red cells.[12] In contrast, several reports have described the association of α-thalassemia (including Hb H disease) with positively charged β subunit variants such as Hb S, Hb C, Hb E, and Hb D.[13-15] In all cases the proportion of these variants

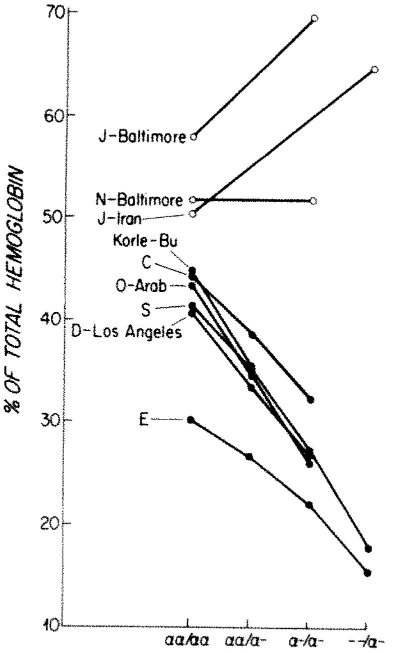

Fig 1. Effect of α-thalassemia on the proportion of negatively charged (○) and positively charged (●) β globin variants in heterozygotes. In all cases Hb A constitutes the great majority of the remaining Hb. In three-gene deletion α-thalassemia, a small amount of Hb H (β_4) is present. Modified with permission.[1]

in heterozygotes correlates inversely with the number of α genes deleted (Fig 1).

The substitution of an aspartic acid residue for a histidine in Hb J-Iran gives this variant a gain of 1.5 negative charge units. The higher negative charge on the surface of the βJ-Iran subunit would be expected to enhance its electrostatic attraction for the normal positively charged α subunit,[12,16,17] thereby allowing the formation of more Hb J-Iran than Hb A in the heterozygote's red cells. In the presence of α-thalassemia, the competition between βA and βJ subunits for the deficient α subunits is greatly enhanced, and even more Hb J-Iran is formed. The same mechanism applies to the observations noted earlier on Hb J-Baltimore. In fact, in vitro competition experiments using purified βA and βJ-Baltimore subunits have verified that when α subunits are deficient, the formation of Hb J exceeds that of Hb A by a factor of 1.5.[16] In contrast, the lower levels of the positively charged variants imposed by α-thalassemia can be explained by decreased electrostatic attraction between the α subunit and the variant β subunit.

In conclusion, the interaction of α-thalassemia with the negatively charged β globin variant Hb J-Iran provides informative and independent support for the importance of electrostatic attraction in the assembly of Hb subunits.[1]

Granulocyte/Macrophage Progenitor Cells From Peripheral Blood and Bone Marrow Differ in Their Response to Prostaglandin E_1

By Carol M. Richman and George D. Johnson

Prostaglandins of the E series (PGE) inhibit proliferation of normal bone marrow granulocyte/macrophage progenitors (CFU-GM). Circulating CFU-GM are known to differ from marrow CFU-GM in many characteristics, and in the present study, we compared the effect of PGE_1 on circulating and bone marrow progenitors in normals and in patients with chronic myelogenous leukemia (CML). PGE_1 caused a dose-dependent inhibition of normal marrow CFU-GM. Circulating CFU-GM were inhibited only at concentrations of 10^{-5} mol/L or greater, and progenitor proliferation was, in fact, significantly stimulated at PGE_1 concentrations between 10^{-8} and 10^{-6} mol/L. Bone marrow CFU-GM from patients with CML were inhibited in a manner similar to that of normal bone marrow. Circulating cells from patients with CML were, however, less sensitive to PGE_1 inhibition than CML bone marrow cells and demonstrated a pattern intermediate between normal circulating and normal marrow progenitors. These studies suggest that peripheral blood and bone marrow contain different progenitor cell populations.

© 1987 by Grune & Stratton, Inc.

PROLIFERATION OF GRANULOCYTE/macrophage progenitors (CFU-GM) in vitro is under the dual control of stimulatory glycoproteins collectively termed colony-stimulating activity (CSA)[1] and inhibitory substances such as prostaglandins of the E series (PGE) and acidic isoferritins.[2-9] Because these substances may also modulate hematopoiesis in vivo,[10-12] abnormal in vitro responses to these regulators have been sought to explain the pathogenesis of a variety of hematologic diseases. For example, insensitivity to PGE has been postulated as a mechanism for the excessive CFU-GM proliferation observed in chronic myelogenous leukemia (CML).[8,13-16] However, studies of prostaglandin regulation in myeloproliferative diseases, including CML, have often compared results obtained by using diseased circulating progenitors with results with normal bone marrow cells.[8,13,16] In normals, peripheral blood and bone marrow CFU-GM differ significantly,[17-24] and prior studies comparing normal marrow with abnormal blood progenitors have not fully explored these potential differences.

The present study was designed to compare the effects of PGE on circulating and marrow progenitors in normal individuals as well as in patients with CML. The results show that normal circulating CFU-GM proliferation is not decreased by prostaglandin E_1 (in physiological concentrations), but rather is significantly increased. PGE_1 does not appear to selectively increase a specific cytological colony subtype. Removal of adherent cells from the normal circulating cell population does not abolish the stimulatory effect if a source of CSA is provided. Bone marrow cells from both normals and patients with CML showed dose-dependent CFU-GM inhibition by PGE_1. Circulating CML cells (unlike normals) were not stimulated by PGE_1 but were less sensitive to PGE_1 inhibition than were CML marrow cells. These results, showing a difference in PGE_1 regulation between circulating and bone marrow CFU-GM, support the concept that the peripheral blood and marrow contain different progenitor cell populations. In addition, circulating CFU-GM from patients with CML respond to PGE_1 in a manner intermediate between the response of normal circulating and normal marrow progenitors.

METHODS

Normal bone marrow and peripheral blood samples were obtained from paid hematologically normal adult volunteers after written informed consent. Bone marrow and/or peripheral blood samples were obtained during routine clinical evaluations of 14 patients (nine males, five females) with Philadelphia chromosome–positive CML. Thirteen patients were in the stable chronic phase, and one had a chronic-phase blood picture (only the blood was studied) with evidence of early blast transformation in the bone marrow. The median age of the patients was 48 years (range, 26 to 72), the median leukocyte count at the time of study was 70×10^9/L (range, 14 to 136), and the median duration of diagnosis was 16 months (range, <1 to 70). Two patients had never been treated; 12 had previous therapy but no treatment for at least 2 weeks before the study.

Heparinized bone marrow aspirates and whole blood samples were separated on Ficoll-Hypaque density gradients (sp gr, 1.077). Mononuclear cells obtained from the interface were washed, depleted of adherent cells in some experiments,[25] and plated at final concentrations of 1×10^5 bone marrow cells/mL or 2 to 4×10^5 peripheral blood cells/mL in a methylcellulose culture system using leukocyte conditioned medium prepared with 1% (vol/vol) phytohemagglutinin (PHA-LCM) as the source of CSA.[26] The concentration of PHA-LCM used (10% of the total culture volume) provides maximal (plateau) stimulation of colony formation in this system. In some experiments, giant cell tumor conditioned medium (GCT-CM) was used as the source of CSA. PGE_1 (Sigma Chemical Co, St Louis) dissolved in ethanol was added to cultures at final concentrations of 10^{-10} to 10^{-4} mol/L. Indomethacin (Sigma) at 10^{-6} mol/L was added to all cultures to decrease endogenous PGE production.[2] Quadruplicate plates were incubated at 37°C in 10% CO_2 and high humidity for 14 days. Colonies (>20 cells) representing CFU-GM were counted by using an inverted microscope. Results were

expressed as the percentage of control colonies: mean colonies with PGE$_1$ × 100/mean colonies without PGE$_1$. Statistical comparisons were performed by using Student's *t* test or paired *t* test. Fifty percent inhibitory doses (ID$_{50}$) were determined by linear regression analysis using a Texas Instruments calculator.

Cytological evaluation of single colonies was performed by removing all the individual colonies from methylcellulose plates with a drawn-out Pasteur pipette, placing each colony on a marked portion of a glass slide (two to three colonies per slide), and staining with Wright's stain. Each colony was classified as neutrophil, monocyte/macrophage, eosinophil, or mixed (neutrophil/macrophage) and the result expressed as the mean percentage of each colony type (± SEM).

RESULTS

PGE$_1$ effect on normal peripheral blood and bone marrow CFU-GM. A comparison of the effect of PGE$_1$ on normal bone marrow and peripheral blood CFU-GM is shown in Fig 1. At prostaglandin concentrations between 10^{-10} and 10^{-4} mol/L, dose-dependent inhibition of marrow CFU-GM was observed. Depletion of adherent bone marrow cells before the assay had no significant effect on PGE inhibition of bone marrow CFU-GM (data not shown). Peripheral blood CFU-GM were, in contrast, stimulated by PGE$_1$ in this concentration range, and results differed significantly from controls at PGE$_1$ concentrations of 10^{-8} and 10^{-6} mol/L ($P < .02$ and $P < .05$, respectively, paired *t* test). Maximal stimulation was achieved at 10^{-8} mol/L PGE$_1$; the response plateaued, and inhibition of circulating progenitors was observed only at PGE$_1$ concentrations exceeding 10^{-5} mol/L. The differences between the effects of PGE$_1$ on bone marrow and peripheral blood colony–forming cells were statistically significant for concentrations of 10^{-8}, 10^{-6}, and 5×10^{-6} mol/L ($P < .001$). Peripheral blood CFU-GM ID$_{50}$ occurred at a concentration of PGE$_1$ in excess of 10^{-5} mol/L, whereas the ID$_{50}$ for bone marrow cells is estimated to be 1.3×10^{-7} mol/L by linear regression analysis.

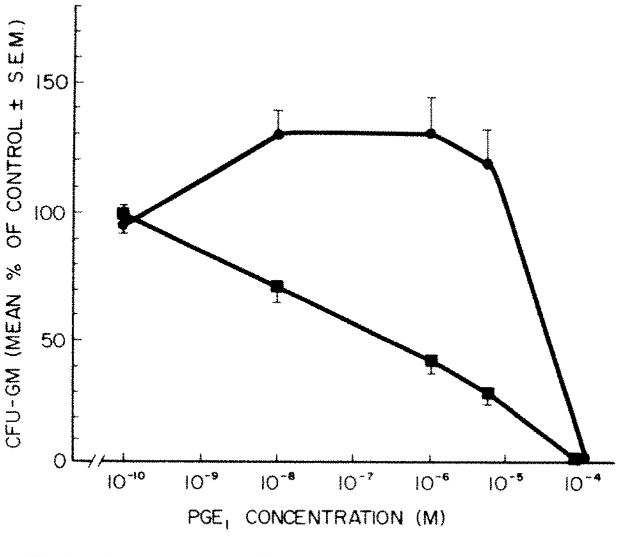

Fig 1. Peripheral blood (PB, n = 25, ●——●) and bone marrow (BM, n = 10, ■——■) cells from normal individuals were cultured with concentrations of PGE$_1$ from 10^{-10} mol/L to 10^{-4} mol/L using PHA-LCM CSA. Dose-dependent inhibition of BM CFU-GM was observed. The ID$_{50}$ determined from linear regression analysis is 1.3×10^{-7} M. PB CFU-GM were stimulated at all PGE$_1$ concentrations $< 10^{-5}$ mol/L. Stimulation is statistically significant at 10^{-8} and 10^{-6} mol/L ($P < .05$ and $P < .02$ respectively). The difference between PB and BM is statistically significant at 10^{-8}, 10^{-6}, 5×10^{-6}, and 10^{-5} mol/L PGE$_1$ ($P < .001, .001, .001, .05$).

To determine whether the type of CSA used to stimulate CFU-GM had any effect on the action of PGE$_1$, we compared PHA-LCM to GCT-CM by using 5×10^{-6} mol/L PGE$_1$. For all five normal bone marrow samples, PGE$_1$ caused greater inhibition of CFU-GM when GCT was used as a source of CSA compared with PHA-LCM ($P < .05$). However, normal circulating progenitors were not inhibited by 5×10^{-6} mol/L PGE$_1$ with either source of CSA.

Effect of CSA and adherent cells on PGE$_1$ stimulation of circulating normal CFU-GM. To evaluate the mechanism of stimulation of normal circulating progenitors by PGE, studies were performed with and without exogenous CSA. In ten experiments, the mean CFU-GM/4 × 10^5 cells was 26 ± 4 with CSA and 20 ± 6 without CSA, which suggested endogenous CSA production. In both CSA-stimulated and -unstimulated cultures, PGE$_1$ at concentrations of 10^{-8} and/or 10^{-6} mol/L significantly increased colony formation (Fig 2). Maximum colony formation occurred at 10^{-6} mol/L PGE$_1$, and the mean CFU-GM/4 × 10^5 cells were similar for cultures with and without exogenous CSA (40 ± 9 and 39 ± 8 respectively).

In ten experiments, nonadherent cells cultured with CSA (PHA-LCM) contained 34 ± 10 CFU-GM/4 × 10^5 cells compared with 1 ± 0 CFU-GM for nonadherent cells cultured without CSA (indicating depletion of endogenous CSA-producing cells). When nonadherent cells were plated with CSA and PGE$_1$, the results were similar to those using

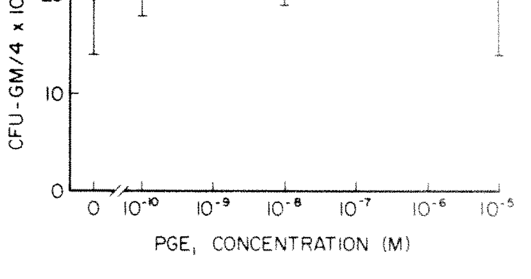

Fig 2. Normal peripheral blood mononuclear cells with (●——●) or without (O---O) exogenous CSA (n = 10) were cultured with PGE$_1$. CFU-GM/4 × 10^5 cells were increased by PGE$_1$ in CSA-stimulated ($P < .05$ at 10^{-6} mol/L PGE$_1$) and -unstimulated cultures ($P < .01$ at 10^{-8} mol/L, $p < .001$ at 10^{-6} mol/L and $P < .02$ at 10^{-6} mol/L).

whole mononuclear cells without adherence depletion, ie, PGE_1 at 10^{-6} mol/L caused significant enhancement of CFU-GM growth ($P < .05$).

In six of nine individuals studied, the maximum colony concentration in the nonadherent cells plated without an exogenous source of CSA was less than 5 colonies/4 × 10^5 cells with or without PGE_1. In one of the nine individuals, CFU-GM increased from 0 without PGE_1 to 6 with 10^{-6} mol/L PGE_1; in a second, CFU-GM increased from 0 to 12; and in a third, CFU-GM rose from 2 without to 51 with PGE_1.

PGE_1 effect on circulating and bone marrow CFU-GM from patients with CML. In patients with CML, CFU-GM from both the bone marrow and peripheral blood exceeded control values only at the lowest PGE_1 concentration (10^{-10} mol/L, Fig 3). At concentrations higher than 10^{-10} mol/L, there was a dose-dependent inhibition for both circulating and bone marrow cells. Unlike normal cells, circulating CML cells were not stimulated by PGE_1. However, blood CFU-GM were more resistant to PGE_1 inhibition than were bone marrow progenitors ($P < .05$ at 10^{-6} mol/L and $P < .01$ at 5×10^{-6} mol/L). For bone marrow, CFU-GM were 47% of control at 10^{-6} mol/L, whereas for circulating cells, values were still 58% of control at 5×10^{-6} mol/L. PGE inhibition curves for normal (Fig 1) and CML bone marrow (Fig 3) were not significantly different except at 10^{-10} mol/L PGE_1 where CML CFU-GM was 114% ± 6% of control whereas normal marrow CFU-GM was 97% ± 5% ($P < .05$). For normal and CML marrow cells, 50% inhibition is projected by linear regression analysis to occur at 1.3 and 4.1×10^{-7} mol/L respectively.

Cytological evaluation of PGE_1 effects. PGE_1 may inhibit macrophage colonies specifically,[4-6,27,28] although some reports suggest inhibition of both granulocyte and macrophage colonies.[3] To determine whether differences in the effects of PGE on circulating and bone marrow progenitors might be secondary to differences in the proportion of macrophage colonies, we characterized the type of colonies in control and PGE-exposed cultures. Individual Wright-stained colonies (see Methods) were analyzed from six peripheral blood and five bone marrow samples from normals (Table 1). There were significantly fewer macrophage colonies in the blood (19% ± 4%) than in bone marrow (38% ± 8%) ($P < .05$, paired t test). PGE_1-containing cultures of marrow had significantly fewer macrophage colonies than did marrow cultures without PGE_1 ($P < .05$). The distribution of cytological types of circulating or bone marrow colonies was otherwise not significantly affected by the addition of PGE_1.

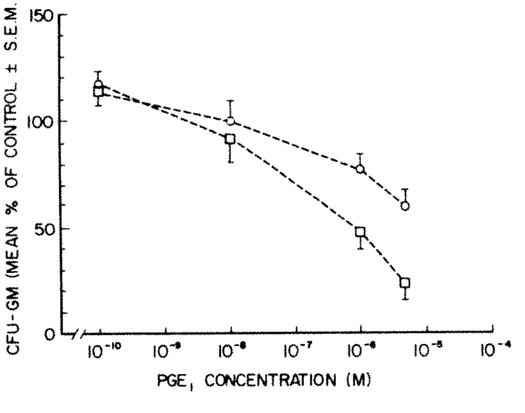

Fig 3. Peripheral blood (PB, n = 14, O---O) and bone marrow (BM, n = 9, □---□) from patients with CML were cultured with 10^{-10} to 5×10^{-6} mol/L PGE using PHA-LCM CSA. Dose-dependent inhibition of both PB and BM CFU-GM was observed at doses exceeding 10^{-10} mol/L. PB CFU-GM are more resistant to PGE_1 inhibition than BM CFU-GM. By linear regression analysis, the ID_{50} for PB is 8.1×10^{-6} mol/L, and for BM it is 4.1×10^{-7} mol/L.

DISCUSSION

Normal peripheral blood and bone marrow granulocyte/macrophage progenitors differ significantly in their response to PGE_1. The inhibition of marrow CFU-GM by PGE_1 observed in the present study is similar to that reported by others.[2,8,13,14,28] Peripheral blood CFU-GM were not inhibited by PGE_1 and were, unexpectedly, stimulated by concentrations in the range of 10^{-8} to 10^{-6} mol/L, an effect not previously reported for normal peripheral blood. PGE_1 augmented CFU-GM in peripheral blood cultures containing an exogenous source of CSA, either PHA-LCM or GCT medium, as well as in cultures stimulated only by endogenous CSA production. The stimulatory effect of PGE_1 on peripheral blood progenitors was not significantly affected by depletion of adherent cells, thereby suggesting that these cells do not solely mediate the stimulatory effect. Nonadherent cells showed negligible spontaneous CFU-GM growth, which indicated adequate depletion of endogenous CSA-producing cells. In six of nine individuals studied, PGE_1 had no effect on nonadherent cells in the absence of exogenous CSA. In the other three, however, PGE_1 stimulated CFU-GM in the nonadherent cell fraction.

Stimulatory effects of PGE on CFU-GM have been noted variably in studies of circulating progenitors in patients with myelofibrosis and myeloid metaplasia (MMM).[16,29] The subpopulation of progenitors in MMM that are stimulated by PGE may be similar to normal circulating progenitors. One

*Percentage of colonies of a given type (mean ± SEM). Six blood samples and five bone marrow samples from normal individuals were studied.

†The difference between monocyte/macrophage colonies with and without PGE is significant at $P < .05$ when using the paired t-test.

might hypothesize that normal bone marrow contains primarily progenitors inhibited by PGE whereas normal blood contains CFU-GM stimulated by PGE and that the response of circulating CFU-GM to PGE would depend on the relative proportion of circulating marrowlike progenitors. Our results in CML showing effects of PGE on peripheral blood CFU-GM that are intermediate between normal blood and normal bone marrow CFU-GM support this notion because CML blood contains some cells that normally reside in the bone marrow. An alternative explanation is that circulating progenitors in these myeloproliferative diseases differ fundamentally from normal progenitors.

The cytological subtype of progenitors in peripheral blood and bone marrow differ, and our study is an agreement with other reports,[22] ie, fewer macrophage and greater numbers of eosinophil progenitors in the peripheral blood as compared with bone marrow. This difference could account for the resistance of circulating CFU-GM to inhibition by PGE if PGE$_1$ primarily inhibits macrophage colonies.[4-6,27,28] However, we observed not just a lack of inhibition with peripheral blood but a stimulation of CFU-GM, thereby suggesting that the presence of fewer committed macrophage progenitors in the peripheral blood does not totally explain the observed differences. Furthermore, cytological analysis of peripheral blood cultures with increased colonies in the presence of prostaglandin showed no consistent subtype of colony that was enhanced, which suggested an effect on an uncommitted CFU-GM.

The observation that circulating progenitors acquire some of the antigens present on marrow progenitors after short-term liquid culture with CSA has led to the suggestion that the blood CFU-GM are more primitive than bone marrow CFU-GM.[19,20] It has been proposed[23] that the situation is analogous to the more primitive erythroid precursor, BFU-E, found predominantly in the blood, and less primitive CFU-E, found predominantly in the marrow.[30] Subpopulations of CFU-GM have been observed in murine bone marrow with varying responses to PGE. Progenitors forming large colonies (assumed to be more primitive) are relatively resistant to PGE inhibition, whereas the more prevalent marrow CFU-GM form smaller colonies and are several orders of magnitude more sensitive to inhibition by PGE.[31] PGE in some reports appears to inhibit a subpopulation of CFU-GM that are in S phase and that express the Ia antigen.[32] Because normal human marrow and peripheral blood are known to differ in cell cycle status,[23] it is possible that such differences could account, in part, for the differences in PGE inhibition that we have observed.

CML bone marrow cells were, in the present study, as sensitive to PGE inhibition as were normal bone marrow cells. This result is in contrast to some reports indicating that CML progenitors from blood and/or bone marrow are extraordinarily resistant to PGE, with CFU-GM approximately 90% of control at PGE doses exceeding 10^{-6} mol/L.[8,13-16,29] Although we noted that CML peripheral blood progenitors were more resistant to PGE than bone marrow progenitors, even the blood CFU-GM were more easily inhibited in our studies than in the studies mentioned earlier. Another report found, as we did, no difference between normal and CML marrow in the degree of prostaglandin-induced inhibition.[33] Differences in culture technique may provide a partial explanation for these disparate results.

In the present study, normal peripheral blood and bone marrow CFU-GM differ significantly in their response to PGE$_1$. Circulating progenitors of patients with CML have PGE$_1$ responses that are intermediate between normal blood and bone marrow. If circulating progenitors represent a more primitive cell than their bone marrow counterparts, as has been suggested,[19,20,23,30] further studies of normal and pathological hematopoietic regulation by using circulating CFU-GM may supplement studies of bone marrow–derived progenitors.

The Deletion in Both Common Types of Hereditary Persistence of Fetal Hemoglobin is Approximately 105 Kilobases

By Francis S. Collins, Jeffery L. Cole, Wendy K. Lockwood, and Michael C. Iannuzzi

The most common forms of hereditary persistence of fetal hemoglobin (HPFH) involve large deletions that remove the adult δ and β genes but leave the paired fetal genes ($^{G}\gamma$ and $^{A}\gamma$) intact. The size of these deletions has previously eluded exact definition. Using pulsed-field gel electrophoresis and the enzyme *Sfi*I, which cuts only rarely in genomic DNA, we have constructed a large-scale restriction map of the β-globin cluster in normal and HPFH DNA. The deletions in HPFH-1, which occurs in American blacks, and in HPFH-2, which occurs in Ghanaian blacks, are found to be approximately 105 kilobases (kb) in length, though the endpoints are staggered by approximately 5 kb. The fact that two previously reported γδβ-thalassemia deletions to the 5′ side of the β-globin cluster are also about 100 kb suggests a common mechanism, possibly involving the loss of a complete chromatin loop.

HEREDITARY PERSISTENCE of fetal hemoglobin (HPFH) is a clinically benign and genetically heterogeneous condition characterized by continued expression of fetal hemoglobin (HbF) into adult life, with relatively balanced globin chain synthesis.[1-4] Several years ago, Southern blotting studies demonstrated that HPFH could be divided into two categories: those in which large genomic deletions removing the δ and β genes were present (deletion HPFH) and those in which the β-globin cluster appeared intact by Southern blotting (nondeletion HPFH).[5-7] In many of the nondeletion forms the overproduction of HbF is observed to be primarily $^{G}\gamma$ or $^{A}\gamma$, and recent cloning studies have identified point mutations in the promoter of the overexpressed fetal gene in most of these conditions.[8-14]

In deletion HPFH, however, there is usually overproduction of both $^{G}\gamma$ and $^{A}\gamma$ chains. The most common deletion type, denoted HPFH-1, occurs in American blacks and has a 5′ breakpoint approximately 4 kilobases (kb) 5′ to the δ gene (Fig 1).[5,7,15,16] HPFH-2, which occurs in Ghanaian blacks, has both its 5′ and 3′ endpoints shifted approximately 5 kb in the 5′ direction, but the total amount of DNA lost is within 1 kb of being the same as in HPFH-1.[6,7,15,16] Interestingly, homozygotes for HPFH-1 and HPFH-2 have no abnormality of phenotype other than their high level of HbF, which suggests that no other essential genes lie within the deletion.

Using cloned DNA from the breakpoints of these and other deletions, several laboratories have attempted to identify the total amount of DNA deleted in HPFH-1 and HPFH-2 by genomic blotting and walking studies. The presence of many repeated and recombinogenic sequences, however, has slowed this effort. Mager et al[17] recently concluded from their own walking efforts and a review of all available maps that the deletions must be at least 85 kb.

We have now applied the technique of pulsed-field gel electrophoresis (PFGE),[18-21] which allows the efficient separation of very large DNA molecules, to determine the actual size of these deletions and found them to be approximately 105 kb. This is remarkably close in size to the large deletions at the 5′ end of the β-globin cluster that cause γδβ-thalassemia, which adds further support to a hypothesis originally proposed by Vanin et al[16] that these deletions are not random but are generated by the loss of a complete chromatin loop.

MATERIALS AND METHODS

Cell lines. The source of HPFH-1 DNA was the cell line LAZ149, derived from a previously described and characterized individual homozygous for the HPFH-1 deletion[7] that was originally established by Dr Herb Lazarus and kindly provided by Dr Bernard Forget. HPFH-2 DNA was obtained from cell line GM2064 (available from the Mutant Cell Repository, Camden, NJ), derived from a homozygote for HPFH-2.[7] Another cell line from an HPFH homozygote, LAZ342, was obtained from Dr Stuart Orkin and was shown to be homozygous for HPFH-2 by Southern blotting (F. Collins, and J. Cole, unpublished observations) and by using the predicted fragment sizes in Table 1 of Tuan et al.[15] DNA representative of the normal β-globin cluster was prepared from the lymphoblastoid cell line 3.1.0.[22]

DNA preparation. DNA for use in PFGE analysis must have a very high molecular weight. Accordingly, we prepared DNA in agarose gel blocks basically as described by Smith et al and Collins et al.[23,24] In brief, cells were counted in a hemocytometer and then mixed with 2% low-melting–temperature (LMT) agarose (SeaPlaque, FMC Corp, Rockland, ME) and pipetted into a Lucite mold. The hardened blocks contained 2×10^5 to 2×10^6 cells in 80 μL and were then incubated for 36 hours in 500 mmol/L EDTA, 1% *N*-lauroylsarcosine, and 2 mg/mL proteinase K at 50°C to lyse the cells. Further incubations with 10 mmol/L Tris, pH 7.4, 1 mmol/L EDTA, (TE), 1 mmol/L phenylmethylsulfonylfluoride, and TE were carried out to purify the DNA. Digestions were carried out for six to eight hours at 37°C or 50°C (*Sfi*I) by placing one block or a fraction of a block into an Eppendorf tube containing the appropriate restriction enzyme buffer in a total volume of 300 μL. We used 80 units of enzyme (all from New England Biolabs, Beverly, MA) for complete digests and 0.5 to 5 units for partial digests.

PFGE. Most gels were run by using the orthogonal field–alternation gel electrophoresis (OFAGE) modification of Schwartz and Cantor's original apparatus.[18,19] The principle involves alternation of two electric fields placed at approximately 90-degree angles.

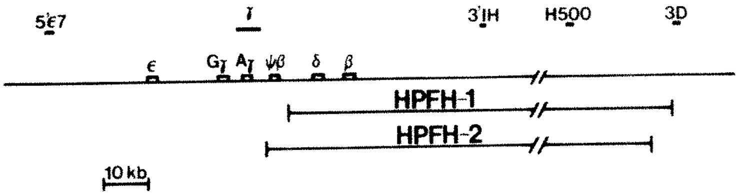

Fig 1. Map of the human β-globin cluster that indicates the limits of the HPFH-1 and -2 deletions. The total size of these deletions was previously undefined but known to be at least 85 kb. The probes 5'ε7, γ, 3'IH, H500, and 3D, which were used for this study, are described in the text.

A few gels were run on a commercially available PFGE apparatus (Pulsaphor, LKB Instruments, Houston). The running buffer was 0.4 × TBE (1 × TBE is 0.089 mol/L Tris base, 0.089 mol/L boric acid, 0.002 mol/L EDTA), and the gels were run at 14°C, 300 V, and 20 hours. Size markers were annealed λ DNA ladders, as previously described.[23] After ethidium bromide staining and photography, the gel was exposed to one minute of 254 nm UV irradiation to nick the DNA and then denatured and transferred to a nylon membrane (GeneScreen Plus, NEN, Boston) in 0.4 N NaOH.

Probes. The γ probe was a 3.5-kb *Hind*III fragment containing the entire $^{A}\gamma$ gene.[3] The 3D probe, kindly provided by Dr Bernard Forget, is a 1.0-kb *Bam*HI-*Eco*RI fragment derived from a genomic clone spanning the breakpoint in HPFH-1.[15] Probe 3D is located approximately 1 kb 3' to the end of this deletion. H500 is a 500-base pair (bp) *Hind*III fragment from a genomic clone kindly provided by Dr Dixie Mager that is located within the HPFH deletions, 9 kb upstream of the breakpoint of the Chinese $^{G}\gamma(^{A}\gamma\delta\beta)^{\circ}$-thalassemia deletion.[17] H500 is therefore approximately 27 kb 5' to 3D and is derived from phage N3'β-1 as described by Mager et al.[17] The 3'IH probe is a 680-bp *Fok*I-*Bgl*II fragment isolated from near the breakpoint of the HPFH-3 deletion and is described by Henthorn et al.[25] The 5'ε7 probe is a 3,264-bp *Eco*RI-*Hind*III fragment located 16 kb 5' to the ε gene[26] and was supplied by Dr Oliver Smithies. All probes were prepared by electrophoresis of the cut plasmids in LMT agarose and labeling of the desired fragment to a specific activity of $>10^9$ cpm/μg by using the random hexanucleotide priming technique of Feinberg and Vogelstein.[27]

Hybridization. Prehybridization and hybridization were performed according to the membrane manufacturer's (GeneScreen Plus) recommendations. Blots were washed to a stringency of 0.1 × SSC (1 × SSC is 0.15 mol/L NaCl, 0.015 mol/L sodium citrate) at 65°C for 15 minutes and exposed against x-ray film with two intensifying screens for one to two days. As long as the blots were not allowed to dry, the probes could be stripped off and the blots rehybridized many times. Stripping was done by placing the blot in 0.4 N NaOH at 42°C for 30 minutes and then in 0.1 × SSC, 0.1% sodium dodecyl sulfate 0.2 mol/L Tris, pH 7.4, at 42°C for 30 minutes. Completeness of stripping was always assessed by exposure to x-ray film. A final hybridization was done with labelled λ DNA in most instances to define the size markers on the blot.

RESULTS

We performed genomic digests of lymphoblastoid cells from normal, homozygous HPFH-1, and two different homozygous HPFH-2 individuals by using a number of restriction enzymes that cut rarely in mammalian genomic DNA. These included *Mlu*I, *Bss*HII, *Not*I, *Pvu*I, *Sac*II, and *Sfi*I, which are all expected to produce fragments of 10 to 1,500 kb.[28] The DNA samples were prepared and restricted in agarose gel blocks, and then the DNA was electrophoresed by PFGE using annealed λ DNA ladders as a size marker (Fig 2). The DNA was transferred to a nylon membrane and hybridized. Only *Sfi*I gave detectable bands on the blot with any of the β-globin probes; all other enzymes gave a signal only at the top of the gel lane, which indicated a very large (>1,000 kb) fragment or gave no signal at all. The same blots rehybridized with nonglobin probes gave the expected single bands in these lanes (data not shown), thereby indicating that the DNA had been properly digested and transferred.

The results with *Sfi*I, however, were useful. This enzyme recognizes the sequence GGCCNNNNNGGCC and cuts

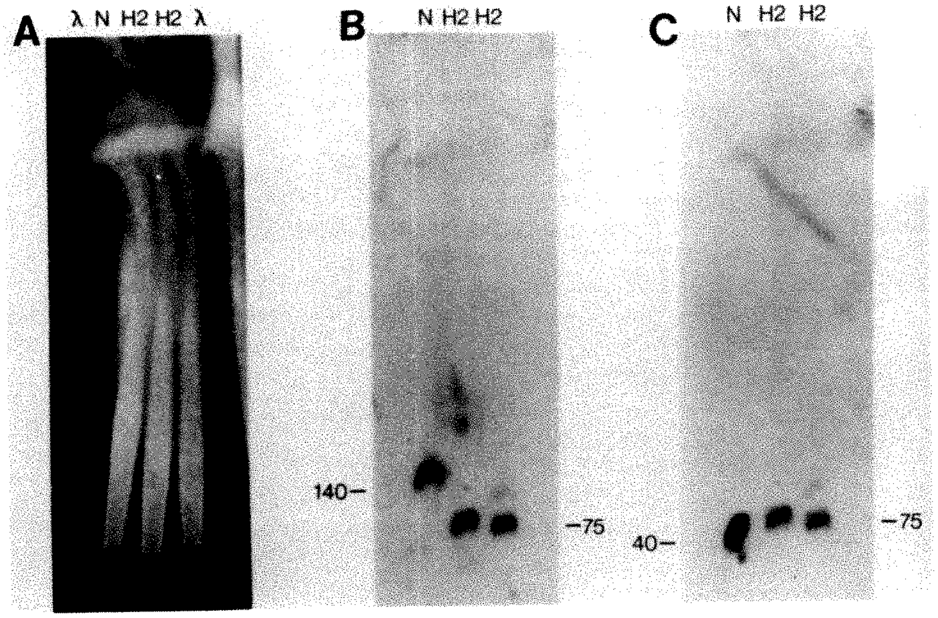

Fig 2. PFGE of normal and HPFH-2 DNA from two different patients. (A) Ethidium bromide stain of gel. The lane marked λ represents annealed λ DNA (genome size, 48.5 kb) used as a size marker. Complete *Sfi*I digests of normal (N) and HPFH-2 (H2) DNAs are shown. (B) Southern blot using the γ probe. (C) Rehybridization of the same blot with the 3D probe after stripping off the γ probe. The indicated sizes of the bands reflect corrections for the amount of DNA in each lane (see Fig 5). The H2 lane on the left is cell line GM2064; on the right is cell line LAZ342.

approximately every 250 kb in human genomic DNA. Unlike the other rare cutters tested, most *Sfi*I sites are not expected to be blocked by methylation because the recognition site does not include a CpG dinucleotide. Probing digests of normal and two different HPFH-2 DNAs (Fig 2) with an $^{A}\gamma$ sequence detects a 140-kb band for the normal and a 75-kb band for the HPFH-2 DNAs. This blot was then stripped, exposed to x-ray film to confirm complete removal of the first probe, and rehybridized with the 3D probe shown in Fig 1, which is just distal to the HPFH-1 breakpoint. The HPFH-2 DNA reveals the same 75-kb band, which is expected because $^{A}\gamma$ and 3D are only about 10 kb apart in the HPFH deletion. In normal DNA, however, a 40-kb *Sfi*I fragment is detected, thereby indicating that at least one *Sfi*I site lies within the deletion region.

It is possible to locate the 5′ end of the normal fragment containing the $^{A}\gamma$ gene exactly because there is a known *Sfi*I site approximately 17 kb 5′ to the ϵ gene for which an extensive 5′ flanking sequence was recently reported by Li et al.[26] Using a double digest of genomic DNA with *Eco*RI and *Sfi*I, we were able to show with a standard Southern blot that this *Sfi*I site cuts to completion in genomic DNA. Furthermore, a 675-bp *Ava*II-*Stu*I fragment of the 5′ϵ7 probe, located just upstream of this *Sfi*I site, hybridizes with a 10-kb *Sfi*I fragment (data not shown). No other *Sfi*I sites exist in the sequenced portion of the β-globin cluster.[3,26]

To complete the restriction map and define the size of the HPFH deletions, it was necessary to determine whether additional *Sfi*I fragments reside within the deletion region. The furthest available probe 3′ to the β gene, denoted 3′IH and derived from the breakpoint of the Indian type of HPFH (HPFH-3), has been determined to lie approximately 55 kb 3′ to the $^{A}\gamma$ gene[25] and therefore would be predicted to reside on the same 140-kb *Sfi*I fragment as $^{A}\gamma$. This was confirmed by hybridization of a PFGE blot (data not shown). From the other direction, Mager et al have cloned contiguous DNA sequences extending 30 kb 5′ to 3D.[17] Restriction digests of this cloned DNA revealed the presence of an *Sfi*I site approximately 19 kb 5′ to 3D (data not shown). A 500-bp *Hind*III fragment located 8 kb 5′ to this *Sfi*I site was gel purified; we denote this as H500. When this is used as a probe against normal and HPFH-2 DNA and the results compared with hybridization of the same blot with the γ probe, it is clear that H500 and γ are detecting the same 140-kb *Sfi*I fragment in normal DNA (Fig 3). That the fragment detected by H500 and γ is the same one and not a coincidental comigration of bands of equivalent size is further demonstrated by the identity of the larger bands, which result from the intentional partial digest used in this blot. The sizes of the partial-digest bands are readily explained by the position of the flanking *Sfi*I sites. As expected, H500 gives no signal from HPFH-2 DNA.

This allows the construction of a complete *Sfi*I map of the β-globin cluster and its 3′ flanking region (Fig 4). One can calculate the size of the HPFH-2 deletion as 140 + 40 − 75 = 105 kb. The calculation of these deletion sizes is quite sensitive to errors in the estimation of the PFGE blot bands. The use of λ concatemers allows interpolation of sizes to an accuracy of about 5 to 10 kb so long as the DNA fragments in the genomic digest lanes are migrating faithfully. We investigated the effect of the amount of DNA in the genomic digests on their electrophoretic mobility (Fig 5). The amount of DNA in a block is calculated from the number of cells used and the presence of 6.7 pg DNA/cell. We found that migration is consistent when the amount of DNA per lane is less than 2 to 3 μg. Above this amount, nonequilibrium effects in the overloaded lane result in a shift upward of the hybridizing band, thus leading to falsely large estimates of size. The size estimates shown in Fig 4 have all been determined by using 2 μg/lane or less of DNA. Allowing for a 5- to 10-kb error in the 40-kb fragment, and another 5- to 10-kb error in the difference between the 140- and 75-kb fragments (the difference is what enters the calculation), we would estimate that the measured HPFH-2 deletion size of 105 kb should be accurate to within approximately 10 to 20 kb.

Previous Southern blotting comparisons of the deletion endpoints in HPFH-1 and HPFH-2 have demonstrated that the total amount of deleted DNA is very similar,[6,7,15,16] with the HPFH-1 deletion being about 1 kb larger. Partial *Sfi*I

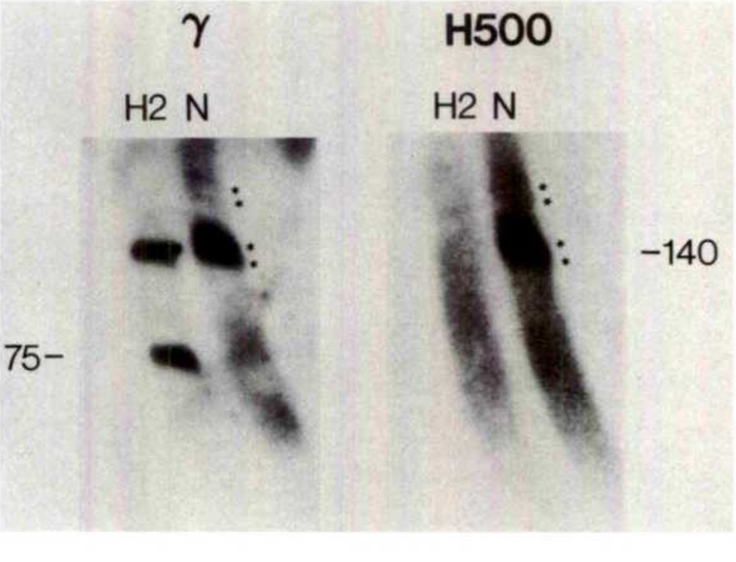

Fig 3. Partial *Sfi*I digests of normal (N) and HPFH-2 (H2) DNA probed with γ and then with the H500 probe that lies within the HPFH deletion. H500 and γ can be seen to detect the same *Sfi*I fragment in normal DNA, as evidenced by identity of the complete and partial digest bands (indicated by dots on the figure). The HPFH-2 DNA is from cell line LAZ342. The partial digest fragments in normal DNA represent approximately 150, 180, and 190 kb. The 140-kb partial digest band in HPFH-2 DNA indicates that the next *Sfi*I fragment to the 3′ side must be approximately 140 − 75 = 65 kb.

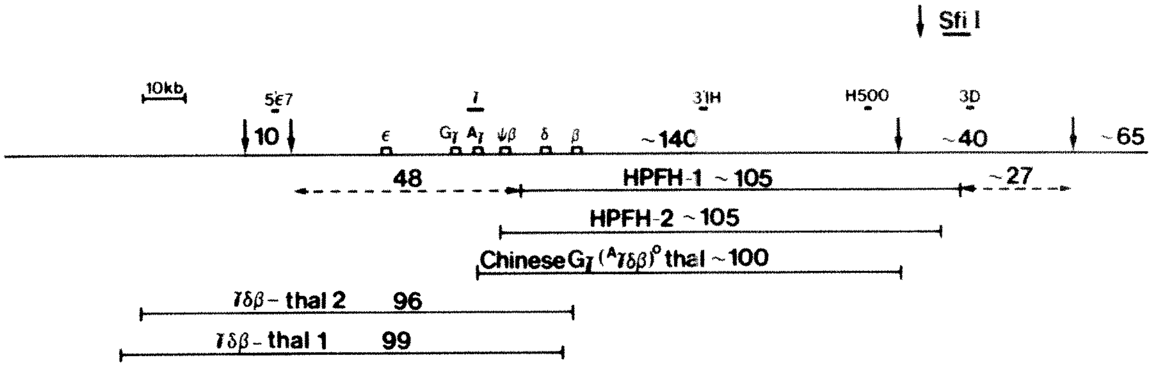

Fig 4. Map of the β-globin cluster. The vertical arrows mark the location of *Sfi*I sites. The sizes of *Sfi*I fragments and genomic deletions are given in kilobases. Note the similarity in size of the five deletions.

digests of HPFH-1 and HPFH-2 DNA were separated by OFAGE, blotted, and probed with the γ and 3D probes (data not shown). The fragments were indistinguishable, as expected because the 1-kb difference would not be resolved with this approach.

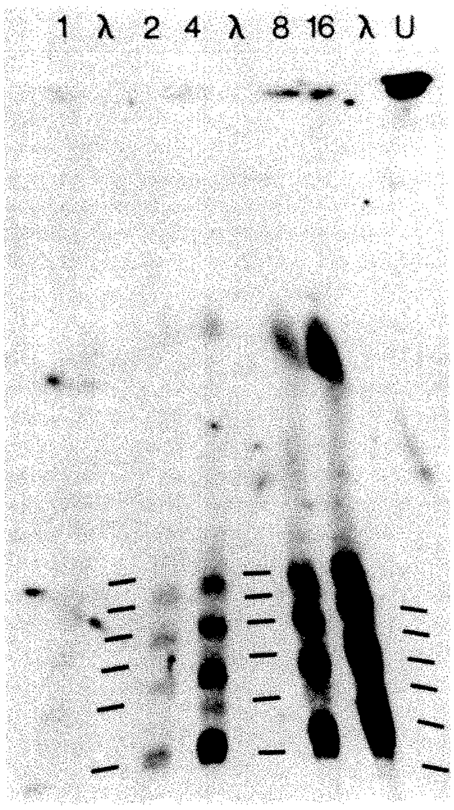

Fig 5. The effect of the amount of DNA per lane on the sizing of restriction fragments by OFAGE. Partial *Sfi*I digests of increasing amounts of normal DNA (1 to 16 μg, as indicated above the lanes and calculated from the number of cells embedded in the block) were electrophoresed in an OFAGE apparatus. Southern blotting and probing with the 3D probe shows that the size of fragments tends to be overestimated if more than 2 to 3 μg DNA is used. (The position of annealed λ DNA markers, genome size 48.5 kb, is indicated by bands drawn on the photograph.) The pattern of *Sfi*I partial-digest bands is entirely consistent with the map in Fig 4, which would predict bands of 40, 105, 180, and 245 kb.

DISCUSSION

The recent introduction of PFGE combined with enzymes that cut only rarely in genomic DNA allows the characterization of large regions that previously were relatively inaccessible to molecular biologic analysis.[28] This technique provides a useful bridge between standard molecular genetic approaches (which are difficult to extend to sizes greater than 50 kb) and cytogenetic analysis (which does not provide resolution below about 2,000 kb). The PFGE blotting approach has recently been applied successfully to the region of the Duchenne muscular dystrophy gene[29-32] and to the human major histocompatibility complex.[22,23] Here we have shown the application of this technology to the human β-globin complex. An *Sfi*I restriction map of the β-globin complex and its 3' flanking region has been constructed and used to determine the size of the HPFH-1 and HPFH-2 deletions without the need for time-consuming and difficult chromosome walking experiments. The map constructed here should be quite useful for analyzing other deletions.

The experiments reported here demonstrate that the deletions in HPFH-1 and HPFH-2 are approximately 105 kb. A third deletion, Chinese $^{G}\gamma(^{A}\gamma\delta\beta)^{\circ}$-thalassemia, has previously been shown to involve the loss of a similar length of DNA as HPFH-1 (about 6 kb less) but with the endpoints shifted relative to the HPFH deletions (Fig 4).[16,17] Thus we can conclude that the Chinese deletion is approximately 100 kb in length. In the 5' direction, there are two other previously described large deletions for which the endpoints have been mapped, both of which give rise to $\gamma\delta\beta$-thalassemia. $\gamma\delta\beta$-Thalassemia 1 was described by Van der Ploeg et al[33] and has its 3' breakpoint 2.5 kb 5' to the β-globin gene, and $\gamma\delta\beta$-thalassemia 2 was subsequently shown by Orkin et al[34] to have its 3' breakpoint located within the β-globin gene. By cloning DNA located at the 5' breakpoints of these forms of $\gamma\delta\beta$-thalassemia, Vanin et al[16] were able to demonstrate that both of these mutations were simple deletions and that the total amount of deleted DNA was very similar. The absolute size of the $\gamma\delta\beta$-thalassemia deletions was subsequently determined by Taramelli et al[35] who performed a cosmid chromosomal walk crossing the entire region of these two deletions and demonstrated that they were 99.4 and 95.9 kb respectively. All five of these deletions, therefore, have removed 100 ± 5 kb genomic DNA, as shown in Fig 4.

Vanin et al,[16] noting that the $\gamma\delta\beta$-thalassemia deletions were of similar but at that time unknown size and that the HPFH deletions were also of similar but unknown size, have suggested a mechanism involving the loss of a complete chromosomal loop during DNA replication. What we have shown in this work is that the 5′ and 3′ deletions are all of approximately the same size, namely, about 100 kb. The model that we propose to explain this phenomenon, which is similar to that previously proposed, is built upon the following observations: (*a*) all of these deletions join nonhomologous DNA sequences,[16] which mitigates against a simple unequal crossing-over mechanism; (*b*) an accumulating body of evidence suggests that DNA is anchored to the nuclear matrix in vivo and is arranged in loops of length 30 to 130 kb[36-38]; (*c*) a simple loss of a chromosomal loop between fixed attachment points would not account for several staggered deletions unless DNA is capable of reeling through the anchorage points; (*d*) this reeling phenomenon may well occur during DNA replication because evidence suggests that DNA replication and topoisomerase activity is concentrated in the matrix[37]; and (*e*) DNA replication is bidirectional in prokaryotes and is probably so in eukaryotes.[37,39,40] In Fig 6 a possible mechanism for the generation of these deletions is depicted. Two matrix attachment points, M_1 and M_2, are postulated to be located physically close together and generate a loop of 100 kb containing the expressed genes of the β-globin cluster. During DNA replication, DNA is reeled into these attachment points from both directions, and daughter strands are reeled out. So long as replication proceeds at the same rate at M_1 and M_2, a faulty connection of the M_1 strand to the M_2 strand (with breaks occurring at M_1A and M_2A or M_1B and M_2B, as marked by arrows in the

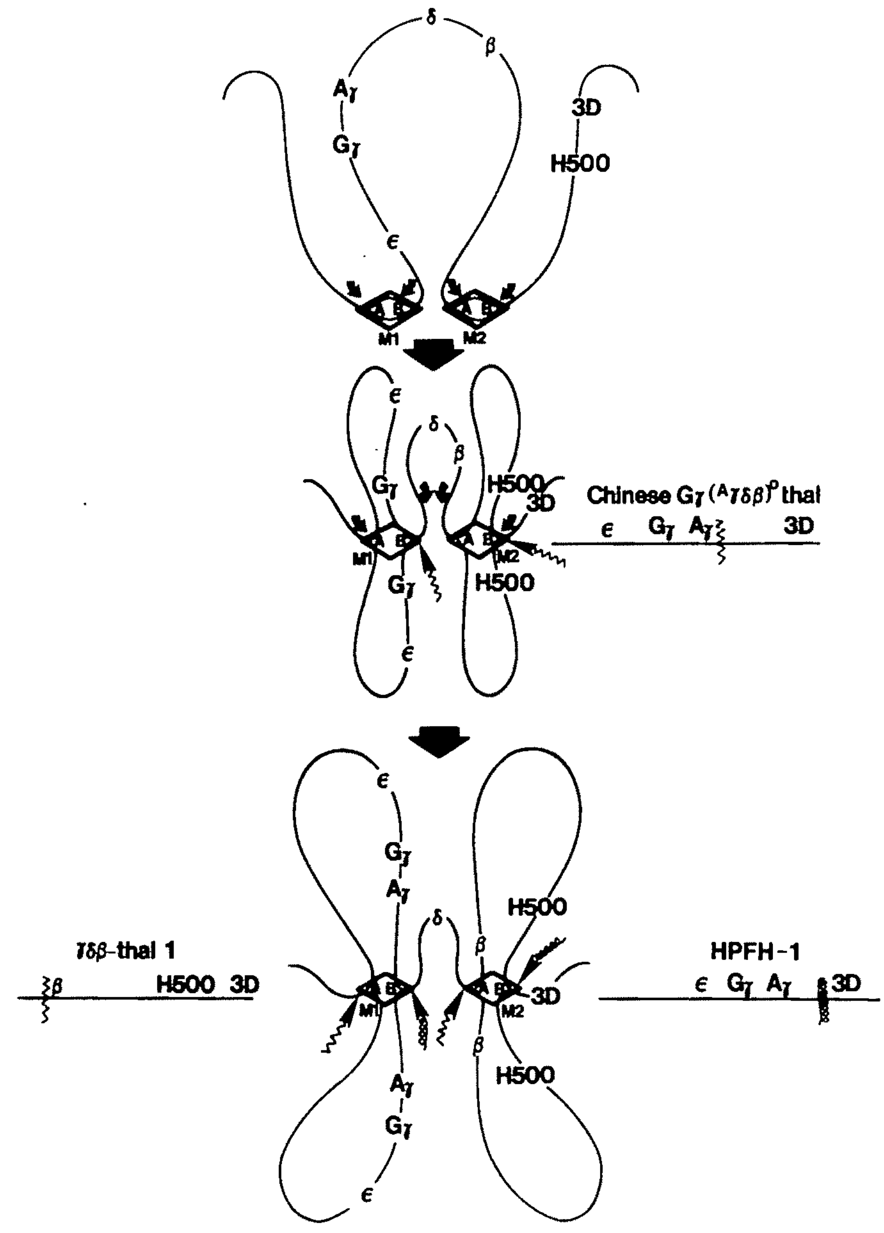

Fig 6. Postulated mechanism for generation of this series of β-globin deletions. M_1 and M_2 are two adjacent matrix attachment points. DNA replication occurs in a bidirectional fashion from these points, which leads to reeling in (heavy arrows) of DNA. Breaks at analogous positions on M_1 and M_2 followed by rejoining would then lead to deletions corresponding to the size of the original loop. Thus, in the middle panel, breakage at arrows marked ∿∿∿ would lead to Chinese $^{G}\gamma(^{A}\gamma\delta\beta)^{\circ}$-thalassemia, and in the lower panel, arrows with ∿∿∿ will lead to $\gamma\delta\beta$-thalassemia 1 and those with ℓℓℓ, to HPFH-1. HPFH-2 and $\gamma\delta\beta$-thalassemia 2 can be accounted for by the same model.

figure) will result in the deletion of 100 kb. Examples are shown in Fig 6. Smaller or larger (up to 200 kb) deletions of varying size would be generated if breakage and rejoining occurred between the A and B attachment points at M_1 and M_2. In fact, several smaller deletions in the β-globin cluster have been described, and at least one deletion has been reported that removes the entire cluster.[1] The model accounts for these but also predicts the observed series of staggered deletions of approximately 100 kb. Note that M_1 and M_2 must be located approximately as drawn in Fig 6 if this loop alone is to account for both the 5′ γδβ-thalassemia and the 3′ HPFH mutations. If adjacent loops are also of 100-kb size, however, the matrix attachment points could be located anywhere in this region.

If this model is correct, one would expect to observe similar phenomena in deletions at other loci, though the size of the deletions would be expected to vary from locus to locus according to the location of nuclear matrix attachment points. Interestingly, Nicholls et al have recently performed a detailed analysis of deletions in the human α-globin locus,[41] and a series of staggered deletions involving the loss of 20 to 30 kb has been identified.

An unexpected finding of this study was the inability to detect bands of measurable (<1,000 kb) size with a wide variety of restriction enzymes that ordinarily generate fragments of 100 to 1,000 kb in mammalian genomic DNA. All of the enzymes tested, except *Sfi*I, have recognition sites containing at least one CG dinucleotide, and current evidence suggests that cutting by these enzymes is blocked by methylation of the cytosines.[28] The ability to generate measurable restriction fragments with these enzymes in other parts of the genome is felt to be attributable at least in part to the presence of so-called *Hpa*II tiny fragment islands, which are highly GC rich sequences often found in the 5′ flanking region of housekeeping genes and usually unmethylated in this setting.[42] The fact that none of these methylation-sensitive enzymes would cut within 1,000 kb of the β-globin cluster suggests that the domain of DNA methylation around this region is very wide, at least in lymphoblastoid cells. In fact, there are *Mlu*I and *Bss*HII sites in sequenced DNA of the β-globin cluster,[3,26] and we have shown that in lymphoblastoid cells these sites do not cut at all in Southern blotting experiments (F. Collins and J. Cole, unpublished data). It would not be surprising if there are other regions of the human genome that are relatively deficient in restrictable methylation-sensitive sites, and this fact will have important consequences for general strategies to construct a large-scale restriction map of the genome.[28]

ACKNOWLEDGMENT

We thank Drs Bernard Forget and Stuart Orkin for HPFH cell lines and Drs Dixie Mager, Oliver Smithies, and Bernard Forget for supplying some of the probes used in this study. We also thank Danielle Rennert for preparing the manuscript and Dr David Ginsburg for helpful comments.

Unique Interactions of Asialo von Willebrand Factor With Platelets in Platelet-Type von Willebrand Disease

By Jonathan L. Miller, Zaverio M. Ruggeri, and Vicki A. Lyle

The present studies demonstrate that platelets from patients with platelet-type von Willebrand disease show specific and saturable binding of asialo von Willebrand factor (AS-vWF) under conditions where such binding is not observed with normal platelets. Although specific binding of ^{125}I–AS-vWF to formalin-fixed normal platelets could not be demonstrated, specific binding to fixed patient platelets was seen with an apparent K_d of 1.3 μg/mL and specific maximally bound ligand of 0.40 μg/10^8 platelets. Preincubation of patient platelets with the antiglycoprotein Ib (anti-GPIb) monoclonal antibody AS-2 reduced total binding close to the level of computer-estimated nonspecific binding. In contrast, binding was not reduced by preincubation with anti-GPIIb/IIIa monoclonal antibody or with 5 mmol/L EDTA. Under stirring conditions, the binding of AS-vWF to fixed patient platelets was accompanied by a strong agglutination response. AS-vWF–induced agglutination was similarly observed in patient but not normal platelet-rich plasma (PRP) in the presence of 5 mmol/L EDTA. In the absence of EDTA, AS-vWF produced a full aggregation response in patient PRP at concentrations as low as 0.1 μg/mL in contrast to the 2 to 20 μg/mL required by normal PRP. Both thromboxane B_2 formation and adenosine triphosphate secretion showed an AS-vWF concentration dependence paralleling the aggregation responses. These studies show that a major difference in the platelets from patients with platelet-type von Willebrand disease is the presence of an exposed, high-affinity binding site associated with GPIb that recognizes AS-vWF.

VON WILLEBRAND FACTOR (vWF) is a protein that plays a major role in platelet adhesive interactions. In an in vitro environment, platelets are agglutinated by vWF in the presence of the antibiotic ristocetin. This agglutination is dependent upon vWF binding to the platelets[1] at the platelet glycoprotein Ib (GPIb) receptor.[2] The mechanism by which vWF may bind in vivo to GPIb, in an environment lacking in ristocetin, is still unknown. After stimulation of platelets by thrombin,[3] adenosine diphosphate[4] and other agonists,[5] vWF may additionally be demonstrated to bind at the GPIIb/IIIa receptor.[6,7]

In contrast to native vWF, desialylated or asialo vWF (AS-vWF) has been shown capable of inducing platelet aggregation in the absence of ristocetin.[8,9] Aggregation was associated with the binding of AS-vWF to platelets and required the presence of free divalent cations. More recently, De Marco et al[10] and Gralnick et al[11] have used monoclonal antibodies to demonstrate that AS-vWF initially binds at the GPIb locus in normal individuals. After this interaction, there is exposure of the GPIIb/IIIa fibrinogen receptor. AS-vWF additionally appears capable of binding to the GPIIb/IIIa receptor complex.

Patients with platelet-type von Willebrand disease exhibit an abnormality of vWF binding. Patient platelets bind vWF in the presence of significantly lower concentrations of ristocetin than are required by normal platelets.[12-14] Additionally, specific and saturable binding of native vWF by patient platelets has been demonstrated in the absence of ristocetin or any other platelet agonist, and native vWF induces aggregation of patient platelets.[15] In view of the fact that desialylation changes the characteristics of vWF binding to platelets, we have undertaken the present studies to explore the interactions of AS-vWF with the abnormal platelets from patients with platelet-type von Willebrand disease.

METHODS

Purification and desialylation of vWF. Native human vWF was purified from human cryoprecipitate (provided by the Greater Syracuse Chapter of the American National Red Cross) as previously described.[15] This vWF retained normal multimeric composition[16] and ristocetin cofactor activity.[17] The purified vWF in phosphate-buffered saline, pH 7.3, was then digested with proteinase-free neuraminidase from *Vibrio cholerae* (Calbiochem, La Jolla, CA) as described by De Marco et al[9] at a ratio of 0.07 units enzyme/mg vWF. After a four-hour digestion, passage over a Sepharose 4B-CL column and subsequent dialysis against 0.02 mol/L Tris, 0.15 N NaCl, pH 7.3, the sialic acid content of the digested protein as well as of native vWF was assayed by the method of Warren.[18] Desialylated vWF to be used in ligand binding studies was labeled with ^{125}I by the method of Fraker and Speck.[19]

Blood processing and platelet function studies. For studies in platelet-rich plasma (PRP), normal or patient blood was drawn into 1/10 vol of 3.8% sodium citrate and the PRP prepared by centrifugation at 900 g for 75 seconds at room temperature (22° to 25°C) as previously described.[15] Unless otherwise specified, for studies of formalin-fixed platelets, platelets were prepared from acid-citrate-dextrose–anticoagulated blood by the method of Macfarlane et al[17] with the modification that the platelets were incubated for two hours at room temperature with a final concentration of 1.4% formalin in the absence of sodium azide. After formalin fixation, the platelets were resuspended in imidazole-buffered saline, pH 7.3, containing no divalent cations. Patient and normal platelets were alternatively processed and formalin fixed for 48 hours exactly as described by Takahashi and Shibata[20] for a smaller number of experiments. For platelet function studies the platelet count was adjusted to 200,000/

μL and the platelets stirred at 1,200 rpm, 37°C, in a Chronolog (Havertown, PA) lumiaggregometer. Platelet-poor plasma (PPP) was used as a blank in the lumiaggregometer. For quantitative assessment of the extent of aggregation, percent aggregation was defined as maximal increase in light transmittance × 100/(light transmittance$_{PPP}$ − light transmittance$_{PRP}$). For studies of platelet dense granule release in PRP, luciferin-luciferase (Sigma Chemical Co, St Louis, MO) was added at a final concentration of 4 mg/mL to monitor the release of adenosine triphosphate (ATP).[21] In some experiments EDTA was added at a final concentration of 5 mmol/L before the addition of platelet agonist. At the end of the aggregation run, the cuvette was removed from the lumiaggregometer and thromboxane production determined as previously described.[22]

Monoclonal antibodies. Monoclonal antibodies AP-1 (anti-GPIb) and AP-2 (anti-GPIIb/IIIa) were a kind gift of Dr Thomas Kunicki of the Blood Center of Southeastern Wisconsin, Milwaukee. Monoclonal antibody AS-2, produced in our laboratory, is directed against the glycocalicin portion of GPIb (J.L. Miller and K.O. Hustad, unpublished observations). Antibodies were purified from ascitic fluid by precipitation with ammonium sulfate followed by affinity purification on Affi-Gel Protein A (MAPS II Kit, Bio-Rad Laboratories, Richmond, CA).

Binding studies. For binding assays, 25 μL of varying dilutions of ^{125}I-AS-vWF was added to 100 μL of a 10^8 platelets/mL suspension of formalin-fixed platelets in imidazole-buffered saline, pH 7.3. After a 30-minute room temperature incubation under nonstirring conditions, the platelets were centrifuged through 20% sucrose containing 2% bovine serum albumin (BSA) as previously described[15] and the platelet-associated radioactivity counted. Analysis of binding constants and Scatchard analysis of binding data were performed with the LIGAND (Scafit) computer program,[23] FORTRAN version 2.3.10 for the IBM PC.

RESULTS

Neuraminidase digestion resulted in the removal of over 90% of the sialic acid content of native vWF (10 nmol sialic acid/mg AS-vWF as compared with 114 nmol/mg native protein). Desialylation did not alter the multimeric composition of the vWF, nor were changes in multimeric pattern seen after iodination (Fig 1). Ristocetin cofactor activity of AS-vWF (119 U/mg) assayed as long as 5 weeks after desialylation did not differ significantly from that of the native vWF from which it had been produced (117 U/mg). Ristocetin cofactor assay of ^{125}I-AS-vWF revealed no loss of activity with respect to the unlabeled protein by 1 week after iodination, over which period of time the binding studies with this ligand were performed.

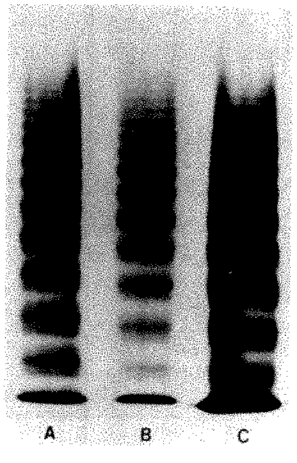

Fig 1. Sodium dodecyl sulfate agarose gel multimeric analysis of AS-vWF (B) and ^{125}I-AS-vWF (C) prepared, as described in the text, from the purified native vWF (A). The point of application is at the top, and the anode is at the bottom. A direct autoradiogram of the ^{125}I-AS-vWF run in lane C showed a similar multimeric pattern (data not shown).

When AS-vWF was added to the PRP from patients with platelet-type von Willebrand disease, a full aggregation response was seen at AS-vWF concentrations as low as 0.1 μg/mL (Fig 2). Increasing AS-vWF concentrations resulted in a more rapid attainment of this response. In contrast, with PRP from normal volunteers, an AS-vWF concentration of 2 to 20 μg/mL was required to achieve a full extent of aggregation. AS-vWF stimulation of thromboxane B_2 formation and of ATP secretion from platelet dense granules showed a concentration dependence very similar to that of the aggregation response both in patients and in normals (Fig 3).

The addition of 5 mmol/L EDTA to the PRP before the addition of AS-vWF fully blocked aggregation, thromboxane B_2 production, and ATP secretion with normal platelets. With patient platelets, in contrast, an initial change in light transmittance quite comparable to that observed in the absence of EDTA was seen after the addition of 2 μg/mL AS-vWF (Fig 2). This change in light transmittance in fact represented an agglutination of platelets rather than true aggregation, as evidenced by the lack of associated thromboxane formation or ATP secretion in the presence of the divalent cation chelator (Fig 3). At a lower concentration of AS-vWF (0.1 μg/mL) just sufficient to produce a full extent (but low initial rate) of aggregation in this patient, the prior addition of EDTA resulted in only a very marginal degree of agglutination (Fig 2).

After formalin fixation, platelet-type von Willebrand disease platelets suspended in medium containing vWF retained their abnormally increased sensitivity to low concentrations of ristocetin (Fig 4). As we have previously observed in the case of washed patient platelets suspended in modified Tyrode's buffer,[15] purified vWF added in the absence of ristocetin was incapable of agglutinating the fixed platelets. In the case of washed platelets, the addition of citrated PPP from a pool of normal donors or from the patients themselves

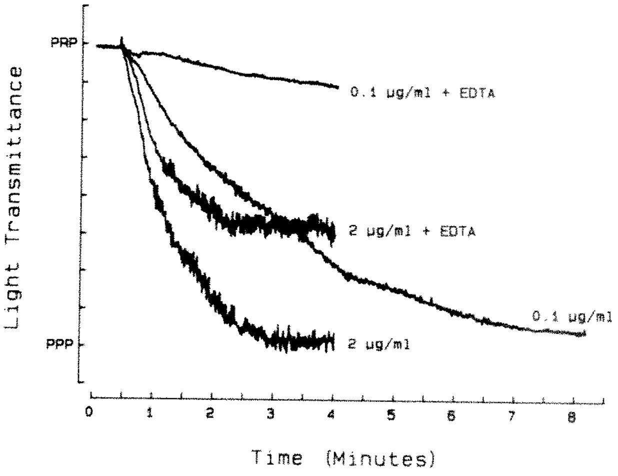

Fig 2. Effect of AS-vWF on citrated PRP from a patient with platelet-type von Willebrand disease. AS-vWF was added (upward deflection of trace) at the final concentrations indicated, in the absence or presence of 5 mmol/L EDTA.

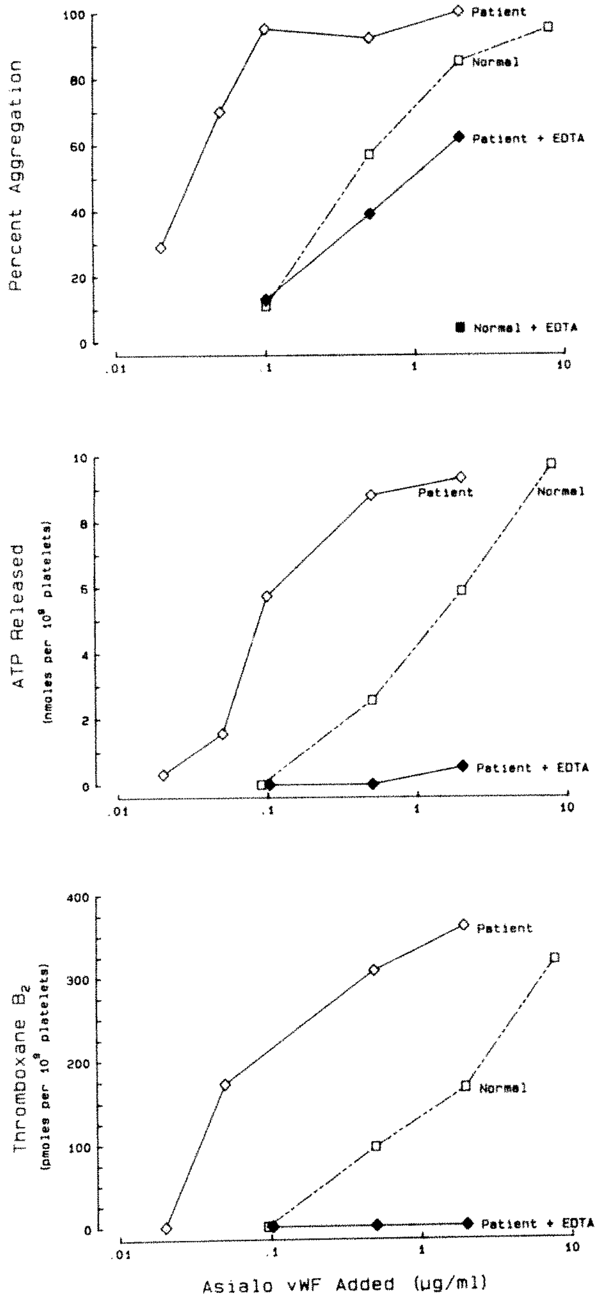

Fig 3. Platelet aggregation, ATP secretion, and thromboxane B_2 production in citrated PRP as a function of AS-vWF concentration in the absence (open symbols) or presence (solid symbols) of 5 mmol/L EDTA added before the AS-vWF. After completion of the lumiaggregation run, the cuvette was removed and thromboxane production subsequently determined.

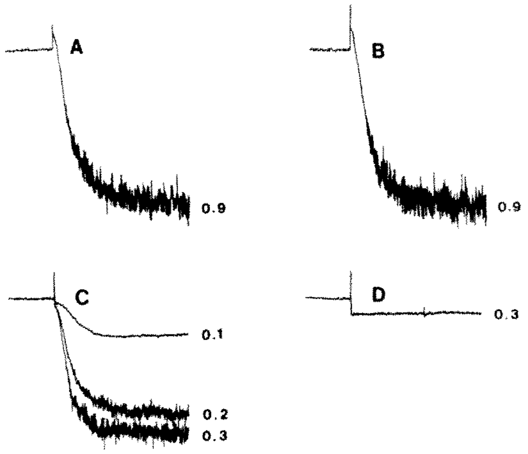

Fig 4. Agglutination of formalin-fixed patient platelets in the presence of native vWF (1.5 U/mL ristocetin cofactor, added as cryoprecipitate before the beginning of trace) and varying concentrations of ristocetin. Ristocetin additions are marked by an upward deflection of traces. The final concentration of ristocetin (mg/mL) is indicated at end of each trace. (A, C) Platelets from a patient with platelet-type von Willebrand disease. (B, D) Platelets from a normal control.

was capable of restoring responsiveness to vWF alone.[15] In contrast, the addition of an equal volume of PPP to a suspension of fixed patient or normal platelets produced no agglutination in the absence of ristocetin. The subsequent addition of either cryoprecipitate or purified native vWF (1 to 4 U/mL ristocetin cofactor activity) also failed to produce an agglutination response. Identical results were obtained when platelets were formalin fixed by the method used by Takahashi and Shibata.[20] Thus, after formalin fixation, the platelets of our patients with platelet-type von Willebrand disease appear to have lost the ability to be agglutinated by vWF in the absence of added ristocetin. They have, however, retained their increased responsiveness to quite low concentrations of ristocetin in comparison with fixed platelets obtained from normal donors.

In contrast to native vWF, the desialylated vWF produced a strong, concentration-dependent agglutination of the formalin-fixed patient platelets in the absence of added ristocetin. Normal platelets identically treated showed no agglutination response (Fig 5). Agglutination of the patient platelets was fully inhibited if the anti-GPIb antibodies AP-1 or AS-2 were added to the platelet suspension (25 to 40 µg/mL, final concentration) before the AS-vWF. Neither the anti-GPIIb/IIIa antibody AP-2 (40 µg/mL) nor the presence of EDTA (5 mol/L) inhibited this agglutination.

To distinguish whether the agglutination induced in patient platelets by AS-vWF was attributable to increased

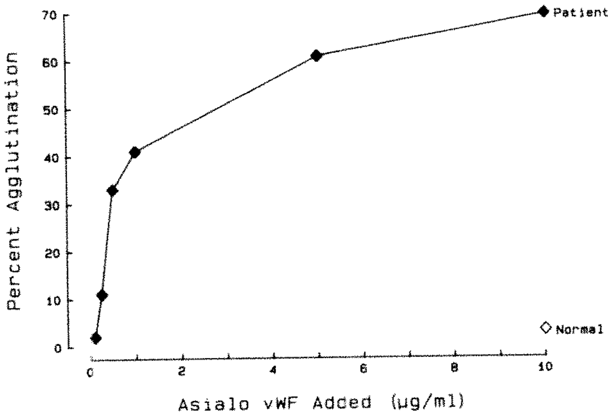

Fig 5. Agglutination of formalin-fixed platelets as a function of AS-vWF concentration.

AS-vWF binding or, instead, to a platelet abnormality subsequent to the initial binding step, we studied the binding of ^{125}I–AS-vWF to fixed platelets. Binding was performed at room temperature under nonstirring conditions. Analysis of the binding of ^{125}I-AS-vWF to patient platelets in the absence of any inhibitor (Fig 6, top panel, buffer condition) by the LIGAND[23] nonlinear curve fitting and Scatchard analysis program (Fig 7) produced estimates of an apparent dissociation constant of 1.3 μg/mL and specific maximally bound ligand of 0.40 μg/10^8 platelets. There was a relatively low residual variance (mean square) of 60 for this fit. The 0.8% nonspecific binding (0.26 μg/10^8 platelets at a 25-μg/mL ligand concentration) estimated by the program for the buffer condition was quite close to the actual binding observed when the platelets were preincubated with the anti-GPIb monoclonal antibody AS-2 (Fig 6, top panel). In contrast, neither the anti-GPIIb/IIIa monoclonal antibody AP-2 (Fig 6, top panel) nor the presence of 5 mmol/L EDTA (data not shown) produced any inhibition of binding. When fixed platelets from normal individuals were used in place of patient platelets in these studies (Fig 6, bottom panel, buffer condition), a specific binding component could not be identified by computer analysis. Moreover, no significant difference in binding to normal platelets was seen in the presence of AS-2 or AP-2, thus suggesting that the observed binding was in fact nonspecific in nature.

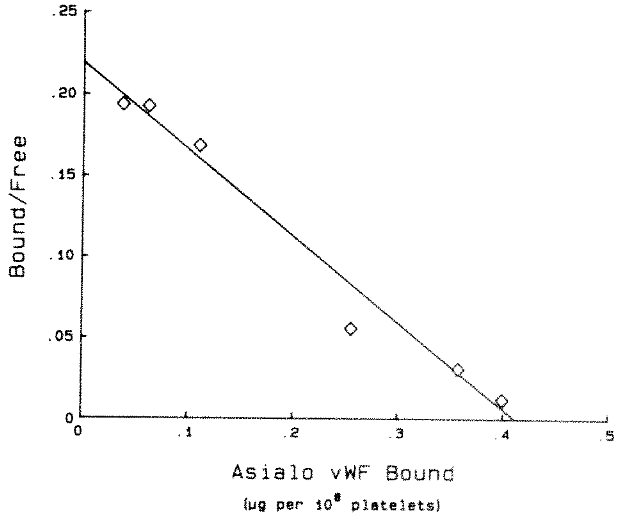

Fig 7. Scatchard plot of the same experiment for the buffer condition of patient platelets shown in Fig 6. Bound/free *v* bound (μg/10^8 platelets) represents the specific binding and is based on an estimate of 0.8% nonspecific binding by the LIGAND[23] computer program. Computer estimates of specific maximally bound ligand and of the dissociation constant for binding were 0.40 μg/10^8 platelets and 1.3 μg/mL, respectively, with a residual variance (mean square) of 60 for the fit.

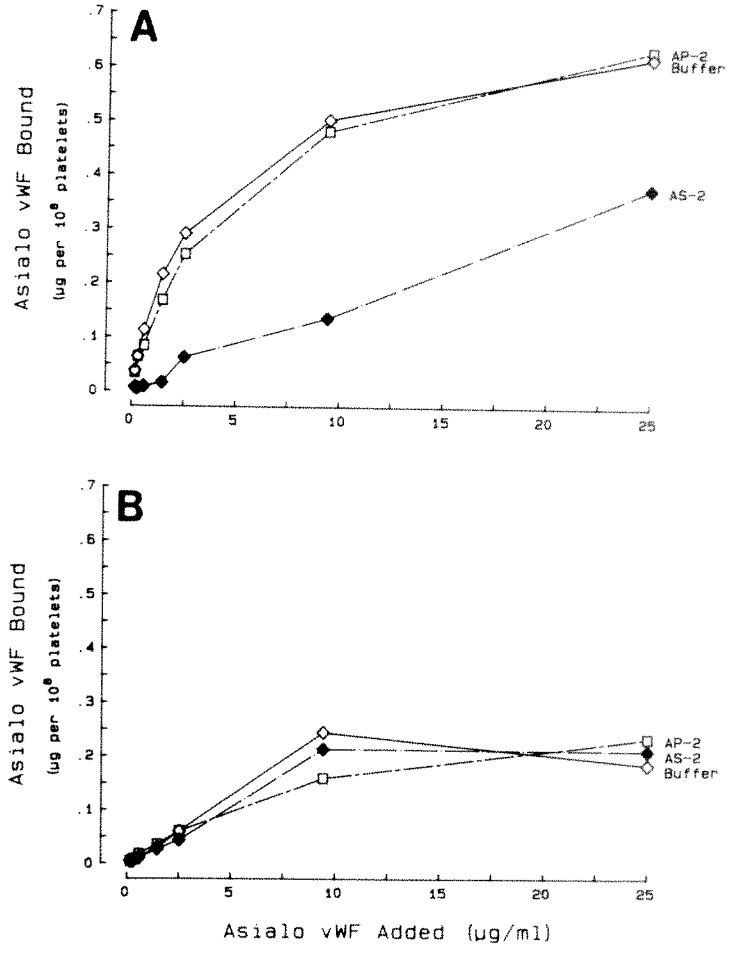

Fig 6. Binding of ^{125}I–AS-vWF to formalin-fixed platelets. Platelet suspensions were brought to a final concentration of 30 μg/mL antibody by adding to 100 μL of a 10^8 platelets/mL suspension of formalin-fixed (A) patient or (B) normal platelets 30 μL AS-2 (anti-GPIb), 30 μL AP-2 (anti-GPIIb/IIIa), or 30 μL buffer. After ten minutes at room temperature, 25 μL of varying concentrations of ^{125}I–AS-vWF was added to bring AS-vWF to the final concentrations indicated. After a further 30-minute incubation at room temperature under nonstirring conditions, the platelets were then centrifuged through a layer of 20% sucrose containing 2% BSA and the platelet-associated radioactivity counted.

When the binding of ^{125}I–AS-vWF to patient platelets was measured in the presence of >30-fold (wt/wt) excess of native vWF, the total amount of ^{125}I-AS-vWF bound was decreased by 20% to 25% (Table 1). This inhibition represented only approximately one third that achievable by the presence of anti-GPIb monoclonal antibody. Ristocetin greatly enhanced ^{125}I–AS-vWF binding to the patient platelets (Table 1). This enhancement was prevented if native vWF was present in the incubation mixture at the time of ristocetin addition.

DISCUSSION

The present studies have established that platelets from patients with platelet-type von Willebrand disease show specific and saturable binding of AS-vWF under conditions where such binding is not observed with normal platelets. Thus, binding of AS-vWF to platelets in the absence of ristocetin is demonstrable after formalin fixation of patient platelets, but not to formalin-fixed platelets from normal subjects. This binding is blocked by monoclonal antibody directed against platelet GPIb but not by antibody against GPIIb/IIIa or by the divalent cation chelator EDTA. This interaction now defines a third major ligand-binding abnormality of these platelets, following the prior demonstration of (*a*) enhanced ristocetin sensitivity for interaction of native vWF and (*b*) the binding of native vWF to metabolically active platelet-type von Willebrand disease platelets in the absence of any stimulating agent.[12,15] The present findings provide further evidence for an abnormality of the GPIb receptor complex in platelet-type von Willebrand disease.

The binding of AS-vWF to formalin-fixed patient platelets resulted in the agglutination of these platelets. Agglutination could also be demonstrated when AS-vWF was added to fresh patient PRP in the presence of 5 mmol/L EDTA. In contrast, as previously reported by other workers,[8,9] no agglutination of normal PRP could be demonstrated in the presence of EDTA. Under conditions where the platelets were metabolically active (PRP without added EDTA), thromboxane formation and dense granule secretion by patient platelets was observed at AS-vWF concentrations at least an order of magnitude lower than that required for normal platelets.

De Marco et al,[10] and Gralnick et al[11] have previously shown that in normal citrated PRP AS-vWF binds initially to GPIb and subsequently to the exposed GPIIb/IIIa receptor. The present studies indicate that in platelet-type von Willebrand disease platelets AS-vWF can bind to GPIb receptor sites even in the absence of free divalent cations. It is presumably the increased reactivity of these binding sites for AS-vWF in the patient platelets that leads in the presence of calcium ions to increased platelet activation, with subsequent thromboxane formation, dense granule secretion, and true aggregation. As in the case of normal platelets, the precise mechanism(s) by which binding at the GPIb site leads to platelet activation and to exposure of the GPIIb/IIIa receptor remains unknown.

The ability of formalin-fixed patient platelets to bind AS-vWF has permitted the study of AS-vWF binding restricted to the platelet GPIb receptor without the complexity of subsequent GPIIb/IIIa exposure that is seen in fresh platelets. Indeed, preincubation of the fixed patient platelets with the anti-GPIIb/IIIa antibody AP-2 (Fig 6) showed no diminution of the binding by AS-vWF. Even at concentrations as low as 0.4 to 1.0 μg/mL AS-vWF, significant binding to patient platelets was detected. This concentration range is quite similar to that at which a significant degree of AS-vWF–induced agglutination of patient platelets is detected. Thus, with AS-vWF concentrations for which approximately 0.1 to 0.5 μg of ligand are bound per 10^8 platelets, a strong agglutination response results. This is also very similar to the amount of AS-vWF that has been found necessary to bind to fresh normal platelets for an aggregation response to be observed.[9] It seems likely, therefore, that the major difference in the platelets from platelet-type von Willebrand disease patients is the increased affinity or more accessible binding of AS-vWF to the GPIb site. Once AS-vWF has bound to the required number of receptors per platelet, agglutination may ensue. Because fixed normal platelets are unable to bind comparable numbers of AS-vWF molecules, such agglutination would not be observed.

In the present studies native vWF appeared unable to produce an agglutination reaction in patient platelets in the absence of ristocetin. This finding is in contrast to the report by Takahashi and Shibata[20] where such an agglutination response was reported. It may well be that, although the patients with platelet-type von Willebrand disease in the present studies and those reported in the Japanese studies show major phenotypic similarities, the precise abnormalities at the vWF receptor region are not identical. Thus, although an abnormal band pattern of GPIb has been reported in the Japanese patients,[24] no GPIb structural abnormalities have yet been found in studies of this disorder by ourselves or others.[12,13] The qualitatively abnormal and high-affinity association of AS-vWF with the platelets from our patients with platelet-type von Willebrand disease may prove a useful

Table 1. AS-vWF Binding to Platelets From Patients With Platelet-Type von Willebrand Disease

Condition	^{125}I–AS-vWF Bound (Percentage of Control)
Buffer control	100
Anti-GPIb antibody AP-1 (40 μg/mL)	35.0 ± 6.1 (6)
Native vWF (44 μg/mL)	76.7 ± 4.1 (6)
Ristocetin (1 mg/mL)	585.2 ± 113.9 (6)
Native vWF (44 μg/mL) + ristocetin (1 mg/mL)	93.7 ± 12.9 (6)

A 25-μL aliquot of ^{125}I-labeled AS-vWF was added to 100 μL of a 10^8 platelets/mL suspension of formalin-fixed patient platelets in imidazole-buffered saline to bring the final concentration of AS-vWF to 1.2 μg/mL. After 30 minutes' incubation at room temperature under nonstirring conditions, the platelets were centrifuged through a layer of 20% sucrose containing 2% BSA and the platelet-associated radioactivity counted. Before addition of the ^{125}I-labeled AS-vWF, native vWF, ristocetin, the combination of both, anti-GPIb monoclonal antibody AP-1, or an equal volume of buffer was incubated with the platelet suspension for ten minutes at room temperature under nonstirring conditions. The total ^{125}I–AS-vWF bound under each experimental condition is expressed as a percentage of the mean total binding for the buffer control. Values shown are means ± SEM for (n) experiments.

tool for the identification of the underlying structural abnormality in these platelets.

ACKNOWLEDGMENT

The authors wish to thank Dr Thomas Kunicki for kindly providing monoclonal antibodies AP-1 and AP-2.

Inhibition of K Transport by Divalent Cations in Sickle Erythrocytes

By Carlo Brugnara and Daniel C. Tosteson

We report experiments on the effect of intracellular divalent cations (Mg, Ca, Mn) on K transport and cell volume in erythrocytes from patients with homozygous hemoglobin S disease (SS cells). When CO-treated SS erythrocytes are exposed to the ionophore A23187, removal of cell Mg markedly stimulates K efflux, whereas increasing cell Mg inhibits K efflux. The K_i for the inhibition by internal free Mg is 0.38 ± 0.10 mmol/L, a value comparable to the concentration of free Mg in normal cells (0.3 to 0.4 mmol/L). When swollen SS cells with increased Mg content were incubated in plasma-like medium, they shrunk much less than swollen SS cells with normal Mg content. Thus, elevation of cell Mg produces inhibition of swelling-induced K movement from SS cells. Internal Ca and Mn also inhibit K movement from SS cells. The inhibition of volume regulation by divalent cations suggests that increases in intracellular divalent ions, especially Mg, could induce a persistent degree of cell swelling in SS RBCs and thereby inhibit intracellular polymerization.

POLYMERIZATION of hemoglobin S and cell sickling are extremely dependent on oxygen tension and hemoglobin concentration.[1] At any given oxygen tension, hemoglobin S concentration is the most important factor in determining the rate of polymer formation and morphological cell sickling. Because hemoglobin concentration is determined by the water and cation content of the RBC, it is important to study how water content and cell volume are regulated in sickle cell anemia. Cell volume is determined in RBCs by transport mechanisms moving cations and anions across the RBC membrane. We recently described a K transport system that is very active in oxygenated SS and CC cells[2,3] and is also present in the least dense (reticulocyte-rich) fraction of normal AA cells.[4,5] K movement through this system allows SS cells to shrink when they are isomotically swollen in vitro or when they are exposed to acid pH. This K movement is not sensitive to inhibitors of the Na-K pump (ouabain, 0.1 mmol/L) and/or Na-K-Cl cotransport (bumetanide, 0.01 mmol/L) systems, and differs from the Ca-activated K permeability first described by Gardos.[6] This pathway shares many properties with the pathway for K transport described by Lauf in sheep RBCs (SRBCs) (reviewed in ref. 7). A similar chloride-dependent pathway has also been described in "young" human RBCs by Hall and Ellory.[8]

Because cell swelling is a logical strategy to ameliorate the clinical course of SS disease,[9] and because this K transport pathway induces a sizable cation and water loss, thus counteracting cell swelling, and may also play a role in the formation of dense dehydrated SS cells, a detailed knowledge of its properties could be helpful in designing future pharmacologic interventions to induce cell swelling in SS cells.

The system for K transport described in low K (LK) SRBCs is modulated by divalent ions.[7] We studied the effect of divalent cations on K transport and cell volume in SS erythrocytes. We found that increasing internal Mg concentration in SS cells has marked effects on cell volume and K transport: An increase in internal Mg directly produces an increase of cell volume and thus a decrease of mean corpuscular hemoglobin concentration (MCHC). Moreover, the net K loss and cellular dehydration induced by acid pH- or swelling in SS cells are markedly inhibited by increased concentrations of internal Mg. Other divalent cations, such as Ca and Mn, share a similar inhibitory action, albeit with different affinities.

MATERIALS AND METHODS

Blood was drawn from patients homozygous for hemoglobin S disease. All patients had received no blood transfusions for at least 3 months prior to sampling. Preparation of RBCs, nystatin-loading procedure, and measurement of K efflux and phthalate density profile were performed as detailed in previous publications.[3] The methods we used to control and adjust Mg levels in erythrocytes and to measure total RBC magnesium with atomic absorption spectrometry were those described by Flatman and Lew.[10]

To study the effect of Mg on cell volume, the phthalate density profile was measured in SS cells incubated for 30 minutes in a medium containing 10 mmol/L NaCl, 130 mmol/L KCl, 0.5, 1, 5, and 10 mmol/L $MgCl_2$, 10 mmol/L Tris-MOPS, pH 7.4 at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, 0.01 mmol/L bumetanide, and 90 μmol/L/cell A23187.

To study the effect of Mg, Ca, and Mn on K efflux, nystatin-swollen SS cells were incubated in isosmotic media containing 140 to 130 mmol/L choline chloride, 0 to 5 mmol/L divalents ($MgCl_2$, $CaCl_2$, $MnCl_2$), and 0 to 15 mmol/L sucrose. These three components were reciprocally varied to maintain constant chloride concentration and osmolarity. The media also contained 10 mmol/L Tris-MOPS, pH 7.40 at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, 0.01 mmol/L bumetanide, 0.010 mmol/L carbocyanine[11] and 0.005 mmol/L chlorpromazine. Incubation times for K efflux measurement were 5 and 15 minutes. The incubation times in these and other experiments were chosen to meet conditions of initial rate and have K effluxes values linear with time. The hematocrit of the flux suspension was 1%, and the concentration of the ionophore A 23187 was 90 μmol/L/cell.

To study the effect of internal Mg, at constant external Mg, nystatin-treated SS cells were incubated in a medium containing 10 mmol/L NaCl, 130 mmol/L KCl, 10 mmol/L Tris-MOPS, pH 7.4 at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, 0.01 mmol/L bumetanide, 90 μmol/L/cell A23187, and either 0.1 mmol/L EDTA or $MgCl_2$ (1 to 2 mmol/L). After 30-minute incubation, the ionophore was removed with four washes with the same medium plus albumin (1 mg/mL). K efflux was measured in a medium containing

140 mmol/L NaCl, 1 mmol/L $MgCl_2$, 10 mmol/L Tris-MES (pH 6.0 to 6.5) or Tris-MOPS (pH 6.75 to 8.0) at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, and 0.01 mmol/L bumetanide. The hematocrit of the flux suspension was 1%, and the incubation times were 5 and 25 minutes at 37°C (each one in triplicate).

To study the effect of internal Mg, at constant external Mg, on the volume regulatory decrease exhibited by swollen SS cells, a protocol similar to the one described above was followed and the cells were then incubated in a medium containing 140 mmol/L NaCl, 4 mmol/L KCl, 1 mmol/L $MgCl_2$, 1 mmol/L phosphate, 10 mmol/L Tris-MOPS, pH 7.4 at 37°C, and 10 mmol/L glucose. MCHC, Na, K, and Mg content and phthalate density profile were measured at the beginning of the incubation and after 12 hours at 37°C. Cell Mg and ATP contents were measured at the beginning and end of incubation and were constant.

RESULTS

Effect of divalent cations on cell volume in SS cells. As shown in Fig 1, when the internal concentration of Mg is increased by using A 23187 in SS cells, cell volume is also increased. This effect is due to the movement of chloride and thus water into the RBC, to balance the reduction in negative charges of nonpermeant solutes induced by Mg ions, and has been previously described in normal human RBCs by Flatman and Lew.[10] Cell swelling is not the only consequence of an increase on the internal Mg content: The increase of the chloride distribution ratio (Cl_i/Cl_o), at constant external pH and external chloride concentration, produces an alkaline shift in internal pH and a reduction of the RBC membrane potential. We also measured the total Mg content in SS and AA cells. Our preliminary data indicate that the total RBC Mg content is 2.5 ± 0.2 (SD, n = 5) mmol/L/cell in SS and 2.3 ± 0.1 (SD, n = 7) mmol/L/cell in AA cells (7.2 and 7.4 mmol/kg hemoglobin, respectively).

Effect of divalent cations on swelling-induced K efflux from SS cells. As in our previous study of CC cells,[3] we found no effect of external Mg on the swelling-induced K flux from SS cells (data not shown). As shown in Fig. 2a, however, when the *internal* Mg content is varied by varying the external Mg concentration in the presence of ionophore A 23187, K efflux from isosmotically swollen SS cells is markedly affected. Removal of internal Mg (by using A23187 and 0.1 mmol/L EDTA), stimulates K efflux from SS cells. When the internal (and external) Mg is increased, K efflux is progressively inhibited. At 0.15 to 0.2 mmol/L external Mg, K effluxes with and without A23187 are equal. This concentration of external Mg, with A23187, yields free and total RBC Mg values similar to those observed in fresh normal human RBCs[10] (C. Brugnara, unpublished observations). The K_i for external Mg, with A23187 added, calculated with the Dixon plot was 185 ± 50 μmol/L (n = 5). This value corresponds to a free internal Mg concentration of 380 ± 100 μmol/L.

To investigate whether other divalent cations have a similar inhibitory action on K transport of SS cells, we also increased the erythrocyte concentration of Ca and Mn. Because any increase of the internal free Ca opens Ca-activated K channels (Gardos effect, ref. 6), inducing a large K loss and also activating the Ca pump with associated increased consumption of ATP and metabolic substrates, we included in the incubation medium 10 μmol/L carbocyanine, an inhibitor of the Ca-activated K channel[11] and 5 μmol/L chlorpromazine, an inhibitor of the Ca pump. We did not use trifluoperazine because it produced cell lysis. The presence of these two drugs did not affect the inhibitory action of Mg on the OB-resistant K fluxes. Indeed, similar results were obtained when the internal Mg was varied with and without carbocyanine and chlorpromazine. Figure 2a shows the effect of external Ca and Mn, with A23187 added, on the swelling-induced K efflux from SS cells. When the internal (and external) concentration of these two divalent ions is increased, there is a marked inhibition of K efflux from SS cells. Mn is a more powerful inhibitor of K movement than Ca, since in two experiments the K_i for inhibition of K efflux by external Ca with A23187 were 300 μmol/L, and 200 μmol/L, whereas the comparable figures for external Mn with A23187 were 50 μmol/L and 70 μmol/L. Increasing concentrations of internal divalent cations inhibit the swelling-induced K efflux despite a concomitant increase in the cell water content that by itself would further stimulate K loss.

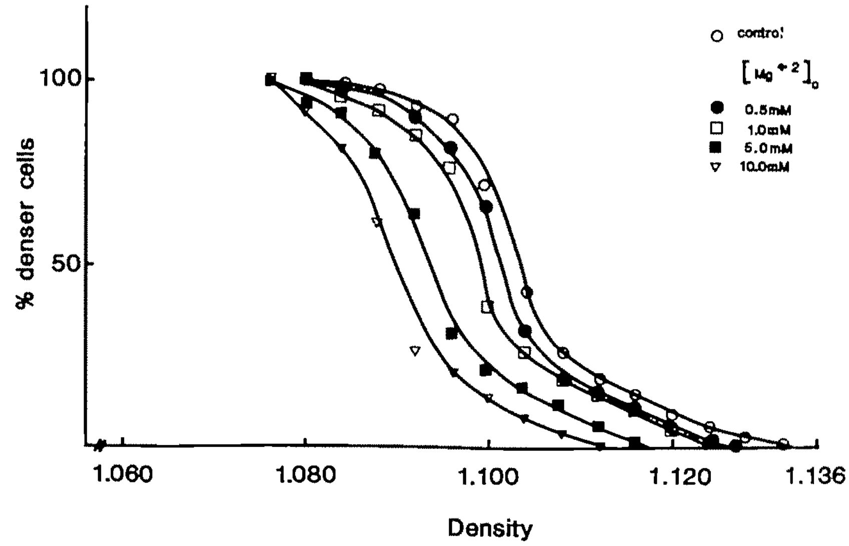

Fig 1. Effect of increasing the erythrocyte Mg content on density profile of SS cells. To increase cell Mg content, SS cells were incubated in a medium containing: 10 mmol/L NaCl; 130 mmol KCl; 0.5, 1, 5, and 10 mmol/L $MgCl_2$; 10 mmol/L Tris-MOPS, pH 7.4 at 37°C; 10 mmol/L glucose; 0.1 mmol/L ouabain, 0.01 mmol/L bumetanide, and 90 μmol/L/cell A23187. After 30-minute incubation at 37°C, the phthalate density profile was measured.

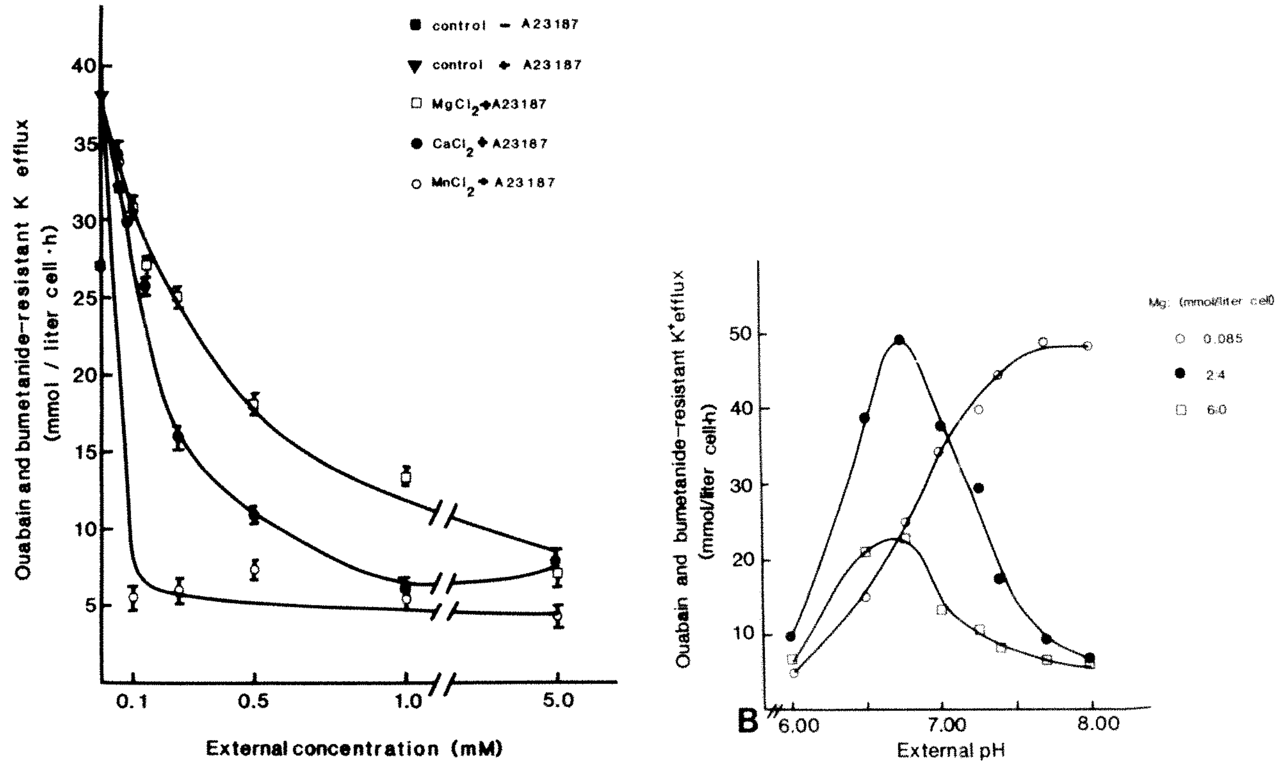

Fig 2. (A) Effect of divalent cations on the swelling-induced K efflux from SS cells. SS erythrocytes were isosmotically swollen by using the nystatin technique; MCHC values before and after nystatin treatment were 35.4 and 26.7 g/dL, respectively. K efflux was measured from cells in which divalent cations content was varied by using A23187 (90 μmol/L/cell) and different external divalent cation concentrations. The efflux media containing 140 to 130 mmol/L choline chloride, 0 to 5 mmol/L divalents ($MgCl_2$, $CaCl_2$, and $MnCl_2$), 0 to 15 mmol/L sucrose (these three components were reciprocally varied to maintain constant chloride concentration and osmolarity), 0.01 mmol/L EGTA, 10 mmol/L Tris-MOPS, pH 7.40 at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, 0.01 mmol/L bumetanide, 10 μmol/L carbocyanine, and 5 μmol/L trifluoperazine. Incubation times for K^+ efflux measurement were 5 and 15 minutes, and the hematocrit of the flux suspension was 1%. (B) Dependence of ouabain- and bumetanide-resistant K efflux on external pH in control SS cells, and in SS cells with increased or decreased Mg content. MCHC, Na^+, and K^+ contents of nystatin-treated SS cells were 31.5 g/dL, 36.5 and 349 mmol/kg hemoglobin, respectively. The cell Mg content was varied with A23187, and the ionophore was then removed, as described in the Materials and Methods section. The total Mg content was 2.6 mmol/L/cell in SS control cells, 0.085 mmol/L/cell in SS cells with low Mg content, and 6 mmol/L cell in SS cells with high Mg content. K efflux was measured in a medium containing 140 mmol/L NaCl, 1 mmol/L $MgCl_2$, 10 mmol/L Tris-MES (pH 6.0 to 6.5) or Tris-MOPS (pH 6.75 to 8.0) at 37°C, 10 mmol/L glucose, 0.1 mmol/L ouabain, and 0.01 mmol/L bumetanide. The hematocrit of the flux suspension was 1%, and the incubation times were 5 and 25 minutes at 37°C (each one in triplicate).

Effect of Internal Mg on the pH dependence of K efflux from SS cells. To rule out the possibility that these effects were due to A23187, and to measure K efflux from cells with different Mg content at constant (1 mmol/L) external Mg, SS cells were exposed to A23187 and different Mg concentrations, and the ionophore was then removed by washing at 37°C with albumin. When the RBC Mg content was increased, K efflux was markedly decreased at any external pH studied (Fig 2b). When the internal Mg was decreased (incubation in 0 Mg + 0.1 mmol/L EDTA), there was a marked change in the pH dependence of K efflux. K efflux was progressively stimulated when the external pH became more alkaline and the inhibition by alkaline pH was abolished (Fig 2b). Different effects were observed when cell volume was changed by altering the osmolarity of the medium at constant pH (7.40). At any given internal Mg concentration studied, K efflux was markedly inhibited when SS cells were shrunken by incubation in hypertonic media (data not shown). Thus, when the free and total cell Mg are markedly reduced in SS cells, there is a dissociation between the inhibitory action of alkaline pH (that is lost) and the inhibitory action of cell shrinkage (that is conserved) on K efflux.

Effect of internal Mg on regulation of cell volume by SS cells. We next studied the effect of varying the cell Mg content on the volume regulatory properties of CO-treated SS cells. SS erythrocytes were isosmotically swollen with the nystatin technique, their Mg content was increased with A23187 and MCHC, Na K contents and phthalate density distribution were measured before and after 12 hours incubation at 37°C in a plasma-like medium containing no transport inhibitor. As shown in Fig 3, swollen SS erythrocytes (total cell Mg 7.5 mmol/kg hemoglobin) shrink more than swollen SS cells with increased Mg content (total cell Mg 16.7 mmol/Kg hemoglobin). The difference in cell volume and cation content at the end of the incubation between SS control and SS cells with increased Mg content is mostly due to a smaller K loss in the high Mg cells (Table 1). There is

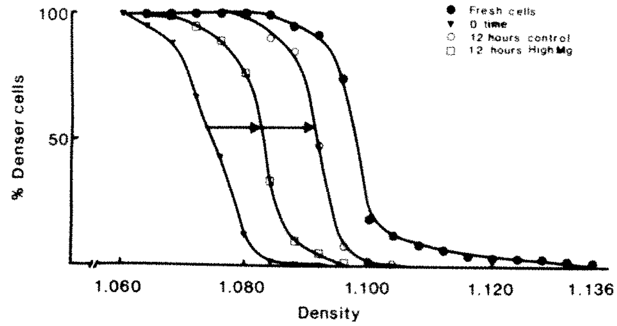

Fig 3. Effect of increasing the erythrocyte Mg content on phthalate density profile of swollen SS cells after 12-hour incubation in an isosmotic medium. The cell water and K contents were increased using the nystatin procedure. The erythrocyte Mg content was then increased by incubating the cells for 20 minutes with 90 µmol/L/cell A23187 in a solution containing 130 mmol/L KCl, 10 mmol/L NaCl, 1 mmol/L $MgCl_2$, 10 mmol/L Tris-MOPS, (pH 7.40) at 37°C, and 10 mmol/L glucose. The ionophore was then removed (as described in the Materials and Methods section), and the cells were then incubated for 12 hours in a medium containing 140 mmol/L NaCl, 4 mmol/L KCl, 1 mmol/L $MgCl_2$, 1 mmol/L phosphate, 10 mmol/L Tris-MOPS (pH 7.4) at 37°C, and 10 mmol/L glucose. This was one of three experiments in different SS subjects.

also a small increase of the cell Na content in the high Mg cells as compared with SS control cells.

DISCUSSION

This report shows that variations in cell Mg affect SS erythrocyte cell volume by two different mechanisms. The first mechanism occurs through a reduction of the net negative charge of the nonpermeant cellular ions due to Mg binding to organic phosphates (10). As a consequence, to maintain electroneutrality, chloride moves into the cells and water follows osmotically, increasing water content and volume[10] (Fig 1). The second mechanism involves a specific inhibitory effect of internal Mg on a K transport pathway that has increased activity in SS and CC cells,[2,3] but is also present in the least dense fraction of normal AA cells.[4,5] This inhibitory effect of Mg counteracts the cell shrinkage produced by this pathway when SS cells are swollen or exposed to acid pH (Figs 2B and 3).

Table 1. Effect of Increasing Total Cell Mg Content on Volume Regulatory Decrease of Swollen SS Cells

Cells	MCHC (g/dL)	Na	K	(Na + K)	Total Mg
		(mmol/kg hemoglobin)			
Fresh cells	35.2	44.3	240.0	284.3	7.4
Swollen SS cells					
0 time	26.7	30.4	475.0	505.4	7.5
12 hours	31.1	47.9	300.0	347.9	7.0
Swollen SS cells, high Mg content					
0 time	26.3	36.0	480.0	516.0	16.7
12 hours	28.4	53.5	361.0	414.5	15.0

Carbon monoxide-treated SS cells were isosmotically swollen by using the nystatin technique. The RBC Mg content was subsequently increased by exposing the RBCs for 20 minutes to 1 mmol/L $MgCl_2$ with 90 µmol/L/cell A23187, in a solution containing 130 mmol/L KCl, 10 mmol/L NaCl, 10 mmol/L Tris-MOPS (pH 7.40) at 37 °C, and 10 mmol/L glucose. After removal of the ionophore, the cells were incubated for 12 hours in a medium containing 140 mmol/L NaCl, 4 mmol/L KCl, 1 mmol/L $MgCl_2$, 1 mmol/L phosphate, 10 mmol/L Tris-MOPS (pH 7.40) at 37 °C, and 10 mmol/L glucose. This was one of three experiments in different SS subjects. Each determination was carried out in triplicate (SD 1% to 3%).

Other variables, namely internal chloride, internal pH, and membrane potential are changed when the internal concentration of divalent ions is increased. The inhibition is almost complete at a concentration of divalent cations in the external medium of 1 mmol/L (Fig 2A). This concentration of external Mg yields in the presence of A23187 a free cell Mg of 1.7 mmol/L (normal value is 0.3 mmol/L) and a total RBC Mg content of 6.5 mmol/L/cell water (normal value is 3.2 mmol/L/cell water). As a consequence, the internal chloride concentration rises, the internal pH increases from 7.25 to 7.29, and the membrane potential decreases from −9.0 to −6.5 mV. These last two changes by themselves could inhibit K movement and this possibility cannot yet be ruled out. The different affinities for divalent cations to inhibit K movement (Fig 2A) suggest, however, that this effect is a specific property of divalent cations rather than a secondary effect due to changes in internal pH and membrane potential.

The regulatory action of internal Mg on K movement is further revealed by the finding that decreasing internal Mg in human SS cells stimulates K efflux (Fig 2A and B). A similar effect has also been reported in LK SRBCs,[7,12] and the activity of the KCl cotransporter has been proposed to be determined by a divalent ion binding site, which is in turn regulated by the degree of protonation of its chemical groups.[7] Indeed, the stimulation of K efflux by removal of internal Mg is also associated with a loss of the bell-shaped dependence on pH of K movement, and K efflux is not inhibited when the internal pH becomes more alkaline (Fig 2B). Thus, the inhibition of this pathway for K transport requires the presence of internal Mg. It is reasonable to suppose that the inhibition of K transport by alkaline pH in the presence of internal Mg (Fig 2B) is due to binding of Mg at some site in the transport system for which Mg and protons compete. A loss of inhibition of K transport by alkalinization is also observed in SS, CC, and AA least dense cells after treatment with *N*-ethylmaleimide (NEM 1 mmol/L) or after isosmotic cell swelling[4] (data not shown). The only difference among these three different conditions is that the increased K efflux due to NEM treatment is not volume sensitive, whereas that due to Mg removal or isosmotic cell swelling is inhibited by cell shrinkage produced by suspension of the cells in hypertonic media.

We have proposed that the high activity of this pathway in CC and SS cells is due not only to the presence of young cells, but also to a direct effect of the positively charged S and C hemoglobins, probably through binding to the RBC membrane.[2-4] Indeed, cells with a moderate reduction of life span, such as those homozygous or heterozygous for C hemoglobin, have a much higher volume and pH-dependent K transport that control AA cells with comparable degrees of reticulocytosis. Although this pathway is active only in the least dense, reticulocyte-rich fraction of normal AA blood, which represents 5% of the whole RBC population,[4,8] it is active in all density fractions of CC and SS cells. Moreover, the K, Cl, and water loss induced by the activation of this transport pathway are not limited to a fraction of young SS cells, since they are easily demonstrable in whole SS blood (Fig 3 and Table 1). Because KCl loss through this pathway produces cell shrinkage, and because this pathway is most active in cells with relatively low density (and thus high cation and water content), it is reasonable to suppose that this pathway is involved in the reduction of K and water content that occurs when normal and SS RBCs become mature in vivo and may also be involved in the formation of dense dehydrated SS cells.

The inhibitory effect of internal Mg on K transport is not an exclusive property of SS cells, but is also observed in the least dense fraction of normal human RBCs.[4] A similar inhibitory action of Mg has been described by Lauf for the volume-dependent K flux of low K SRBCs.[12] Many of the properties of this K transport pathway in human RBCs are similar to those of the KCl cotransport described by Lauf in SRBCs.[7] Like human RBCs, high K sheep reticulocytes have a volume- and chloride-dependent pathway that is then inactivated in mature cells.[13] This pathway is present in all density fractions of low K SRBCs. Volume regulation through this pathway has been recently demonstrated in sheep reticulocytes.[14] In both human (SS and AA) and LK SRBCs, inhibition of K transport is produced not only by internal Mg, but also by other divalent cations, such as Ca and Mn. In both LK SRBCs and SS cells, Mn seems to be the most potent inhibitor, since complete inhibition of K efflux is achieved with internal Mn concentrations below 150 μmol/L.

Mg has also some important effects on other cation transport systems in RBCs: its presence is required for the activity of the Na-K ATPase,[15] of the Ca-ATPase,[16] and of the Ca-activated K channel.[17] External (but not internal) Mg has a marked inhibitory effect on the Na and K fluxes mediated by the bumetanide-sensitive Na-K-Cl cotransport.[18]

The Mg effect and other properties differentiate the K transport system we describe here from the deoxygenation-induced fluxes of SS cells. The volume-, pH-, and chloride-dependent K movement that we have described in carbonmonoxide treated SS cells (and in CC and AA cells) is inhibited by cell Mg, is insensitive to DIDS (4,4′-diisothiocyanostilbene-2,2′ disulforic acid), is not associated with an increased Na influx, and markedly decreases cell volume.[2-4] Preliminary reports also suggest that chloride-dependent K movement is inhibited when SS cells are deoxygenated.[19]

The deoxygenation-induced K movement in SS cells is chloride-independent[20] and partially inhibited by DIDS,[21] is associated with a marked increase of the Na permeability,[20,21] and does not produce changes in cell volume.[20] Deoxygenation of SS cells induces a marked increase of K and Na permeabilities and also of the internal free Mg concentration.[22] These findings seem to indicate that the deoxygenation-induced Na and K fluxes move through transport pathways different from the system we describe and are mediated instead by pathways that are influenced by membrane stretching.[23]

Mg is known to have important biologic regulatory functions.[24] In human RBCs, the total cell Mg content is 2 to 3 mmol/L/cell (3 to 4 mmol/kg/cell water) and the free Mg concentration is 0.3 to 0.4 mmol/kg/cell water.[10,25] ATP and other nucleotides are the most important RBC buffer system for Mg,[10] and only a small fraction of Mg is bound to cell proteins or 2,-3-DPG. Total RBC Mg content is elevated in the least dense fraction of normal RBCs and decreases as cell density increases.[26] Because the least dense fraction contains the youngest circulating RBCs, this observation could partially explain previous reports of elevated RBC Mg in sickle cell anemia and in other anemias characterized by marked reduction of RBC life span.[27,28] Preliminary reports on total Mg content of density-separated SS cells suggest that the total Mg content is lower in irreversibly sickled cells.[29] Clearly, future measurements of both, total and free RBC Mg contents, will have to be performed in SS erythrocytes separated according to density. The ratio of free to bound Mg in RBCs is markedly affected by the state of oxygenation of hemoglobin. Upon deoxygenation, ATP binds to deoxyhemoglobin, releasing Mg, and the free Mg concentration markedly increases.[22] One study reported that the K and Mg concentrations in normal erythrocytes (and lymphocytes) are positively correlated, so that cells with a higher Mg concentration tend to have a higher K concentration and therefore a higher water content.[30]

Genetic factors play an important role in determining the erythrocyte Mg content.[31] Because the Mg content is genetically determined, and since Mg has such an important effect on cell volume and K transport, it is possible that the genetic regulation of cell Mg is one of the "additional" genetic modulators of sickle cell disease.[32]

ACKNOWLEDGMENT

We are indebted to Dr Lillian McMahon of the Boston Sickle Cell Center for kindly providing patients for our study. We thank Dr H. Franklin Bunn for his support, advice, and criticism.

Refinement of Lymphoma Cytogenetics by the Chromosome 18q21 Major Breakpoint Region

By Edward Lipford, John J. Wright, Walter Urba, J. Whang-Peng, Ilan R. Kirsch, Mark Raffeld, Jeffrey Cossman, Dan L. Longo, Ajay Bakhshi, and Stanley J. Korsmeyer

A small (2.8-kilobase, kb) major breakpoint region localized to segment 18q21 rearranges in $>$70% of t(14;18)(q32;q21) lymphomas. This rearrangement interrupts the *Bcl*-2 gene and introduces it into the Ig locus at 14q32. The rearrangement between the joining region (J_H) of Ig on chromosome 14 and the 18q21 region creates a translocation-specific DNA rearrangement. We generated probes that distinguish the 14;18 juncture on the derivative (der) 14 and der (18) chromosomes, providing a molecular approach to t(14;18) identification. Approximately 60% of unselected follicular lymphomas, 20% of diffuse large cell lymphomas, and 50% of adult undifferentiated non-Burkitt lymphomas demonstrated 14;18 rearrangements within the major breakpoint region. Examination of DNA for 14;18 rearrangements resolved the identity of 14q+ chromosomes in two patient's cells that lacked an obvious reciprocal partner. Identification of the exact restriction fragments that mediate translocations complements routine cytogenetics. The detection of DNA rearrangements does not require dividing cells or the presence of an identifiable reciprocal partner and can detect clonal translocation rearrangements when the neoplastic cells are only a minority of all cells present.

SPECIFIC CHROMOSOMAL translocations occur in a wide variety of neoplasms, suggesting that these rearrangements may play a direct role in tumor pathogenesis. Moreover, particular types of neoplasms possess a unique or highly associated translocation.[1,2] These findings generated the thesis that genes could be identified flanking these breakpoints and would participate in transformation.[3] Human lymphoid neoplasms are proving a fruitful model to examine this postulate. The phenotypic landmark genes of Ig and the T cell receptors within B and T cell tumors, respectively, have proven to be the sites of interchromosomal recombinations.[4-6] Established c-*onc* genes or putative transforming genes have been identified at the far side of these breakpoints.[7-15]

We and other researchers previously cloned the chromosomal breakpoint on the der (14) chromosome of the t(14;18)(q32;q21) that is found in $\sim$80% of follicular B cell lymphomas.[10-12] Analysis of the der (14) revealed that a new gene, *Bcl*-2, from chromosome segment 18q21 moved into the immunoglobulin (Ig) locus at the 5′ end of joining (J_H) regions.[10-17] In contrast, we noted that diversity (D_H) regions of Ig mediated the juncture with 18q21 on der (18) chromosomes.[17] This argues that the t(14;18) occurs early in development at the first step of Ig gene rearrangement when a pre-B cell is attempting a D_H to J_H rearrangement.[17] We also noted that a small 2.8-kb major breakpoint region (mbr) on chromosome segment 18q21 was the site of rearrangement in $>$70% of the t(14;18) lymphomas.[17] Consequently, we prepared probes that identify the sites of 14;18 chromosomal juncture on the der (14), as well as the der (18) reciprocal partner. Because the t(14;18)(q32;q21) translocation is the most common translocation found in human lymphomas[18,19] and since a high percentage (70%) of these can be detected by gene rearrangement, we used this molecular marker of translocation to approach unresolved issues in lymphoma cytogenetics. Karyotypic analysis of lymphomas can sometimes result in an indeterminant classification of 14q+; in some series, this classification was $\sim$20% of cases.[20,21] This occurs because a der (14) chromosome is obvious but no certain reciprocal partner can be identified. Many of these 14q+ chromosomes appear to break at 14q32. In this study, we used 14;18 gene rearrangement to demonstrate that 14q+ lymphomas can be typical t(14;18) translocations.

MATERIALS AND METHODS

Isolation and analysis of DNA. High-mol-wt DNA was isolated directly from lymph node biopsies, from cells teased free from such biopsies, or from cell lines. Nuclei were first prepared by lysing cells in 0.25% Triton X-100, 0.25 mol/L sucrose, 50 mmol/L Tris (pH 7.5), 25 mmol/L KCl, and 5 mmol/L MgCl$_2$ on ice. Nuclei were subsequently washed twice in the sucrose buffer without Triton X-100 and were resuspended in this buffer and 0.3/mg/mL proteinase K, 1% sodium dodecyl sulfate (SDS), and 15 mmol/L EDTA (tetrasodium, pH 7.5) was added for 3 hours at 37°C. Samples were extracted with phenolchloroform until clean; the DNA was precipitated and samples were resuspended in 10 mmol/L Tris and 0.1 mmol/L EDTA. These genomic DNAs were digested to completion with *Hind*III or *Bam*HI restriction endonuclease, size-fractionated over agarose gels by electrophoresis, and transferred to nitrocellulose paper.[22] Purified cloned DNA restriction fragments were radiolabeled with ^{32}P by random hexanucleotide priming for use as probes.[23] Genomic blots were hybridized to ^{32}P probes with specific activities of 1 to 5 $\times$ 10^8 cpm/μg in 10% dextran sulfate, 40% or 50% formamide, 4$\times$ SSC, 1$\times$ Denhart's solution, and 10 μg/mL salmon sperm DNA. Blots were washed three times in 2$\times$ SSC, 0.1% SDS at room temperature, and twice in 0.1$\times$ SSC, 0.1% SDS at 50°C, and autoradiography was performed.

Preparation of probes. Genomic DNA probes from the mbr of chromosome segment 18q21 involved in the t(14;18)(q32;q21) translocation were constructed (Fig 1A). A 1.5-kb *Hind*III-*Eco*RI

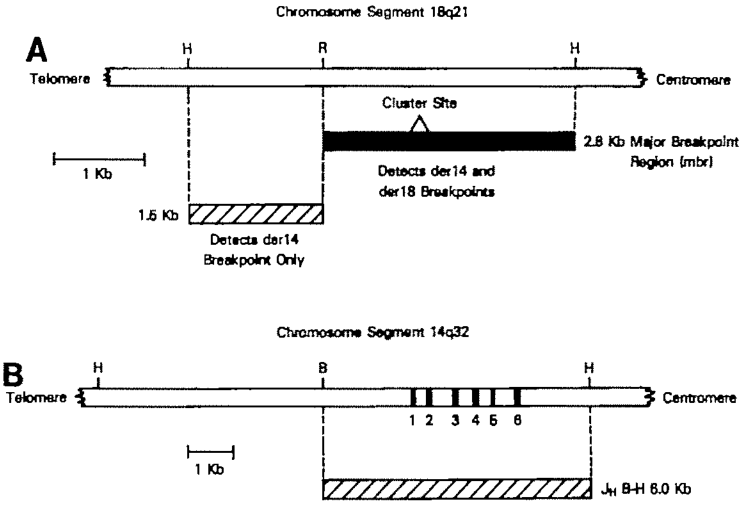

Fig 1. (A) Chromosomal orientation of the 4.3-kb *Hin*dIII genomic region of 18q21 where most t(14;18) breakpoints occur. These chromosomal breakpoints cluster within a small 150-bp region of the 2.8-kb *Eco*RI-*Hin*dIII major breakpoint region (mbr). When used as a probe, this 2.8-kb fragment recognizes the interchromosomal rearrangement on both the (der) 14 and (der) 18 breakpoints. In contrast, the telomeric 1.5-kb *Hin*dIII-*Eco*RI fragment detects the chromosomal breakpoint on only the (der) 14. (B) The 6.0-kb *Bam*HI-*Hin*dIII fragment containing the joining (J_H) segments used to detect rearrangements of the normal immunoglobulin heavy chain gene on chromosome 14 as well as the chromosomal breakpoint on the (der) 14.

fragment was initially isolated from the der (14) chromosomal breakpoint of cell line SU-DHL-6.[11] A region flanking this fragment was previously shown to be of chromosome 18 origin by somatic cell hybrids.[17] We determined the exact chromosomal location of this 1.5-kb *Hin*dIII–*Eco*RI fragment that would be used as a probe. This fragment was subcloned into pBR327, nick-translated with ^{3}HdNTPs and used in chromosome in situ hybridization as previously described.[4] Analysis of 71 metaphases from phytohemagglutinin (PHA)-stimulated lymphoblasts of a normal male revealed that 8.5% of all grains (14 of 165) were located on the long arm of chromosome 18 at band q21 (Fig 2). By Poisson analysis, the *Hin*dIII-*Eco*RI 1.5-kb probe was uniquely located at band 18q21 ($P \ll .05$). This probe was used to isolate a cosmid clone containing a 45-kb insert from the germline region of chromosome 18.[17] The entire 4.3-kb *Hin*dIII fragment containing the major site of rearrangement in t(14;18) lymphomas was subcloned from this cosmid isolate. A 2.8-kb *Eco*RI-*Hin*dIII fragment constitutes the centromeric portion and possesses the 150-base pair (bp) cluster site where most of these translocations focus (Fig 1A).[17] Consequently, this probe is capable of detecting the site of interchromosomal juncture on both the der (14) and der (18) reciprocal products in ~70% of t(14;18) translocations. In contrast, the 1.5-kb *Hin*dIII-*Eco*RI region lies telomeric to this breakpoint site and is translocated to the der (14) chromosome. Therefore, this 1.5-kb probe detects only the der (14) breakpoint rearrangement in *Hin*dIII-digested DNA. *Hin*dIII digests of lymphoma DNAs were comigrated on agarose gels with DNA from nontranslocated control sources of cells (fibroblasts, normal leukocytes), and Southern blots were hybridized with these two probes.

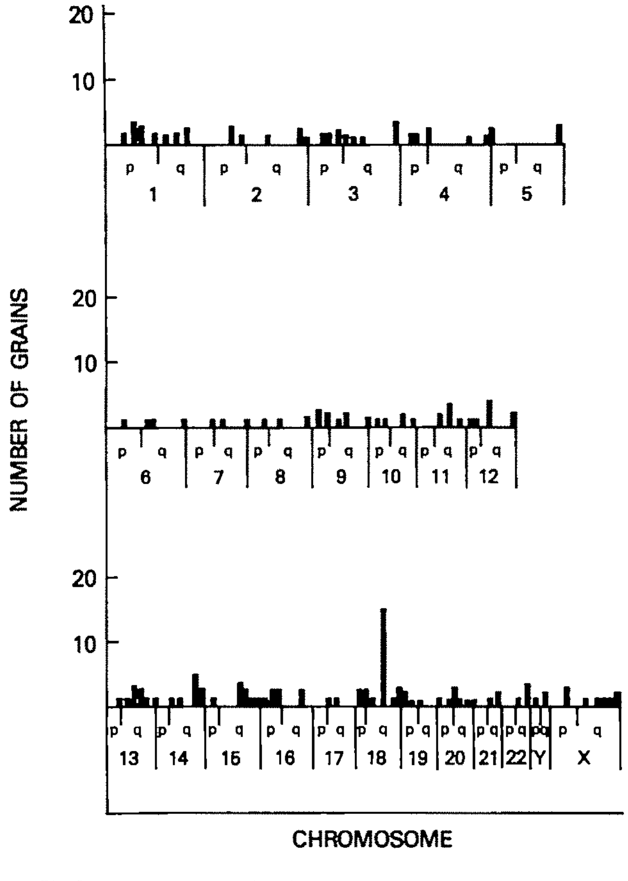

Fig 2. Bar graph of distribution of grains by chromosomal in situ. The *Hin*dIII-*Eco*RI 1.5-kb probe was localized to chromosome segment 18q21 with no other significant site of distribution.

The t(14;18)(q32;q21) breakpoints are also clustered on chromosome 14, occurring at the 5′ end of immunoglobulin joining (J_H) subsegments.[10-12,16,17] Therefore, we used a 6.0-kb *Bam*HI-*Hin*dIII probe containing the J_H region that recognized an 11.0-kb *Hin*dIII fragment in its germline form (Fig 1B).[24] This probe detects both the rearranged V/D/J allele residing on the normal chromosome 14 as well as the site of chromosomal juncture on the der (14) chromosome. These two J_H rearrangements can be discriminated by hybridizing the J_H probe and the chromosome 18 *Hin*dIII-*Eco*RI 1.5-kb probe to comigrated *Hin*dIII-digested lymphoma DNA. A single rearranged *Hin*dIII fragment containing the site of 14;18 juncture will hybridize to both probes (Fig 1).

RESULTS

A 14q+ lymphoma is a t(14;18) by rearrangement of the major breakpoint region. Lymphoma case 731, a diffuse large cell lymphoma, possessed a karyotype with a 14q+ chromosome but no obvious reciprocal partner in all 18 metaphases examined (Fig 3). Two normal chromosome 18s were noted, and no candidate for a der (18) was observed. Despite this, Southern blot analysis with the chromosome 18q21 origin *Hin*dIII-*Eco*RI 1.5-kb probe and the J_H probe from 14q32 demonstrated a 14;18 rearrangement (Fig 4). Comigration of *Hin*dIII-digested DNA from case 731

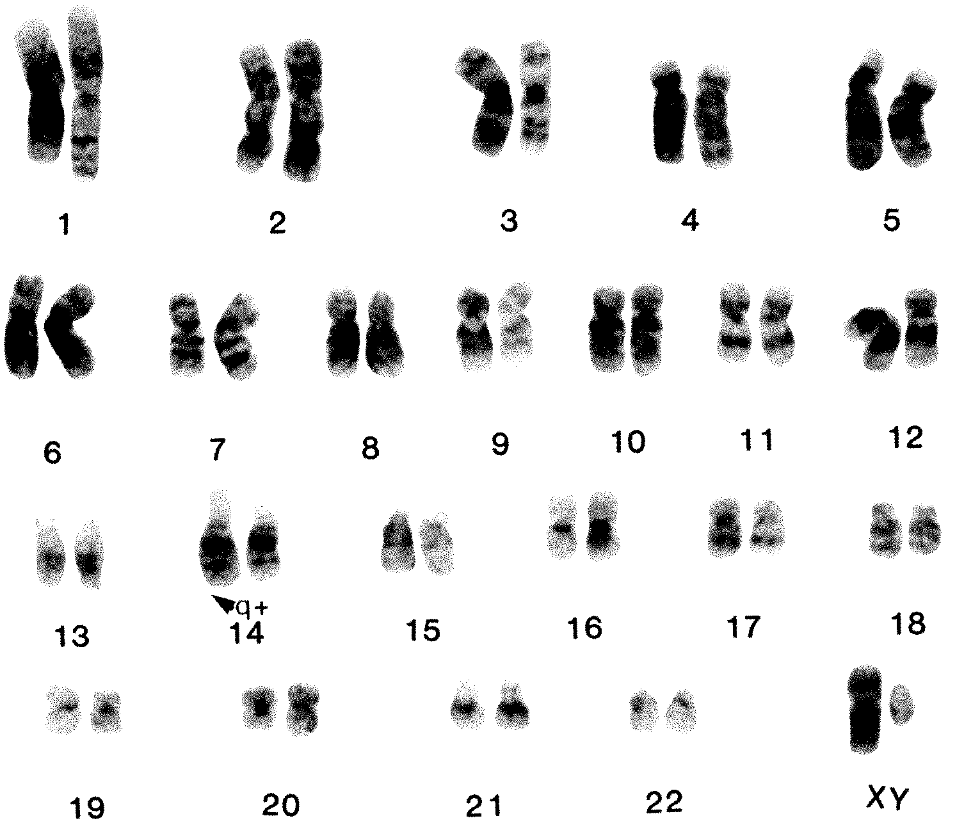

Fig 3. Cytogenetic analysis of lymphoma case 731 revealed a 14q+ chromosome with no obvious reciprocal partner.

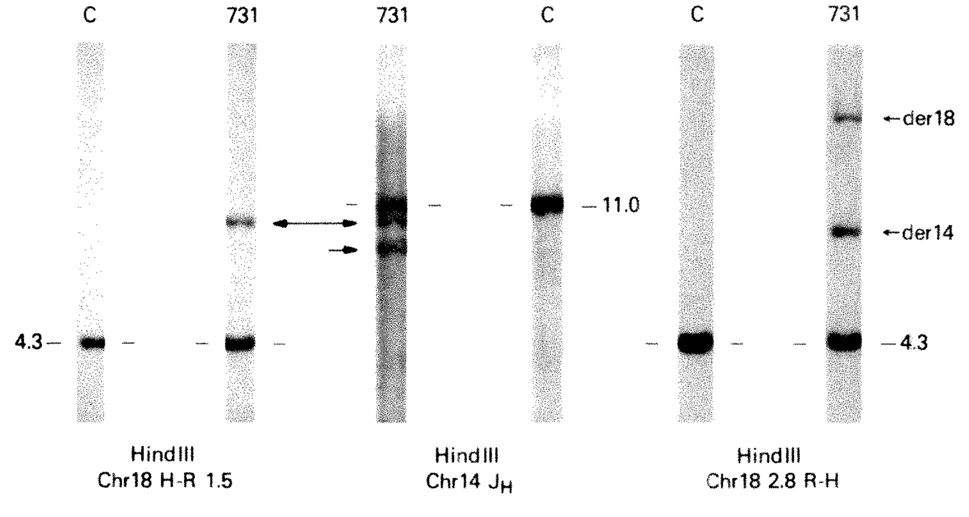
revealed a single rearranged fragment that hybridized with both the chromosome 14 and 18 probes (Fig 4). This could also be demonstrated in *Bam*HI-digested DNA, in which a rearranged fragment possessed both J_H and chromosome 18 information (not shown). The 1.5-kb *Hind*III-*Eco*RI probe (Fig 1A) detected the site of 14;18 rearrangement on the der (14) in case 731 (Fig 4). We also used the 2.8-kb *Eco*RI-*Hind*III mbr as a probe (Fig 1A), and it detected sites of 14;18 rearrangement of both a der (14) and (18) chromosome (Fig 4). Although a der (18) chromosome was not seen in the available metaphases of case 731, molecular genetic examination proved that this reciprocal interchromosomal rearrangement was still present within some lymphoma cells.

Loss of the der (18) chromosome in a t(14;18) cell line. Another lymphoma provided the opportunity to observe the loss of a derivative chromosomal partner over time. A newly established cell line RL-7 was initiated from a diffuse undifferentiated (small noncleaved, non-Burkitt) lymphoma. Cytogenetic evaluation of the initial six metaphases after 30 days of culture indicated the presence of a 14q+ chromosome and two normal chromosome 18s without an obvious reciprocal partner (Fig 5). Southern blot analysis of this RL-7 cell line revealed a typical 14;18 der (14)

Fig 4. Genomic DNA from a lymph node biopsy of case 731 was digested with *Hind*III and comigrated on gels with a control (C) source of DNA with germline genes. Hybridization with the chromosome 18 *Hind*III-*Eco*RI 1.5-kb probe and the immunoglobulin J_H region reveals a common rearranged *Hind*III fragment identifying the (der) 14 chromosomal breakpoint (dual-headed arrow). The chromosome 18 *Eco*RI-*Hind*III 2.8-kb probe detects a (der) 18 as well as the (der) 14 breakpoint. Germline position of the 4.3-kb chromosome 18 region and the 11.0-kb immunoglobulin J_H region (--).



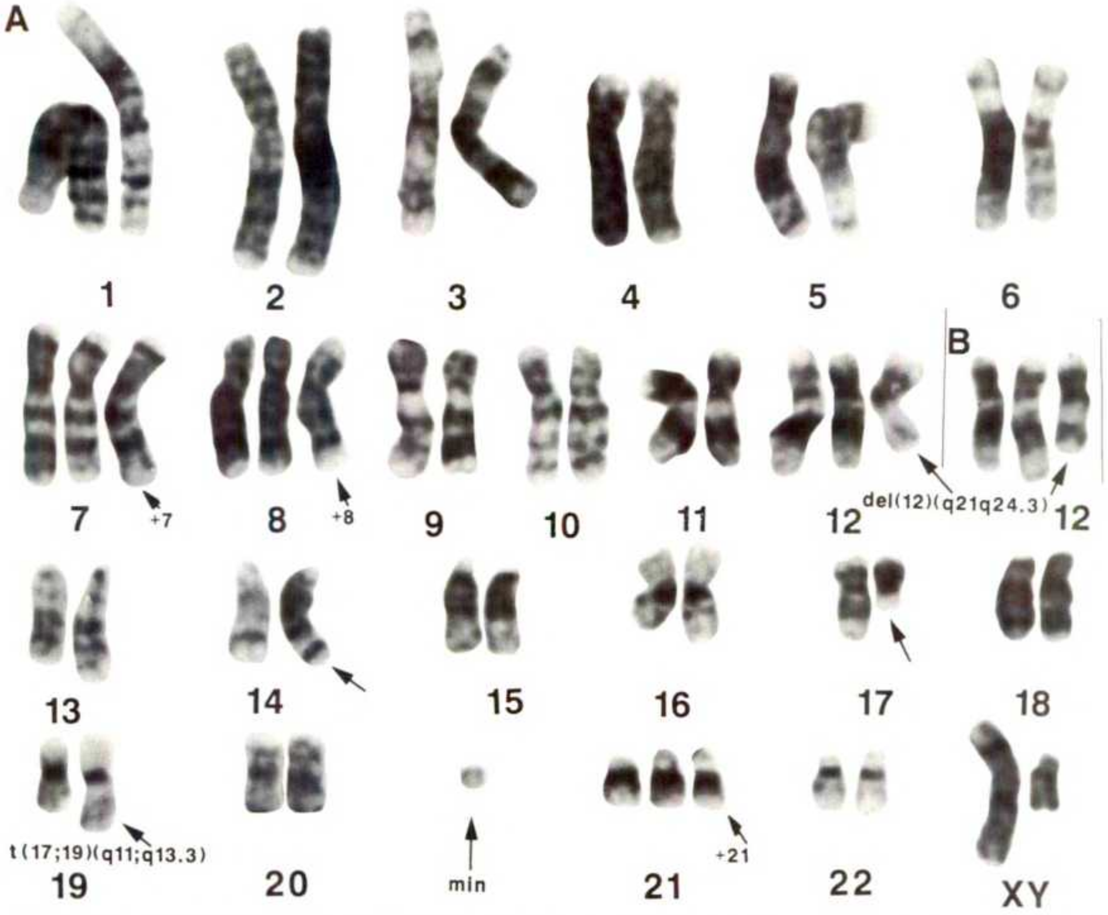


Fig 5. Cytogenetic analysis of lymphoma cell line RL-7 at day 30 revealed a 14q+ chromosome but no obvious reciprocal partner. Numerous other cytogenetic abnormalities were present, but two normal chromosome 18s were observed: A complete G-banded karyotype from cell A and a partial karyotype from cell B. Cell A had 51 chromosomes: 51, XY, +7, +8, +21, +del (12) (q21q24.3), 14q+, t(17;19) (q11; q13.3), +min. Cell B: partial karyotype showed normal 12 and the deleted 12.

chromosomal rearrangement (Fig 6). The identical rearrangement of the der (14) breakpoint and of the normal chromosome 14 Ig gene was present in the fresh lymphoma cells obtained from ascites as well as the cell line (Fig 6). Thus, the original lymphoma in vivo and the in vitro cell line were identical with respect to their t(14;18) translocation. Cytogenetic analysis of the original ascites lymphoma cells revealed the presence of a der (18) chromosome together with two normal chromosome 18s (Fig 7). Therefore, this lymphoma appeared to undergo a process of clonal evolution in which the normal chromosome 18 was duplicated and the der (18) was lost. This prompted a more extensive cytogenetic examination of metaphases from the RL-7 cell line at various time points after establishment. Table 1 shows that all 20 metaphases of the original in vivo lymphoma cells from ascites had a der (18) and two normal chromosome 18s. In contrast, the der (18) appears to be progressively lost over time in the RL-7 cell line. At day 1 and 2 of culture, all metaphases possessed a der (18) chromosome, whereas by 1 month <50% had a der (18) (Table 1).

Unaltered breakpoint rearrangement during histologic progression from follicular to diffuse lymphoma. Molecular analysis of the ascites cells (A 1431) and the RL-7 cell line revealed the presence of some der (18) type rearrangements (Fig 8), as would be predicted by the more extensive cytogenetic analysis. The identical der (14) as well as der (18) breakpoint rearrangements were present in the diffuse undifferentiated cells of the A1431 ascites and the RL-7 cell line. Moreover, lymph node biopsy (658) performed 5 years earlier exhibited a follicular (mixed small and large cell) histology yet also possessed the identical der (14) and der (18) rearrangements (Fig 8). Thus, the histologic progression from follicular to a diffuse undifferentiated lymphoma occurred in the same neoplasm. In addition, this progression to a more aggressive lymphoma was not associated with any further rearrangement of either chromosomal breakpoint (Fig 8). Lymph node biopsy 658 illustrates the sensitivity of the gene rearrangement approach in detecting clonal translocation rearrangements even when the neoplastic cells are a minority of all cells present (Fig 8).

18q21 major breakpoint region (mbr) rearrangements in nonfollicular lymphoma. The 18q21 major breakpoint region (mbr) rearranges and thus contains the chromosomal breakpoint in ~60% (11 of 17) of unselected follicular lymphomas we have examined in this and prior studies.[11] By extrapolation, this argues that >70% of follicular lympho-

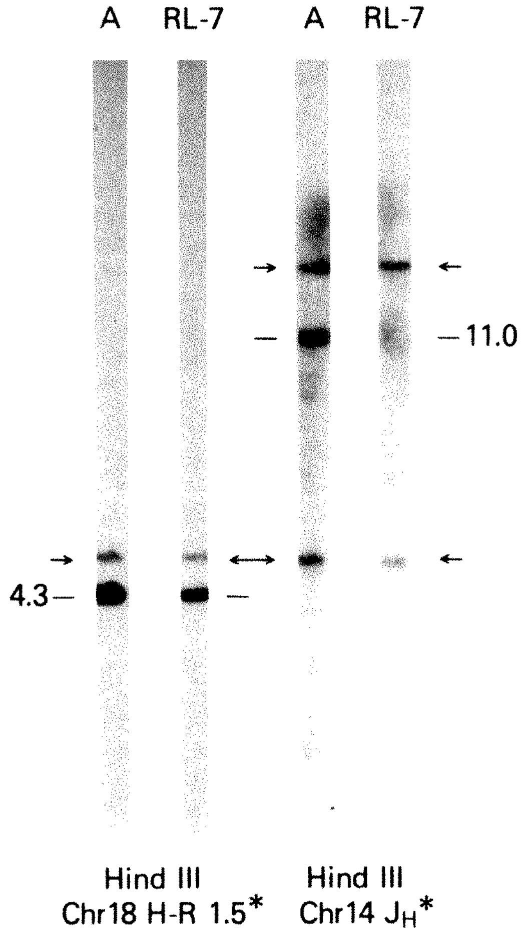

Fig 6. Genomic DNA from the original ascites cells of lymphoma case 1431 (A) was compared with the established cell line (RL-7). A single rearranged *HindIII* fragment hybridized to both the chromosome 18 and chromosome 14 probes and identified the 14;18 juncture on the (der) 14 (dual-headed arrow). Germline-sized *HindIII* restriction fragments (--). The larger sized rearrangement detected by the J_H probe (single-headed arrows) results from the V/D/J on the normal chromosome 14.

mas that actually possess a t(14;18) translocation by cytogenetics cluster their breakpoints within this region. Follicular lymphomas can progress over time to more aggressive neoplasms of diffuse large or undifferentiated cell types.[25] We wished to estimate the incidence of 18q21 mbr rearrangement within lymphomas not of follicular type. Within diffuse large cell lymphomas, 4 of 20 (20%) demonstrated a rearrangement within the mbr (Table 2). Adult undifferentiated (small, noncleaved) non-Burkitt lymphoma represents a histologic subset of diffuse aggressive lymphomas.[26] The features that are believed to distinguish these undifferentiated lymphomas from Burkitt lymphoma are an increased variation in the size of nuclei and the prominence of nucleoli. Adult undifferentiated non-Burkitt lymphomas are almost always of B cell type. They are usually diffuse, but nodular patterns have been noted, suggesting that they might be of follicular center cell origin.[27] Four of eight (50%) examined revealed a 14;18 rearrangement (Table 2). Only one of these cases represented a known histologic progression from prior follicular lymphoma (case 1431).

DISCUSSION

The presence of unique or highly associated chromosomal translocations in distinct types of neoplasms implies that their breakpoint regions are near genes contributing to neoplasia.[3] These characteristic translocations can often be discerned by routine cytogenetic analysis of metaphase spreads with the aid of banding techniques. The accuracy and efficiency of cytogenetics has improved considerably in recent years such that definitive chromosomal analysis is possible in most cases of non-Hodgkin's lymphoma. Even these techniques, however, are not uniformly successful in determining the precise nature of the interchromosomal partners, as the 14q+ lymphomas illustrated in this study. Instances of unresolved karyotypes often reflect the limitations inherent in cytogenetic techniques.

We used the well-circumscribed chromosomal breakpoint within the Ig J_H region on chromosome 14 and a defined 2.8-kb mbr on chromosome 18 to demonstrate t(14;18) translocations in lymphomas with unresolved cytogenetic assignments. Because most of these breakpoints cluster within a very small 150-bp region of 18q21, we were able to construct probes capable of discriminating the site of interchromosomal rearrangement on the der (14) *v* the der (18) chromosome (Fig 1). This capability provides the opportunity to follow the natural history of these two reciprocal partners throughout the course of lymphomas. In case 731, only 18 metaphases could be obtained; all of these demonstrated a 14q+, but no obvious reciprocal partner was present. Gene rearrangement studies proved this to be a juncture with 18q21 on the der (14), however, and demonstrated the presence of der (18) type rearrangements within the lymphoma biopsy tissue. This indicates that the der (18) chromosome was present only in a subpopulation of cells or that, alternatively, this juncture site was buried within an unrecognized complex translocation. The A1431 lymphoma and its cell line (RL-7) provided the opportunity to document an evolution of the chromosomal pattern over time. The initial uncertainty in cytogenetic classification of the RL-7 cell line resulted from a duplication of the normal chromosome 18 and the loss of the der (18). The t(14;18) results in the movement of the *Bcl*-2 gene from 18q21 to the der (14). Thus, the duplication of a normal chromosome 18 would result in a copy number of 3 for *Bcl*-2. Using a discriminatory S_1 protection assay, we determined, however, that only the translocated *Bcl*-2-Ig fusion product is transcribed whereas the *Bcl*-2 gene on the normal chromosome 18 is suppressed.[15] Perhaps this particular der (18) chromosome was mitotically unstable and simply prone to nondisjunctional loss. Prior examples of the duplication of normal chromosome 18, the presence of unpaired der (14)s, as well as duplication of the der (18) have been noted.[18-21] Both cases studied here illustrate that in many situations it may prove to be more efficient and conclusive to demonstrate the presence of a specific gene rearrangement than to be dependent on the availability of larger numbers of metaphases.

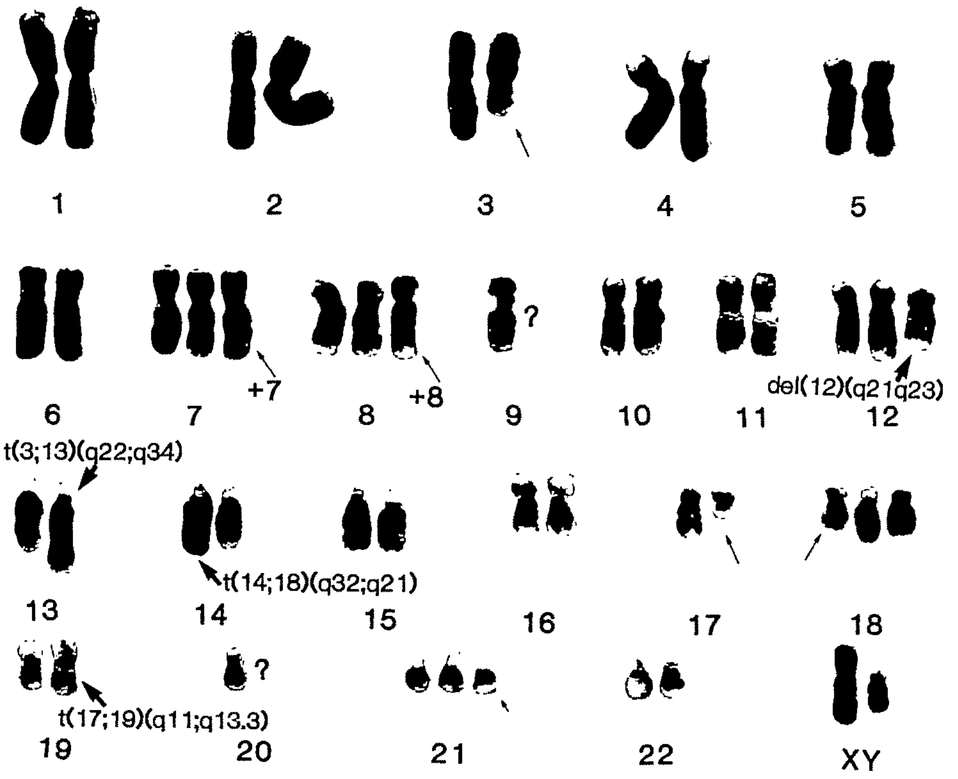

Fig 7. Cytogenetic analysis of fresh lymphoma ascites cells of case 1431 revealed the presence of a t(14;18)(q32;q21) with an 18q− as well as a 14q+ chromosome. In addition, two normal chromosome 18s were present.

The t(14;18) translocation is most highly associated with follicular lymphomas in which perhaps 85% of the small cleaved cell type bear the translocation.[18,19] Curiously, structural analysis of the t(14;18) breakpoint indicates that it occurs at a pre-B cell stage of development despite the mature B cell phenotype of the ultimate lymphoma. Moreover, follicular lymphomas followed over time may progress to diffuse large cell histology in up to 40% of instances.[28] We found typical 14;18 rearrangements in ~20% of the diffuse large cell lymphomas examined (Table 2). This is a lower incidence than in unselected follicular lymphomas (60%), suggesting that many diffuse large cell lymphomas do not arise from prior follicular center cell based lymphomas. Other histologic entities, including immunoblastic lymphoma (Table 2), chronic lymphocytic leukemia, pre-B cell acute lymphoblastic leukemia, and Burkitt lymphoma lacked 14;18 rearrangements.[11] In contrast, many of the adult undifferentiated non-Burkitt lymphomas demonstrated 18q21 mbr rearrangements, supporting previous speculation that this entity may often have a follicular center cell origin.

Table 1. Cytogenetic Characterization of Original Lymphoma and Cell Line

Source of Cells	Time (No. of Metaphases)	Chromosome 14 and 18 Findings
Ascites cells (No. 1431)	(20)	20: der (14), der (18), two normal 18s
RL-7 cell line	Day 1 (6)	5: der (14), der (18), two normal 18s 1: der (14), der (18), one normal 18
	Day 2 (2)	2: der (14), der (18), two normal 18s
	Day 5 (9)	8: der (14), der (18), two normal 18s 1: der (14), two normal 18s, no der (18)
	Day 30 (16)	7: der (14), der (18), two normal 18s 9: der (14), two normal 18s, no der (18)

Thus, use of a single probe from the mbr at 18q21 can detect the breakpoint rearrangement in >70% of t(14;18) follicular lymphomas as well as in some diffuse lymphomas. Southern blot detection of translocation rearrangements is capable of complementing and refining routine cytogenetics in several settings. Definitive DNA breakpoint rearrangements do not require the presence of an obvious reciprocal chromosomal partner, do not require the lymphoma cell to be dividing, and can detect translocated cells even if they comprise but 1% to 5% of all cells present. In addition, the remaining 30% of t(14;18) rearrangements will also be definable by using the cloned genomic regions that encompass and flank the 5′ and 3′ ends of the *Bcl*-2 locus.[29-31] Indeed, a restricted minor breakpoint region may exist at the 3′ end of this gene.[29] Molecular recognition of variant breakpoint sites will be considerably enhanced by use of additional technologies. This includes pulsed-field gel electrophoresis, in which it is possible to detect chromosomal rearrangements even if the breakpoint falls several hundred kilobases beyond the classic region.[32,33] Moreover, chromosomal in situ hybridization as shown in Fig 2 can be performed directly on tumor cells and demonstrate definitive

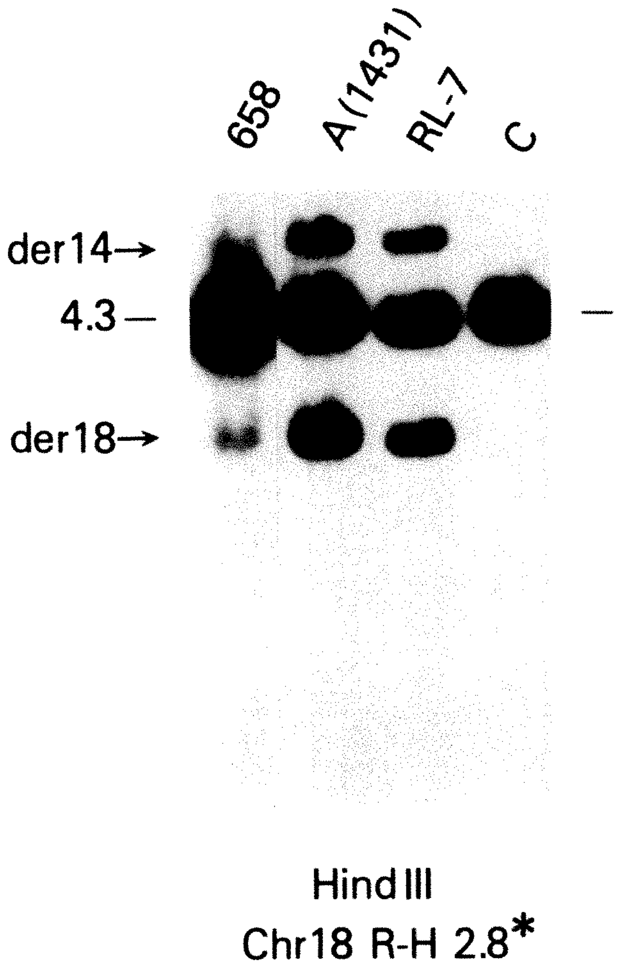

Fig 8. *EcoRI-HindIII* 2.8-kb major breakpoint region probe detects the presence of (der) 18 as well as (der) 14 chromosomal rearrangement sites (arrows). The 4.3-kb germline chromosome 18 region was present (--) on the normal allele and within admixed nonlymphoma cells. The identical (der) 14 and (der) 18 rearrangements were present in the diffuse undifferentiated cells of the ascites A(1431) and cell line (RL-7) as well as the preceding follicular lymphoma (658).

Influence of Hydroxyurea on Fetal Hemoglobin Production In Vitro

By Barbara A. Miller, Orah Platt, Sandra Hope, George Dover, and David G. Nathan

Cytotoxic drugs increase circulating fetal hemoglobin levels. We examined the mechanism by measuring the fetal hemoglobin produced per BFU-E–derived erythroblast following hydroxyurea treatment in vivo and in vitro. Treatment of four sickle cell patients increased the percentage of circulating F reticulocytes. The frequencies of bone marrow or peripheral blood BFU-E or CFU-E–derived colonies and their fetal hemoglobin content were unaffected. In all cases, the number of erythroid cells/progenitor-derived colony increased. To explore further the effect of hydroxyurea on fetal hemoglobin production, we added 50 µmol/L hydroxyurea to cultures of peripheral blood BFU-E–derived erythroblasts on 1 of 9 days (day 5 through 13) to nine samples. These BFU-E were derived from the peripheral blood of normal donors, sickle trait donors, and sickle cell anemia patients and from the bone marrows of monkeys. This concentration of hydroxyurea was selected so that the frequency of BFU-E and their size was moderately decreased. Addition of hydroxyurea to these progenitor-derived erythroid cells had no effect on fetal hemoglobin content per cell. Neither did transient exposure of progenitors to hydroxyurea prior to culture in nontoxic concentrations (0 to 500 µmol/L) result in a significant increase in fetal hemoglobin content in progenitor-derived erythroblasts. These data suggest that hydroxyurea does not directly alter the HbF program expressed by progenitor-derived erythroid cells. Instead, it enhances hemoglobin F content secondarily, possibly by inducing alterations in erythropoiesis.

CELL CYCLE-dependent cytotoxic drugs recently have been shown to increase fetal hemoglobin (HbF) levels in non-human primates and in humans. When administered at appropriate doses and schedules, both S and M phase-specific agents have this capability.[1-7] Clinical studies of these drugs suggest that they may be useful in the treatment of certain patients with sickle cell anemia.[3,6] 5-Azacytidine (5-Aza) was the first S phase-specific agent to be studied.[2,3] The mechanism of its HbF-enhancing effect was believed to be related to its capacity to demethylate putative promotor regions of γ globin genes, which in turn stimulate γ globin expression.[2,3] Our experience with hydroxyurea indicated that hypomethylation immediately 5′ to γ genes may be a secondary effect of such drugs.[6] Other mechanisms of action have since been proposed: cytoreduction and rapid recruitment of erythroblasts directly from progenitors with higher fetal hemoglobin programs,[7-9] and direct induction of downstream maturation of progenitor cells.[8] Studies of baboons treated with 5-Aza and of monkeys with 5-Aza, hydroxyurea, and vinblastine support the cytoreduction hypothesis.[7,8] Clinical studies with 5-Aza and hydroxyurea suggest a complex action, due at least in part to a direct nontoxic effect on progenitors and precursors.[6,10]

We report measurements of BFU-E–derived erythroblast fetal hemoglobin content in four patients with sickle cell anemia (SCA) treated with hydroxyurea. In addition, hydroxyurea was added to cultures of peripheral blood BFU-E–derived erythroblasts to determine whether a direct effect on fetal hemoglobin production could be demonstrated. Two of these patients had previously responded to hydroxyurea in vivo.[6] No direct effect of hydroxyurea on fetal hemoglobin synthesis in BFU-E–derived erythroblasts was demonstrated in vitro, but treatment with hydroxyurea in vivo stimulated individual erythroid progenitors to form larger colonies of erythroid precursors in vitro.

These results demonstrate that hydroxyurea does not directly alter the HbF program established in erythroid progenitors or erythroid precursors derived from progenitors. It appears, instead, to exert its HbF stimulatory effect by its effect on erythropoiesis.

MATERIALS AND METHODS

Bone marrow and peripheral blood samples. Patients 1 through 4 had sickle cell disease with protracted painful crises and were treated, after informed consent, with a 3-day (patients 3, 4) or 5-day (patients 1, 2) course of hydroxyurea at 50 mg/kg/day divided into three oral doses. All patients had normal renal function as measured by serum creatinine, BUN, and creatinine clearance, but these measurements do not imply that the patients cleared the administered hydroxyurea at a rate similar to that of normal subjects. Results of treatment of patients 1 and 2 were previously reported.[6] Bone marrow and peripheral blood samples were drawn in preservative-free heparin or acid-citrate-dextrose (ACD) for assessment prior to treatment and 18 to 72 hours following completion of hydroxyurea therapy.

Peripheral blood samples were also obtained from normal AA volunteers, an AS parent, and from SCA patients aged >3 years who were not transfused within 6 months, and had no painful crisis within 7 days. Bone marrow samples were also obtained from two normal *M. fasicularis* monkeys who had not been bled or treated previously with any cytotoxic drugs.

Informed consent was obtained within institutional guidelines prior to treatment and procurement of blood and bone marrow samples. Simian marrow samples were obtained with the kind assistance of Dr Norman Letvin, under the guidance of the Commit-

tee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources.[11]

Analysis of percentage of F reticulocytes and percentage of HbF in peripheral blood. Analysis of percentage F reticulocytes in the peripheral blood of SCA patients was performed as previously described.[12] Analysis of percentage of HbF in the peripheral blood was performed by the alkali denaturation technique.

Methyl cellulose culture of peripheral blood and bone marrow mononuclear cells. Blood and marrow samples were diluted with tissue culture medium (Iscove's modified Dulbecco's medium, IMDM), layered over Ficoll-Hypaque (Pharmacia, Piscataway, NJ) and centrifuged for 20 minutes at 2,200 rpm at 18°C. The cells at the interface were collected, washed, and plated at 1 to 2 × 10^5 cells/mL in 35-mm Petri dishes (Falcon) in a mixture containing 0.9% methylcellulose, 30% fetal calf serum (FCS, Gibco, Grand Island, NY), 9.0 mg/mL deionized bovine serum albumin (BSA, Sigma, St Louis, fraction V), 1.4 × 10^{-4} mol/L β-mercaptoethanol, 5% Mo cell line-conditioned medium as a source of BPA (generously provided by Dr David Golde) and with 2.0 U/mL crude erythropoietin (Toyobo) in IMDM. The plates were incubated in humidified 4% CO_2 at 37°C for 7 and 14 days.

The frequency of bone marrow CFU-E (7-day culture) and BFU-E (14-day culture) and of peripheral blood BFU-E–derived colonies/1 × 10^5 cells was assessed in patients who had been treated in vivo with hydroxyurea. The number of cells per erythroid colony, the picograms of fetal and total hemoglobin, and the percentage of fetal hemoglobin per progenitor-derived cell were also measured. Approximately 50 to 100 progenitor-derived colonies were plucked per sample, an aliquot was counted, and the average number of erythroid cells per colony was determined. When samples were plucked in duplicate or triplicate, the mean number of cells per colony ±1 SD was determined. Statistical significance of changes noted following treatment was determined with Student's paired *t* test.

Hydroxyurea (Squibb, Princeton, NJ, 97.6% pure) was added to erythroid culture dishes on days 3 through 13 following initiation of cultures derived from normal controls, AS controls, patients with SCA, and two monkeys. The drug was brought to a final concentration of 0 to 100 μmol/L, added at only one time point per dish, and was allowed to remain in the dish until completion of the 14 days of culture. In a second group of experiments, samples were pretreated with 5 to 500 μmol/L hydroxyurea in IMDM with 20% FCS and 2 U/mL erythropoietin (Amgen, Thousand Oaks, CA) at 37°C for 18 hours, washed, and then cultured. The number of BFU-E–derived colonies, the number of cells per colony, and the hemoglobin content of BFU-E–derived erythroblasts were assessed at 14 days. In some experiments, 5-Aza was substituted for hydroxyurea at a final concentration of 0.01 mmol/L.

Radioligand assay of HbA and HbF. Erythroid colonies were "plucked" and counted. A precisely measured volume was transferred to a second tube and pelleted, and the pellet was resuspended in 0.5 mg/mL carrier sheep Hb (300 to 400 μL) containing 0.02% Na-azide. This suspension was sonicated, microcentrifuged, and stored at 4°C.

Radioligand assay of total or fetal hemoglobin in picogram per BFU-E–derived cell was performed as previously described.[13,14] Each sample was assayed in triplicate to determine picograms of fetal or total hemoglobin. The percentage of HbF in such cells was calculated from the mean picograms of fetal and total hemoglobin measurements.

RESULTS

Effect of in vivo hydroxyurea treatment on in vitro hemoglobin F production. All four SCA patients treated with a single course of hydroxyurea immediately responded with increased circulating F reticulocytes (shown in Table 1). This represented an absolute increase since neither total RBCs nor percentage of total reticulocytes were affected. In general, F reticulocyte levels peaked at 7 days, remained elevated for at least 14 days, and returned to baseline by 21 days after initiation of treatment. A significant change in circulating HbF was not observed in this brief treatment period. To determine the effect of this treatment on the capacity of bone marrow BFU-E and CFU-E and peripheral blood BFU-E to proliferate and to produce fetal hemoglobin in the erythroblasts to which they give rise, BFU-E–derived colonies were cultured from the marrow and peripheral blood of patients prior to the initiation of hydroxyurea treatment

and 18 to 72 hours following completion. Results are shown in Tables 1 and 2.

The effect of hydroxyurea treatment on the frequency of bone marrow and peripheral blood BFU-E–derived colonies 18 to 72 hours after cessation of treatment was variable, and statistically significant changes in colony number were not observed. In every case, however, the number of erythroid cells per BFU-E–derived colony increased following treatment (Table 1) and this change was statistically significant ($P < .05$). Despite the increase in the number of cells per BFU-E–derived colony and the wide range of HbF programs in the patients under study, the treatment failed to induce any change in fetal or total hemoglobin production per BFU-E–derived erythroid cell. Results of assessment of the influence of hydroxyurea treatment on proliferation and hemoglobin production in CFU-E–derived colonies are shown in Table 2. Again, no significant change in CFU-E–derived colony number was noted. CFU-E colony size was consistently larger after treatment, but results were not statistically significant ($P < .1$), possibly due to small sample size. No influence of treatment on the HbF program was expressed in progenitor-derived cells.

Influence of hydroxyurea on the hemoglobin F program in vitro. To assess the effect of hydroxyurea on the production of fetal hemoglobin by BFU-E–derived erythroblasts in vitro, 0, 1, 5, 25, 50, or 100 μmol/L hydroxyurea was added to culture dishes from SCA patients on day 7. Results of three experiments are shown in Table 3. Although colony number decreased with increasing hydroxyurea concentrations, no significant increase in fetal hemoglobin content was noted. The percentage of fetal hemoglobin decreased in two of these experiments following hydroxyurea addition, possibly because of a toxic effect since maximum fetal hemoglobin synthesis in culture occurs at this time period.[14] To determine whether the effect of hydroxyurea on hemoglobin synthesis is influenced by the stage of progenitor-derived cell maturation, the drug was added to peripheral blood BFU-E–derived cultures on days 3 through 13 of the culture period. It was added once to each dish and was not removed. A final concentration of 50 μmol/L was chosen because this dose reduced the number of BFU-E–derived colonies to 50% of control cultures when added on day 7, enough to demonstrate activity of hydroxyurea with a minimal cytotoxic effect. Addition of the drug at this concentration earlier than day 4 of culture resulted in significant inhibition of colony growth. Patients with a wide range of HbF programs were studied, including one AA adult, one AS parent, and five patients with SCA, three of them selected for their high HbF programs. Cultures of bone marrow BFU-E of two monkeys with elevated HbF programs were also studied. Results are shown in Fig 1. Despite addition of hydroxyurea on 9 different days of culture to nine samples with variable HbF

Effect of addition of 0 to 100 μmol/L hydroxyurea to day 7 BFU-E-derived colonies from the peripheral blood of three SCA patients.

*Number of BFU-E-derived colonies/1 × 10^5 peripheral blood mononuclear cells.

†Percentage of HbF in BFU-E-derived erythroblasts on day 14 calculated from measurement of picograms of total and fetal hemoglobin per cell by radioligand assay.

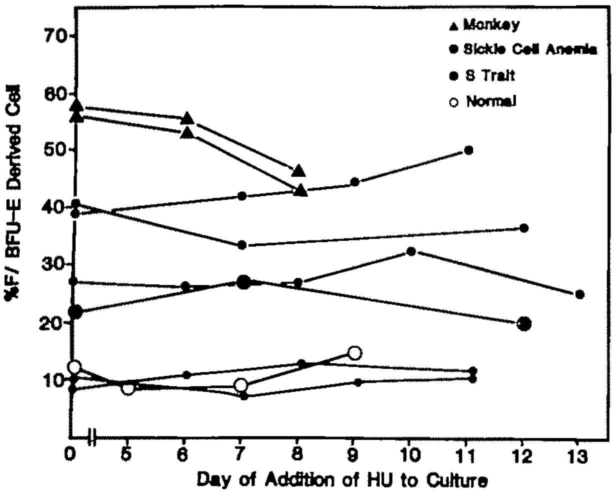

Fig 1. Influence of hydroxyurea on the HbF program in vitro. Percentage of hemoglobin F measured by radioligand assay in peripheral blood or bone marrow (monkey only) BFU-E–derived cells following addition of hydroxyurea at a final concentration of 50 μmol/L to methyl cellulose cultures on days 5 through 13. Day 0 indicates control cultures to which no hydroxyurea was added. Cultures were continued for 14 days, and assays were then performed.

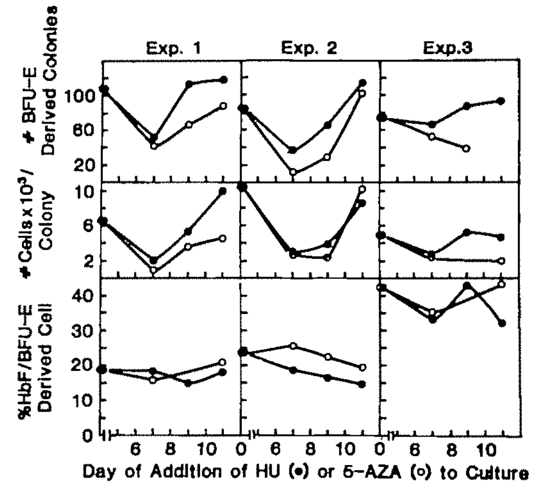

Fig 2. Influence of hydroxyurea and 5-Aza on peripheral blood BFU-E proliferation and fetal hemoglobin accumulation. Three patients were studied. The frequency of colonies (number/1 × 10^5 cells), the number of cells/BFU-E–derived colony, and percentage of fetal hemoglobin/BFU-E–derived cell were measured on day 14 following addition of 50 μmol/L hydroxyurea or 0.01 mmol/L 5-Aza to the cultures on days 4, 7, 9, or 11. Day 0 indicates control cultures to which no hydroxyurea was added. Shown are effects of the drugs on proliferation when added before day 12 of colony growth and lack of effect on HbF production.

programs, no significant effect of the drug on hemoglobin F production was detected.

The effect of a transient exposure to hydroxyurea was studied by pretreating progenitor cells with 0, 5, 50, 100, and 500 μmol/L hydroxyurea for 18 hours prior to culture. Results of three experiments are shown in Table 4. No change in colony number was observed following this short exposure despite the use of tenfold higher hydroxyurea concentrations than those used in continuous exposure experiments. No statistically significant increase in fetal hemoglobin content was observed, although small increases in fetal hemoglobin content were noted in some of the treatment groups.

Comparative influence of hydroxyurea and 5-Aza on peripheral blood BFU-E proliferation and hemoglobin synthesis. To compare the effect of hydroxyurea with that of 5-Aza on the BFU-E–derived erythroblast hemoglobin programs, three patients were studied in more detail. Hydroxyurea 50 μmol/L or 5-Aza 0.01 mmol/L was added to

Effect on hemoglobin F production by BFU-E–derived cells of pretreatment of peripheral blood mononuclear cells from three patients with SCA with 0 to 500 μmol/L hydroxyurea.

*Number of BFU-E–derived colonies/1 × 10^5 peripheral blood mononuclear cells.

cultures of the peripheral blood BFU-E of three SCA patients on days 4, 7, 9, or 11. The influences of these treatments on the number of BFU-E/1 × 10^5 cells, number of cells per BFU-E–derived colony, and the hemoglobin program expressed as percentage of fetal hemoglobin per BFU-E–derived cell were assessed; the results are shown in Fig 2. When added prior to or on day 4, colony growth was nearly obliterated and the effect on fetal hemoglobin synthesis could not be determined. The number of BFU-E–derived colonies and the number of cells per BFU-E–derived colony were decreased following addition of either cytotoxic drug to the cultures, demonstrating that both drugs were active. Despite this dramatic effect on progenitor proliferation, neither 5-Aza nor hydroxyurea influenced the percentage of fetal hemoglobin produced in the progenitor-derived erythroid cells. Neither drug significantly altered the picograms of fetal hemoglobin per cell in treated colonies, even in cultures with decreased cell proliferation (data not shown).

DISCUSSION

The mechanism by which cell cycle-specific cytotoxic drugs stimulate HbF and F cell production are not known. Two broad hypotheses have been explored. One is based on drug-induced modifications of DNA (such as hypomethylation of globin promoter regions)[2,3] and the other on cytokinetic considerations.[7,9] The two may be related. For example, we previously determined that changes in DNA methylation can occur as a result of administration of hydroxyurea as well as 5-Aza.[6] Hypomethylation and F cell production may both be secondary manifestations of drug-induced differentiation.

To study this complex problem, we evaluated the effects of in vivo treatment with hydroxyurea on BFU-E and CFU-E–derived cells of four patients. Although the frequencies of CFU-E or BFU-E–derived colonies were not regularly affected, the proliferative capacities of these colony-forming cells were markedly enhanced without alteration in the quantity of HbF produced per progenitor-derived erythroid cell (the HbF program). Different results might have been obtained if additional points had been chosen for the study, but ethical considerations demanded that bone marrow aspirates be performed only twice. Because F reticulocytes remained elevated for 7 to 14 days after the posttreatment progenitor proliferation and HbF programs were assessed, we conclude that the sustained increase in F reticulocytes was not the result of a direct effect of the drug on the capacity of CFU-E or BFU-E–derived proerythroblasts to produce HbF. Rather, the data suggest that the drug influenced the number of proerythroblasts (and hence reticulocytes) produced by each progenitor.

We also assayed the percentage of fetal hemoglobin produced following treatment of maturing BFU-E–derived erythroblasts with hydroxyurea or 5-Aza in vitro. The ability of the radioligand assay of progenitor-derived cells to detect different HbF programs is clearly shown in Fig 1. The culture and assay system measures the accumulation of hemoglobins F and A following a 14-day period during which erythroblasts are derived from progenitors and mature. Drug treatment of BFU-E–derived erythroblasts as they mature in the culture permits analysis of the effects of treatment on erythroid cells that are nearly synchronized in a particular stage of maturation. This sharply contrasts with the treatment of bone marrow aspirates that contain cells of all stages of erythroid maturation. In addition, previous studies showed that this system has the capacity to detect factors that influence the quantity of fetal and adult hemoglobin produced per cell.[15,16] Neonatal progenitor-derived erythroblasts alter the percentage of hemoglobin F made in vitro following coculture with sodium butyrate[15] and γ-interferon (γ-IFN).[16] Adult progenitor-derived erythroblasts have been shown to produce less fetal hemoglobin following coculture with γ-IFN[16] and more fetal hemoglobin following bromodeoxyuridine treatment.[17] The data from the present study demonstrate that HbF production in progenitor-derived cells is not altered by treatment with hydroxyurea. Unlike other factors,[15-17] hydroxyurea cannot influence hemoglobin F production in erythroblasts directly derived from BFU-E.

The present results do not support the simple cytotoxic hypothesis that we[5-7] and other researchers[8] have previously presented. We suggested that the drugs kill mature and rapidly dividing erythroblasts and progenitors, forcing their replacement with erythroblasts immediately derived from spared progenitors.[18] Such progenitor-derived erythroblasts produce more fetal hemoglobin than do erythroblast-derived erythroblasts.[19] That concept was largely based on studies in simians in which the F cell response is regularly preceded by transient reticulocytopenia and loss of mature marrow erythroid progenitors (CFU-E).[5-7] Neither was observed in these human studies. Indeed, Dover et al recently observed that when hydroxyurea treatment resulted in marrow toxicity, hemoglobin production was *less* likely to increase.[20] SCA patients with minimal renal dysfunction exhibited the most cytotoxicity and the least F reticulocyte response to hydroxyurea.[20]

Our studies support a complex cytokinetic explanation for hydroxyurea-induced stimulation of the F reticulocyte response.[8] Most erythroblasts present in normal marrow are not directly derived from progenitors but are instead the products of previous erythroblast division.[18] Normal marrow erythroblasts contain 20 pg hemoglobin/cell but <1 pg to undetectable quantities of HbF per cell, whereas erythroblasts derived from normal peripheral blood or bone marrow BFU-E and CFU-E contain 20 pg total hemoglobin, and 1 to 2 pg fetal hemoglobin.[14] A brief course of hydroxyurea in vivo may result in stimulation of the proliferative thrust of surviving progenitors and/or promote their premature differentiation into erythroblasts.[21] Either event would increase the marrow fraction of progenitor-derived erythroblasts, which produce greater quantities of γ globin than do erythroblasts derived from erythroblasts. The extent to which the HbF per F cell rises in vivo is likely to depend on the inherent ability of the particular progenitor population to produce hemoglobin F.

In summary, the studies we report demonstrate that hemoglobin F production in progenitor-derived erythroblasts from AA, AS, and SCA individuals and monkeys is not directly altered in vitro by treatment with hydroxyurea. Treatment of SCA patients with hydroxyurea in vivo affects the numbers of progeny per erythroid progenitor but does not have any demonstrable influence on fetal hemoglobin production per progenitor-derived erythroblast. Because hydroxyurea does not appear to reregulate fetal hemoglobin production in differentiating erythroid cells, we propose that hydroxyurea secondarily enhances the synthesis of HbF by inducing alterations in erythropoiesis.

δ Glycophorin (Glycophorin B) Gene Deletion in Two Individuals Homozygous for the S−s−U− Blood Group Phenotype

By C-H. Huang, K. Johe, J.J. Moulds, P.D. Siebert, M. Fukuda, and O.O. Blumenfeld

Blood cells from two unrelated individuals whose erythrocytes exhibit respectively N S−s−U− and MN S−s−U− blood group phenotypes were examined by immunoblotting, periodic acid-Schiff (PAS) staining, and Southern blotting. Protein bands characteristic of δ glycophorin (glycophorin B) were absent from the immunoblots of whole erythrocyte lysates when probed with polyclonal glycophorin antisera and from isolated erythrocyte membranes stained with PAS reagents. Genomic DNA from the two individuals' leukocytes was digested with a panel of restriction enzymes and probed with α M glycophorin cDNA obtained from human K562 leukemic cell line. The *EcoRI, PstI,* and *KpnI* restriction site patterns were identical to those of S+s+U+ controls in fragment numbers and relative size but differed from controls in band intensities. Restriction mapping with *HindIII, PvuII, SacI, MspI,* and *BamHI* revealed that S−s−U− individuals lack fragments that are reproducibly observed in S+s+U+ controls, and most likely encode δ glycophorin. Using truncated 5′ and 3′ cDNA segments as probes and comparing, in control individuals, hybridization intensities of fragments with amino acid sequence homologies, we have inferred the assignment of restriction fragments to the α and δ glycophorin genes. Our results suggest that the absence of δ glycophorin in the two S−s−U− individuals is a result of deletion of the entire δ glycophorin gene. This is the first report of a glycophorin gene deletion.

GLYCOPHORINS α and δ (glycophorins A and B) are glycoproteins of the human erythrocyte membrane that carry the antigens of MNSs blood groups.[1,2] Serologic family studies have established that αM and αN, as well as δS and δs glycophorins, are products of respective allelic genes.[3] Chemical structural analyses identified amino acid substitutions that distinguish αM from αN glycophorins and those that specify δS and δs glycophorins.[4-6] The U blood group phenotype is serologically closely associated with the S and s determinants, but the structural association of the U antigen with δ glycophorin is less clear.[7,8]

Glycophorins αN and δ are highly homologous, being identical within the amino terminal 26 residues and sharing homologies in their remaining sequences*.[1,5,6,9] Human α and δ glycophorin genes are closely linked on the long arm of chromosome 4.[3,6,10] Recently, evidence obtained from αM glycophorin cDNA and oligonucleotide probes indicated that α and δ glycophorins are encoded by separate and distinct single copy genes.[11,12]

Although a number of variant MNSs blood group phenotypes have been identified by serologic studies,[1,2,6] few have been characterized by protein and carbohydrate structural analyses.[13-20] To understand the genetic basis for the origin and expression of variant glycophorins, we have undertaken studies on the organization of the glycophorin genes in individuals exhibiting variant MNSs phenotypes. In this report we present evidence derived from protein and genomic DNA analyses that erythrocytes of two unrelated individuals homozygous for the S−s−U− blood group phenotype lack δ glycophorin as a result of a δ glycophorin gene deletion.

MATERIALS AND METHODS

Blood samples. Blood samples from two unrelated S−s−U− donors (M.E.K. and M.L.A.) and certain controls (S+s+U+) were provided by the Community Blood Center, Dayton, OH. Control blood samples were also obtained from laboratory personnel. The MNSsU blood group phenotypes of the variant erythrocytes were: donor M.E.K., M−N+S−s−U−; donor M.L.A., M+N+S−s−U−. Serologic typing was performed using sera available at the Consultation Laboratory of Gamma Biologicals. M and N status was tested with antisera from human, animal, and lectin sources. Anti-S, anti-s, and anti-U were human source reagents, and at least three samples of each were used. U-negative status was confirmed by absorption-elution studies.

Polyacrylamide gel electrophoresis (PAGE) and immunoblot analyses. Fresh erythrocytes were washed three times with phosphate-buffered saline (PBS) containing inhibitors of proteolysis and lysed by mixing 0.025 mL packed erythrocytes with 0.75 mL 1× (sodium dodecyl sulfate (SDS)-polyacrylamide gel) sample buffer.[21,22] Ten microliters of the whole lysate was subjected to electrophoresis on SDS-10% polyacrylamide gels.[21] Gels were blotted onto nitrocellulose as described by Towbin et al,[23] and glycophorins were visualized by autoradiography after consecutive incubations with one of two polyclonal rabbit antisera and then with ^{125}I-labeled protein A.[24] One antiserum was raised against intact α MN glycophorin, the second against the carboxyl terminal peptide of α MN glycophorin (peptide C, residues 82 through 131).[20] Whereas the glycophorin antiserum reacts with both α and δ glycophorins, the antipeptide C serum detects only α glycophorin and shows no crossreaction with δS or δs glycophorin.[20,21]

Erythrocyte membranes were prepared as previously described.[4] To 0.50 mL membrane suspension was added 0.25 mL 3× sample buffer and 10 μL subjected to electrophoresis. Gels were stained with Coomassie blue or periodic acid-Schiff (PAS) reagent.

Genomic DNA restriction mapping analysis. Genomic DNA was isolated from the peripheral leukocytes of EDTA-anticoagulated blood as described by Kunkel et al[25] with minor modifications. All DNAs were larger than 50 kilobases (kb) using intact λ DNA as marker.

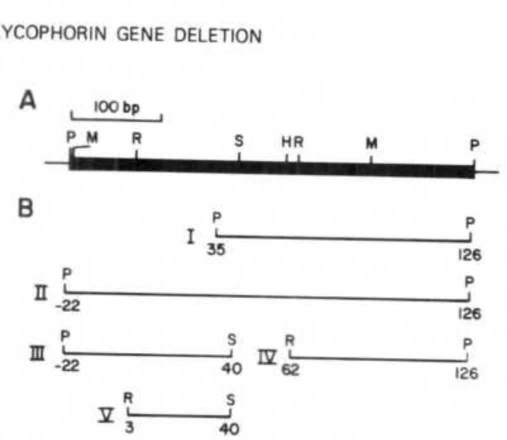

Fig 1. (A) Partial restriction map of α glycophorin cDNA insert. Restriction endonucleases are denoted as P, *Pst*I; M, *Mbo*I; R, *Rsa*I; H, *Hpa*II; and S, *Sac*I. (B) Probes used for nucleic acid hybridization. Roman numerals designate probes. Probes I and II were generated by *Pst*I from glycophorin cDNAs, pHGpA-1, and pHGpA-3, respectively[12]; probes III through V were generated, as shown, by cleavage of pHGpA-3 with *Pst*I, *Rsa*I, and *Sac*I. Numbers at beginning and end of each probe indicate amino acid residues of α glycophorin they encompass. cDNAs lack the codons of the last five residues of α glycophorin, which contains a total of 131 residues.

Genomic DNAs were digested with restriction endonucleases (New England BioLab, Beverly, MA; Boehringer Mannheim, Indianapolis), under conditions recommended by the manufacturers, in a ratio of 4 to 5 U enzyme/μg DNA at 37°C for 15 hours. Blotting transfer of DNA fractionated by agarose gel electrophoresis was performed as previously described.[26]

Recombinant plasmids, pHGpA-1, and pHGpA-3 harboring the glycophorin cDNAs, were isolated from transformed *Escherichia coli* RR1 cells[12] and further purified by cesium chloride density-gradient centrifugation as described.[27] A partial restriction map of α M glycophorin cDNA inserts was predicted from their nucleotide sequences (Fig 1A). The cDNA hybridization probes are depicted in Fig 1B (I through V). The probes were removed from the plasmids by appropriate restriction enzymes, purified by electrophoresis in low-melting agarose (Bio-Rad, Richmond, CA) or 6% to 8% polyacrylamide gels, excised and labeled with [α-^{32}P]dCTP (Amersham, Arlington Heights, IL) using random primers (Pharmacia, Piscataway, NJ) and Klenow fragment of DNA polymerase I (Bethesda Research Laboratories, Gaithersburg, MD) as described by Feinberg and Vogelstein.[28] The specific activities of these primer-extended probes ranged from 2.1×10^9 to 3.4×10^9 cpm/μg.

Nucleic acid hybridizations were performed essentially as described.[29] The hybridization and washing techniques were standardized as follows: To each blotted nitrocellulose filter (~200 cm^2) was added 10 mL hybridization solution containing 5 × SSC (1 × SSC = 0.15 mol/L NaCl + 0.015 mol/L Na$_3$ Citrate, pH 7.0), 5 × Denhardt (1 × Denhardt = 0.1% Ficoll, 0.1% polyvinylpyrrolidone (PVP) and 0.1% bovine serum albumin, BSA), 10 mmol/L EDTA (pH 8.0) and 200 μg/mL sonicated salmon sperm DNA. Prehybridization was carried out at 65°C for ~10 hours; hybridization was carried out overnight at the same temperature, following addition to the hybridization solution of the appropriate radioactive probe at a final concentration of 4 to 5×10^6 cpm/ml. Highly stringent washing conditions were as follows: 2 × SSC, 0.1% SDS at room temperature for 30 minutes and then at 60°C for 30 minutes, and finally in 0.1 × SSC, 0.1% SDS at 60°C for 1 hour. Occasionally, repeated hybridizations of a single nitrocellulose filter were carried out with different probes; in those cases, the bound probes were removed from the filter after each use by washing in TE buffer (10 mmol/L Tris, 1 mmol/L EDTA, pH 8.0) at 68°C for 1 to 2 hours. The blots were exposed to Kodak XAR-5 film against two intensifying screens at −80°C for 3 to 4 days.

RESULTS

Absence of δ glycophorin in S−s−U− erythrocyte membranes. Immunoblots show that the erythrocyte membranes of both S−s−U− individuals lack the δ glycophorin monomer and dimer bands (3b and 6) when compared with a normal control (Fig 2A). These bands are readily identified in the S+s+U+ control erythrocytes by reaction with antiglycophorin serum and lack of reaction with antipeptide C serum (Fig 2A and B).[21] The absence of δ glycophorin characteristically located in the PAS 3 band (2) is also seen in membrane preparations stained with PAS reagent (Fig 2C).

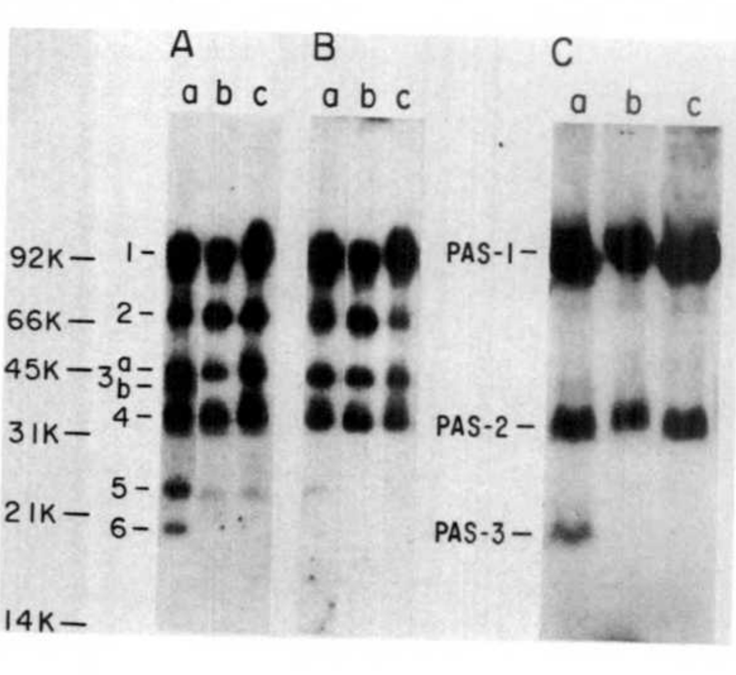

Fig 2. Glycophorins in erythrocytes and isolated membranes of S+s+U+ control and S−s−U− variants. (A and B) Immunoblots of SDS 10% polyacrylamide gels of intact erythrocytes probed with antiserum to α glycophorin (in A) and antiserum to α glycophorin carboxyl terminal peptide C (residues 82 through 131) (in B). (C) Schiff-stained gel of isolated membranes: (a) control M+ N+ S+s+U+ individual; (b) donor M.E.K. (M−N+ S−s−U−); (c) donor M.L.A. (M+ N+ S−s−U−). Vertical numbers (left) refer to mol wt markers and glycophorin bands present in erythrocytes of the control individuals; the pattern of the control individual's erythrocytes is representative of >100 individuals examined.[21] Bands 1 and 4 as well as PAS1 and PAS2 correspond to α glycophorin dimer and monomer; bands 3b and 6 correspond to δ glycophorin dimer and monomer respectively; PAS3 correspond to δ glycophorin.[2]

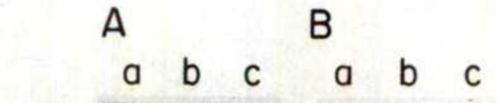

Fig 3. Autoradiograms of Southern blots of *EcoRI* (A) and *PstI* (B) digests of genomic DNA of S+s+U+ controls (a) and S−s−U− individuals [(b) donor M.E.K., (c) donor M.L.A.]; 7.5 μg DNA was resolved by 0.8% agarose gel electrophoresis, blotted, transferred, and hybridized with probe II (Fig 1B). Size markers for the restriction fragments (in kb) were the *HindIII* digests of λ DNA.

Genomic DNA restriction analysis. Genomic DNA of S+s+U+ control and S−s−U− individuals was first examined using restriction enzyme digestions and the α glycophorin cDNA insert from pHGpA-3 (probe II in Fig 1B) as hybridization probe. For all enzymes used except *Msp*I whose digests exhibit a restriction fragment length polymorphism (RFLP)[30] (described below), restriction site patterns shown in control are representative of DNA of ∼20 M, N, S+,s+,U+ individuals examined. For all these enzymes, the possibility that differences in restriction site patterns in DNA of S−s−U− individuals might result from RFLP is therefore excluded.

As shown in Fig 3, fragments of S−s−U− DNA digested with *Eco*RI and *Pst*I are identical to those of the DNA of control individuals except for the weaker intensity of the smallest size bands; this was also observed in control and variant DNA patterns with Kpn I digests (gels not shown). In contrast, *Hind*III, *Pvu*II, *Sac*I, *Msp*I, and *Bam*III digestions all demonstrated distinct restriction maps that showed the absence of specific bands in the DNA of S−s−U− individuals as compared with S+s+U+ controls (Figs 4 and 5). To identify fragments that encompass the amino (5′) and carboxyl (3′) terminal regions of α and δ glycophorins, pHGpA-1 and -3 cDNAs as well as three truncated probes generated from them were used. The sizes of the respective fragments are listed in Table 1; hybridization patterns are shown in Figs 4 and 5.

The restriction site patterns revealed by *Hind*III digestion and probe II hybridization show the absence in DNA of two bands 6.7 kb and 3.4 kb, in the S−s−U− individuals as compared with the control. From hybridization patterns of S+s+U+ DNA with the 5′ and 3′ specific probes, we conclude that these fragments may derive from δ glycophorin genes. (Table 1 and Fig 4A III and IV). The remaining *Hind*III fragments seen in the DNA of both S+s+U+ and S−s−U− individuals most likely derive from the α glycophorin gene.

The hybridization signals of the α glycophorin gene fragments are nearly equivalent, whereas those of bands absent in S−s−U− DNA differ significantly; under identical hybridization and washing stringency conditions, the intensity of the 3′ 3.4-kb fragment was consistently weaker than the intensity of the 6.7-kb amino terminus specific band (Fig 4A III and IV). These intensity differences further support the assignment of the hybridizing bands, absent in S−s−U− variants, to the δ glycophorin gene, because amino acid sequence homologies of α and δ glycophorins are much more extensive in the amino terminal than in the carboxyl terminal region of the glycophorin polypeptides*.[5,9,31] The remaining more strongly hybridizing bands found in both control and variant DNAs are correspondingly assigned to the α glycophorin gene. These observations support the conclusion that α and δ glycophorins are encoded by separate single-copy genes.[12]

Analysis of *Pvu*II hybridization patterns led to a similar conclusion (Fig 4B III and IV and Table 1). The 7.3-kb fragment of α glycophorin hybridizes strongly with the 3′ probes but weakly with the 5′ probes. Because the latter probes encode the α glycophorin polypeptide through residue 40 (Fig 1B), this suggests that an intron may be present in the vicinity of residues 35 through 40 and that the 7.3-kb and 1.9-kb fragments may contain all the coding sequences for α glycophorin.

*Sac*I digestion shows the absence in S−s−U− individuals of a single 8.0-kb fragment (Fig 4C and Table 1). In the control, this fragment hybridized with all probes used, and as noted previously in *Hind*III and *Pvu*II digests, 5′ probes III and V showed a much stronger hybridization signal than the carboxyl terminus-specific probe IV (Fig 4C). These observations strongly suggest that the 8.0-kb fragment contains the total coding sequence for δ glycophorin and may be large enough to include most of the noncoding sequences that immediately flank the δ glycophorin gene. The presence of a single *Sac*I fragment indicates, in addition, that the *Sac*I site residing within the α glycophorin coding region (Fig 1A) is eliminated in the δ glycophorin gene. This is in agreement with the amino acid sequence data that suggests a deletion in δ glycophorin of codons 27 through 55 of α glycophorin*.[9]

Restriction analysis using *Bam*HI and *Msp*I revealed even larger size DNA deletions in the two S−s−U− individuals (Fig 5A and Table 1). The *Msp*I 14.2-kb fragment includes

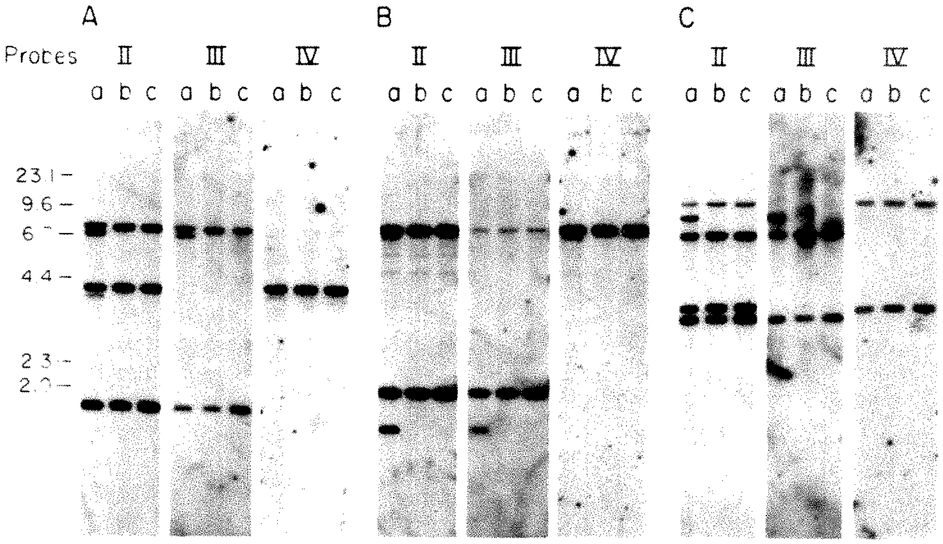

Fig 4. Autoradiograms of Southern blots of *Hind*III (A), *Pvu*II (B) and *Sac*I (C) digests of genomic DNA of S+s+U+ controls (a) and S−s−U− individuals [(b) donor M.E.K., (c) donor M.L.A.]. DNA 7.5 μg was resolved on 0.8% agarose gels and hybridized with probes shown in Fig 1B. When blots were rehybridized with probe V, a pattern identical to that observed with probe III was obtained. Size markers as in Fig 3.

the δ glycophorin gene, but the 11.7-kb fragment is one of a pair of RFLP alleles (the other one being the 7.3-kb fragment) linked to the α N glycophorin gene.[30] The 14.2-kb fragment is analogous to the *Sac*I 8.0-kb fragment in that it hybridized strongly with probe III but weakly with probe IV (Table 1). The 14.2-kb *Msp*I fragment most likely encompasses the total coding sequence of δ glycophorin gene. This is because the single cutting site for *Msp*I, within the coding region of α glycophorin gene

$$\left(\text{codons 58 through 59 or } \begin{matrix}\text{ACC} & \text{GGA}\\ \text{Thr} & \text{Gly}\end{matrix}\right)$$

may be absent in δ glycophorin gene due to a different codon specifying δ glycophorin at position 29. This residue in δ glycophorin is the position of the δS/δs allelic substitution, Thr and Met in δs and δS, respectively,[5] and is aligned with Thr 58 (ACC), in α glycophorin*.[9,31] Assuming a single base change between the codons, it is likely that the codon for Thr-29 in δ glycophorin would be ACG, given the unique codon for Met, ATG. Such an ACG codon would indeed eliminate the *Msp*I site. This conclusion is supported by our failure to differentiate SS, ss or Ss genotypes using *Msp*I.[30]

DISCUSSION

In this report, we provide evidence that two unrelated individuals who exhibit the S−s−U− blood group phenotype lack erythrocyte δ glycophorin and that the absence of this protein correlates with deletion of the δ glycophorin gene. This is the first documentation of a glycophorin gene deletion. This was concluded primarily from comparative restriction mapping of genomic DNA from control and variant donors using as probes previously cloned cDNAs and probes derived from different regions of these DNAs that encode defined amino and carboxyl terminal regions of α and δ glycophorins. Specific fragments were absent in five different enzyme digests of S−s−U− DNA, that in control DNA hybridized with the 5′ or 3′ terminal probes or with both. The conclusion that the fragments missing in the variant individuals derived from δ glycophorin gene was inferred primarily from our ability to relate, in controls, the relative intensities of bands in given digests to regions of high and low homology in the amino acid sequences of α and δ

§Restriction fragments for *Msp*I digests hybridized with probes III and IV not shown; hybridizations with probes I and V were not carried out (ND).

glycophorins. This allowed us to assign fragments as originating from the α or the δ glycophorin gene.

This study complements previous findings[12] and results in a more conclusive identification of the gene origin of restriction fragments. This became possible not only by comparison of control and variant maps, but also through the use of cDNA fragment probes. In contrast to previously used synthetic oligonucleotides that were complementary to α glycophorin cDNA sequences, the larger truncated probes could detect fragments derived from δ glycophorin genes despite possible mismatches (that might prevent oligonucleotide hybridizations) arising from sequence divergence of α and δ glycophorin genes.

Our conclusion that the entire coding sequence of the δ glycophorin gene is deleted is based primarily on the absence in S−s−U− donors of an 8.0-kb *Sac*I and a 14.2-kb *Msp*I fragment, fragments that were present in the S+s+U+ controls and hybridized with both the 5′ and 3′ hybridization probes; additional evidence was provided by the absence in the other digests of one pair of fragments, one hybridizing in control DNA strongly with the 5′ probe and the other with much less intensity with the 3′ probe. Although the sizes of the deleted fragments suggest that the entire δ glycophorin gene is deleted, using the cDNA probes we cannot now define the total size or the 5′ and 3′ endpoints of the deletion.

It became clear in the course of these studies that the restriction fragments observed in S−s−U− individuals originated exclusively from α glycophorin. The patterns shown by these fragments and their assignment to the regions of α glycophorin they encode are similar to those noted previously.[12] In addition to these observations, however, the use of the 5′ and 3′ terminus-specific cDNA probes revealed in several digests two fragments that originate from the amino terminus of α glycophorin gene and in the *Sac*I digests two carboxy terminus-specific fragments. Our data indicate at least two exons in δ glycophorin gene and suggest that the genomic organization of α glycophorin gene may be more complex.

The S−s−U− phenotype of erythrocytes of the two individuals examined here correlates with the lack of δ glycophorin in membranes of these cells; the demonstration that the δ glycophorin gene is deleted from both chromosomes in each individual provides proof that these phenotypes correlate with the genotypes of the donors: donor M.E.K., αN δ^{0}/αN δ^{0}; and donor M.L.A., αM δ^{0}/αN δ^{0}. Such a straightforward relationship may not necessarily be observed in all cases. Other mechanisms, including defects in transcriptional, translational, or posttranslational processing may be operative in other individuals of the S−s−U− phenotype.

The possibility of alternative origins for the phenotype was recently revealed through a study of a Dantu blood group variant.[32] As shown, erythrocytes of an individual exhibiting MN, Dantu, s+ phenotype lacked δ glycophorin, despite the s+ phenotype. We have explained this apparent inconsistency by demonstrating that the Dantu variant glycophorin is a hybrid δ-α structure, which evidently retains the s specific antigenic determinant in the δ glycophorin portion of the molecule. It will be of interest to determine if the δ glycophorin gene is deleted in Dantu individuals. The complexity of the glycophorin gene described here and further implied by our previous studies as well as by the presence of many serologically identified blood group variants, suggests that the glycophorin gene locus will be particularly informative in studies of human gene recombination.

Gene deletion is a common mechanism underlying some human genetic disorders, most notably thalassemias.[33] Certain thalassemias occur in geographically defined groups of individuals, for which it has been hypothesized that the absence of α or β globin gene may have represented a selective advantage. It is therefore of interest that the S−s−U− blood group phenotype is prevalent among selected populations, in particular among Blacks from certain regions in Africa where the incidence of this phenotype is 1% to 35%[34] as compared with an incidence of <0.001% in the white population. Our current studies are thus an important first step in understanding of the origin of the S−s−U− phenotype. It remains to be shown whether this phenotype is always characterized by the δ glycophorin gene deletion and whether when the deletion occurs a single origin or multiple evolutionary origins are implicated.

ACKNOWLEDGMENT

We express our appreciation to Mary Lou Guizzo, Community Blood Center, Dayton, OH for providing us with the bloods used in our study. We thank E. Fay Ricksy for preparation of this manuscript. We also thank Dr Howard Steinman for critical review of the manuscript.

Kinetic Evaluation of the Pool Sizes and Proliferative Response of Neutrophils in Bacterially Challenged Aging Mice

By Gerald Rothstein, Robert D. Christensen, and Buddy Ray Nielsen

Clinical observations during infection suggest that in aged patients, the kinetic or proliferative responses of neutrophils to infection may be deranged. To test this hypothesis, the neutrophil responses of 6-month-old and 30-month-old mice were compared. After intrapulmonary injection of *Escherichia coli*, young mice exhibited neutrophilia and diminution of the neutrophil storage pool (NSP) by a mean of 6.4×10^6 neutrophils/two femurs. This was accompanied by an increase in the pool of CFU-GM from a control value of 1.1×10^5 cells/two femurs (range 0.7 to 1.4) to 1.5×10^5 (1.1 to 1.9) ($P < .05$) and the thymidine suicide (relative proliferative rate) of CFU-GM rose from 27% (19 to 42) to 51% (31 to 61) ($P < .05$). Furthermore, the CFU-GM of infected young mice displayed enhanced differentiation to the neutrophil series. In contrast, old mice exhibited a greater mean diminution of the NSP: 12.8×10^6 neutrophils. Also, old mice experienced a reduction in CFU-GM from 2.3×10^5 (1.0 to 3.9) (controls) to 1.3×10^5 (1.2 to 1.5)/two femurs ($P < .05$), a reduction in the proliferation of CFU-GM and reduced differentiation of CFU-GM to neutrophils. These experiments establish that the neutrophil response of infected old mice is disordered, with exaggerated depletion of the NSP and lack of stimulus-driven granulocytopoiesis as reflected by a paradoxical reduction in the number and proliferative rate of precursors. This defect may be compounded by decreased differentiation of precursors to neutrophils.

© 1987 by Grune & Stratton, Inc.

TO SUSTAIN an adequate neutrophil supply, an appropriate balance must exist between the kinetics of neutrophil release from the marrow, intravascular turnover of neutrophils, and the production of neutrophils by progenitors. An example of the changes that occur in this balance can be found during infection. In dogs infected with staphylococci, release of cells from the neutrophil storage pool (NSP) is accelerated acutely, resulting in an increase in the size of the blood neutrophil pool.[1] In rats infected with streptococci, outflow of neutrophils from the NSP is sufficient to diminish the NSP appreciably.[2] In compensation, the number and proliferative rate of progenitor cells increase and the marrow neutrophil reserve is restored.[2] Thus, the neutrophil response to significant infection includes of a series of events: release of neutrophils from the marrow, an elevation of the blood neutrophil concentration, and the activation of homeostatic mechanisms by which the number and proliferation of neutrophil precursors are increased to restore the neutrophil supply.

Clinical observations suggest that in aged humans, the neutrophil response to bacterial challenge may be deranged. Murphy and Fine reported a high incidence of neutropenia in aged patients with bacteremic pneumococcal pneumonia and correlated neutropenia with an increased risk for mortality.[3] Although not kinetically defined, these observations could reflect either disordered neutrophil release from the NSP, an increased marginal pool of blood neutrophils, or a diminished compensatory proliferative response. Such defects would be of clinical relevance, and the mechanisms responsible for them would be of basic biologic interest as well.

For these reasons, we compared the response of young and old C57Bl/6 mice to a standardized challenge with *Escherichia coli* K1. The effect of bacterial challenge on the sizes of the various pools of neutrophils was evaluated, as was the ability of the animals to respond by accelerating neutrophil production.

MATERIALS AND METHODS

Animals. Six-month-old or 30-month-old male C57Bl/6 mice were obtained from Charles River Laboratories (Stone Ridge, NY) under the auspices of the National Institute of Aging. Each of the animals was shipped in an individual one-mouse compartment and was housed individually at the University of Utah Vivarium until use within 1 to 6 weeks of arrival. When killed, animals were examined by autopsy for gross evidence of tumors, renal disease, hepatic disease, or inflammatory lesions. Animals exhibiting these abnormalities were excluded from the study.

Examination of the blood and bone marrow. Mice were narcotized by CO_2 inhalation, and blood was obtained from the vena cava. The nucleated cells were counted electronically, and differential counts of 100 cells were performed on Wright's stained smears. Absolute concentrations of neutrophils were calculated from the nucleated cell counts and differentials.

Bone marrow was flushed from both femurs according to the method of Chervenick and colleagues.[4] Cells were counted electronically and 500-cell differential counts were performed, using Wright's stained smears and established criteria for identification of cells.[4] Absolute numbers of the various marrow cells were calculated from the nucleated cell counts and differentials. All studies of hemic cells involved killing the animal; consequently, no serial measurements were performed in individual mice.

Cultures of CFU-GM. Cultures of CFU-GM were performed in 35-mm plastic dishes, using semisolid methylcellulose medium in a manner previously described.[5] Cultures contained 5% postendotoxin serum, a concentration that exerted maximal stimulatory effect for the formation of colonies from both young and old mice. Cultures were incubated for 7 days at 37°C in a 7% CO_2 atmosphere. Colonies (>50 cells) were scored with the aid of a stereomicroscope.

Thymidine suicide experiments were carried out in a manner similar to that described by Byron.[6] Marrow cells were incubated at 37°C for 20 minutes in 2 ml of Hank's Balanced Salt Solution (HBSS) containing 0.1 mCi ^{3}HTdR (New England Nuclear, North

Billerica, MA) with a specific activity 80 Ci/mmol. Corresponding control cells were incubated in an equivalent amount of ^{1}HTdR. ^{3}HTdR uptake was inhibited competitively by adding 30 mL cold HBSS with 15% fetal calf serum (FCS) and 100 g/mL ^{1}HTdR. The cells were centrifuged at 200 × g for 12 minutes and were washed twice in the HBSS-cold thymidine serum solution. The thymidine suicide was taken as the proportional decrement in colonies when CFU-GM were pretreated with ^{3}HTdR, as compared with ^{1}HTdR.

The morphology of colonies was examined by aspirating all clearly isolated colonies from culture dishes with a capillary pipette, and then smearing them on coverslips for Wright's staining. Differential counts were performed on at least 50 cells for each colony; if sufficient numbers of cells were present, 100 cells were counted.

E coli expressing the K1 antigen were kindly supplied by Dr Harry Hill, University of Utah. Organisms were grown overnight in Tryptic Soy Broth (TSB) and washed three times in phosphate-buffered saline (PBS) prior to resuspension at 10^4 to 10^6 CFU/μL in PBS for injection with a Hamilton syringe. Concentrations of *E coli* were estimated by measuring the absorbance of suspensions at 600 nm, and the numbers of viable CFU were verified by quantitative culture in TSB agar.

Data were evaluated statistically with Student's *t* test, the Wilcoxon rank-sum text, or the Fisher exact test. Considering the usual sample sizes of four to eight values, these maneuvers are effective in evaluating the validity of apparent differences but could fail to detect more subtle differences that might not achieve statistical significance with relatively small numbers of values.

RESULTS

Weights of the 53 young mice (33.34 ± 0.32 g) (mean ± SEM) and the 50 old mice (33.29 ± 0.42 g) did not differ.

Mortality after inoculation with E Coli. Six-month-old (young) animals were inoculated transthoracically into the right lung with 1 μL/g body weight of a PBS suspension containing various doses of *E coli*. All five animals that received 10^6 *E coli*/g died within 48 hours. Of ten mice that received 10^5/g, six died within 48 hours, and the remainder survived until they were killed after 96 to 116 hours. No mortality occurred in 53 young mice or 50 old mice that received 10^4 *E coli*/g, nor were there any deaths among 17 mice after injection with 1 μL/g of PBS.

Effect of bacterial challenge (10^4 CFU/g) on circulating and marrow neutrophils. Four noninfected young mice displayed blood neutrophil concentrations of 1.6 × $10^3/\mu$L (0.7 to 2.1) (mean and range); four old controls exhibited neutrophil concentrations of 2.4 × 10^3 (2.0 to 2.9) ($P = .057$). The peak concentration of neutrophils was observed 2 hours after inoculation for both groups; four young mice had a peak of 3.3 × 10^3 (2.4 to 4.6) neutrophils per μL; four old mice exhibited a peak of 6.2 × 10^3 (3.3 to 11.3)/μL ($P = .057$). After 6 hours, the neutrophil concentrations for both groups had returned to their control ranges.

The mean value for the marrow's NSP (metamyelocytes plus band plus segmented neutrophils) of noninfected old mice was 47% larger than that for young control animals (Fig 1). After bacterial inoculation, the NSP diminished to a similar absolute value for both groups (Fig 1). After 4 hours, however, the NSP of old animals was depleted by a mean of 12.8 × 10^6 cells/two femurs (59% depletion); whereas the young animals experienced a smaller depletion: a mean of 6.4 × 10^6 cells/two femurs (43% depletion). Twenty-four hours after inoculation, the NSP of young animals had begun significant repletion; by 48 hours, the number of cells in the NSP had returned to the range of control values. In contrast, the NSP of old animals remained significantly smaller than that of noninfected controls, and was not repopulated even after 48 hours ($P < .005$).

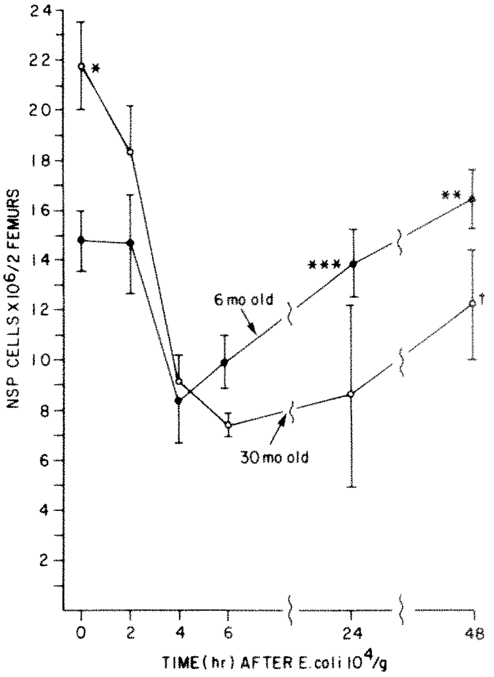

Fig 1. Effect of *E coli* inoculation on the neutrophil storage pool. Means for groups of four to seven 30-month-old mice (○) and for four to eight 6-month-old mice (●). Brackets indicate SE. *$P < .01$ *v* 6-month-old controls; **$P < .005$ *v* 6-month-old mice at 4 hours; ***$P < .03$ *v* 6-month old mice at 4 hours; and †$P < .005$ *v* 30-month-old controls.

Four hours after inoculation, the pool of morphologically recognizable proliferative precursors (blasts, promyelocytes, and myelocytes) was unchanged in young animals, but after 48 hours had increased to a mean of 145% of that for controls ($P < .02$) (Fig 2). In contrast, after 4 hours, the proliferative pool of old animals was reduced to a mean of 56% of the control value ($P < .05$) and remained depressed at 24 hours (Fig 2). Forty-eight hours after inoculation, old animals exhibited repletion of the proliferative pool to control values. As controls, 11 old mice and six young mice received injections of 1 μL PBS/g and did not exhibit neutrophilia or alterations in the marrow cellularity.

Changes in the number and proliferative rate of CFU-GM. In young mice, the femoral pool size of CFU-GM was unchanged at 4 hours but after 48 hours, had increased to a mean of 145% of the control value (Fig 3). In old mice, the mean number of CFU-GM fell to 46% of the control after 4 hours and remained reduced (55% of control) at 48 hours.

The thymidine suicide of CFU-GM for eight young control mice was 27% ± 3%, and for 6 old control mice it was 39% ± 4% ($P = .054$) (Fig 4). Thereafter, bacterial chal-

Brackets indicate SE. $^*P < .04$ *v* 6-month-old controls; $^{**}P < .002$ *v* 6-month-old controls; $†P < .04$ *v* 30-month-old controls, $< .002$ *v* 6-month-old at 48 hours.

lenge induced distinctive and different alterations in the thymidine suicide of CFU-GM from the two groups. After 4 hours, the mean thymidine suicide of inoculated young animals had risen ($P < .04$), achieving a peak mean value of 51% ± 4% at 48 hours ($P < .002$ *v* control). In contrast, in old animals, the thymidine suicide of CFU-GM fell within 4 hours and at 48 hours was still depressed as compared with that of 30-month-old controls ($P < .04$) or 6-month-old animals at 48 hours ($P < .002$).

Next, the effect of a larger, ~50% lethal, bacterial inoculum was tested. Twenty-one young mice were given 10^5 *E coli*/g; 10 died within 48 hours. Six old mice received the same weight-standardized dose and three died within 48 hours. Forty-eight hours after inoculation, CFU-GM from four young survivors and three old survivors were evaluated (Table 1). Young mice responded to the larger inoculum with an even greater increase in the number of CFU-GM as well as an increase in the thymidine suicide of CFU-GM. In contrast, old mice displayed a reduced population and thymidine suicide of CFU-GM. In aged mice, the high dose of bacteria induced a significant further decrement in the number of CFU-GM as compared with the smaller nonlethal dose of 10^4/g ($P < .05$) (Table 1).

Morphological studies of the progeny of CFU-GM in vivo. Twenty-eight to 38 colonies were aspirated from 7-day-old cultures and examined morphologically. In this way, the proportion of neutrophils within colonies was determined for groups of three to four old or young animals. The data for control animals and for animals who had received *E. coli* 48 hours previously are shown in Table 2. With bacterial challenge, young animals significantly decreased the propor-

tion of colonies devoid of neutrophils. In contrast, in old animals, the mean number of colonies with no neutrophils nearly doubled (from a control value of 24% to 46%). In addition, the proportion of colonies containing 34% to 100% neutrophils declined from 34% (control) to 11% in old animals inoculated with 10^5 *E coli*/g ($P < .05$), but did not change in the young mice.

DISCUSSION

In noninfected animals and humans, the production and utilization of neutrophils are balanced, so that relatively constant pools of proliferative and stored mature neutrophils are sustained.[7] During infection, the system is perturbed. Cells are acutely released from the NSP into the blood, increasing the blood neutrophil pool and decreasing the size of the NSP.[1,2] In compensation, there is an increased proliferative effort, and the neutrophil supply is restored.[2] These kinetic and proliferative responses depend on an intact system of regulatory stimulators (or inhibitors) and target cells capable of an appropriate response. The present studies were carried out on the premise that during perturbation of granulocyte kinetics by a standardized infectious challenge, the regulation of neutrophil kinetics and proliferation could be evaluated in groups of young and aging animals.

First, we examined pool sizes and proliferation in the steady state. Femoral marrow was studied quantitatively, and the data were taken to reflect total marrow cellularity, since previous measurements indicate a similar marrow distribution in young and old mice.[3,8,9] The total marrow cellularity of old mice was greater than that of young animals. These data agree with those of Boggs et al.[10] Williams and co-workers also noted an increase in marrow cellularity in old mice, but this difference was not apparent when values were adjusted for the animals' body weight.[9] In our experiments, the old mice also exhibited an increased NSP, an increased proliferative pool, and an increased pool of CFU-GM. None of these increases were due to differences in body mass, because young and old animals did not differ in weight. In addition, old mice exhibited an increased thymidine suicide of CFU-GM. Because the time for DNA synthesis is fixed in mammalian cells,[11] an increase in thymidine suicide is considered a reflection of a shortened cell cycle duration and therefore an increased rate of proliferation. Thus, baseline neutrophil production may be greater in old mice as compared with young adult mice.

After a nonlethal challenge with *E coli* (10^4/g), young mice exhibited a reduction in the NSP and neutrophilia as neutrophils were released into the blood. Then the population of immature granulocytes and of CFU-GM increased, and the thymidine suicide rate of CFU-GM also increased. The increase in proliferative effort is the consequence of stimulus-driven granulocytopoiesis, which facilitates repopulation of the NSP.

Old mice exhibited a greater degree of neutrophilia than did young animals. Esposito and Pennington noted similar degrees of neutrophilia in 24-month-old and 6- to 8-month-old mice challenged with bacteria although the older mice exhibited slightly but consistently lower values.[12] We are hesitant to compare our results with theirs, however, because in the present study older mice and a different organism were used. In our experiments, inoculated old mice lost a greater number of neutrophils from their NSP, and the proportional depletion of the NSP was also greater. These data reflect an intact stimulus and response for neutrophil release, but one resulting in a greater degree of depletion of the NSP in old mice. Even so, neutrophil supply was not sufficiently compromised at the dose of 10^4/g to induce neutropenia. Neutrophil counts were not measured after the high dose of *E coli.* Kinetically, the exaggerated depletion of the NSP is the net consequence of inflow of neutrophils to the NSP from the mitotic compartment and exit of cells into the blood. We did not directly measure neutrophil release, but our studies suggest that diminished proliferation contributes to the exaggerated depletion and to delayed repletion of the NSP. In support of this, the population of immature granulocytes fell acutely in old animals and then returned to control levels rather than remaining stable and then rising as it did in young mice. The size of the pool of immature granulocytes was undoubtedly influenced by movement of immature cells into the NSP. This was accompanied by a reduction in the number of CFU-GM however, suggesting that reduced inflow into the immature cell pool was also a factor. The significance of a reduced pool of CFU-GM appears to be compounded by a reduction in the differentiation of CFU-GM to the neutrophil series in vitro. In contrast, in inoculated young mice, differentiation to neutrophils was increased. An even more pronounced fall in the number of CFU-GM was observed in old mice given the high dose of 10^5 *E coli*/g, whereas the high dose of *E coli* yielded a further increase in CFU-GM in young mice. The reduction in the pool of GFU-GM was not accompanied by an increase in the proliferative rate of CFU-GM, which actually fell after both the high and low doses of *E coli*. Therefore, inoculated old mice did not respond with increased granulocytopoiesis. Although the mechanisms responsible for this are not clear, candidate explanations include insufficient production of a necessary stimulator, production of an inhibitor of proliferation, or hyporesponsiveness of precursors to stimulators.

It has been proposed that during aging, mitotically capable cells lose their ability to proliferate. Hayflick has demonstrated loss of replicative potential in senescent diploid cell lines,[13-15] and Dell'Orco et al correlated the life span of fibroblasts with their number of cell doublings.[14] In addition, Albright and Makinodan showed that hematopoietic stem cells from old animals produced relatively few spleen colonies in irradiated recipients.[17] Lipschitz et al demonstrated reduced numbers of CFU-GM, BFU-E, and CFU-E in elderly anemic subjects,[18] and reduced iron incorporation by aged murine erythroid cells in vitro[19] and in vivo.[20] On the other hand, Boggs et al did not identify a proliferative defect in aging cells used to repopulate W/W^v mice,[21] but reported a sluggish repair of anemia in phlebotomized aged mice.[22] Williams et al reported a reduction in the numbers of BFU-E, CFU-E, and CFU-GM in 42-month-old (but not 6-month-old) mice caged in groups.[9] This abnormality does not appear to be restricted to aging mice, however, since other researchers have reported a reduction in hematopoietic spleen colonies derived from 3- to 5-month-old mice housed in groups.[23] The kinetics of the neutrophil response and its effect on proliferation have not been evaluated in group-housed mice, and the factors responsible for depressing precursors are not at all clear. In the present study, mice were shipped and housed singly. Despite these precautions, we cannot exclude the possibility that factors such as shipping (or other factors unknown to us) may have influenced or primed the hematopoietic system of aging mice, thus contributing to their response to infection.

We applied a standardized stimulus to evaluate neutrophil kinetics in bacterially challenged old mice. The response of old mice differed from that of young animals, and was characterized by (a) an exaggerated depletion of the NSP, (b) a paradoxical diminution of the pool sizes of CFU-GM and their progeny, (c) a paradoxical lack of accelerated proliferation of CFU-GM, and (d) a diminished differentiation of CFU-GM to neutrophils. These changes reflect an absence of the expected stimulus-driven granulocytopoiesis which appropriately increases the neutrophil supply in young mice. As yet, the effect of this abnormality on host resistance is unknown, although in the present short-term experiments, no increase was observed in the mortality of infected aged animals. We propose that the model of bacterially challenged aged mice may be useful in identifying the mechanisms responsible for these abnormalities.

Homing Receptors on Human and Rodent Lymphocytes—Evidence for a Conserved Carbohydrate-Binding Specificity

By L.M. Stoolman, T.A. Yednock, and S.D. Rosen

Lymphocyte recirculation begins with the attachment of circulating cells to the structurally distinctive postcapillary venules of lymphoid organs termed high-endothelial venules (HEVs). In both rodents and humans, the attachment of lymphocytes to the HEVs of peripheral lymph nodes (PNs) on the one hand and gut-associated lymphoid tissues (GALTs) on the other appears to involve discrete adhesive structures on the surfaces of the interacting cells. In rodents, we previously showed that a carbohydrate-binding receptor at the lymphocyte surface participates in the attachment to the HEV of peripheral nodes. The studies reported herein document the involvement of a similar receptor in the selective attachment of human peripheral blood lymphocytes to the HEVs of PNs. We argue that the close functional relationship between the human and rodent receptors indicates that this component of the adhesive interaction has been conserved through evolution.

© 1987 by Grune & Stratton, Inc.

LYMPHOCYTES continuously migrate from the bloodstream into lymphoid organs. This process distributes normal lymphocytes throughout the lymphoid system and may facilitate the dissemination of lymphoid malignancies. In peripheral lymph nodes (PNs) and gut-associated lymphoid-tissues (GALTs) (ie, Peyer's patches or appendix), transvenular migration begins with the attachment of circulating lymphocytes to postcapillary venules with a distinctive cuboidal endothelium (the high endothelial venules or HEVs).

Several lines of evidence indicate that this adhesive interaction is organ selective. In the rat, monospecific antisera have been developed that block the attachment of recirculating lymphocytes to the HEVs of either PNs or GALTs.[1,2] In the mouse[3] and human[4] systems, T cells as a population show preferential binding to the HEVs of PNs whereas B cells bind preferentially to the HEVs of GALTs. In addition, murine lymphomas have been identified that bind to the HEVs of PNs or GALTs with nearly absolute fidelity.[5] These data suggest that the attachment of lymphocytes to the HEVs of PNs on the one hand, and GALTs on the other involve different adhesive structures on the surfaces of the interacting cells.

Candidate adhesion molecules on the lymphocyte surface (referred to as homing receptors) have been isolated from rodents. In mouse, a ubiquinated glycoprotein (gp) termed gp 90mel-14 appears to be the PN-homing receptor.[6-8] In the rat, distinct gps with PN-HEVs and GALT-HEVs binding activities have been detected in thoracic duct lymph. Considerable evidence suggests that these factors are shed lymphocytic homing receptors.[9,10]

We have been interested in the biochemical basis of the adhesive interaction between lymphocytes and the HEVs. Previous work indicates that a carbohydrate-binding receptor on the lymphocyte surface participates in the attachment of rodent lymphoid cells to PN-HEVs in vitro[11,12] and in vivo.[13] In the mouse, this receptor is either identical or closely related to gp 90 Mel-14.[14] In addition, we have shown directly that carbohydrate moieties on the PN-HEVs are required for lymphocyte attachment.[15] These results support the hypothesis that organ-selective migration across the PN-HEV begins with the binding of a lectin-like receptor on lymphocytes to a carbohydrate-containing ligand on the endothelial surface.

In this article, we present evidence that the attachment of human peripheral blood lymphocytes to PN-HEVs also involves a carbohydrate-binding receptor on the lymphocyte surface. The binding specificity of the receptor is similar to its counterparts on rodent lymphocytes. The preservation of carbohydrate binding specificity across species lines suggests that the recognition/binding domains of the adhesive structures on lymphocytes and HEVs have been conserved through evolution.

MATERIALS AND METHODS

Chemicals

Heparin (H3125), chondroitin sulfate (C3254), hyaluronic acid (H7630), all phosphorylated monosaccharides, bovine serum albumin (BSA) (A7906), trypsin type III (T8253), borax (B9876), boric acid (B0252), cyanogen bromide (C6388), cacodylic acid (C0250), disodium EDTA (ED2SS), Histopaque (1077), poly-L-lysine (P1524), clostridial neuraminidase (2133), and paraformaldehyde (P6148) were obtained from Sigma Chemical (St Louis). PPME, the polyphosphomonoester core from *Hansenula hostii* phosphomannan,[16] was the generous gift of Dr M. E. Slodki (U.S. Department of Agriculture, Northern Regional Research Center, Peoria, IL). Lyophilized thrombin was obtained from Parke-Davis (Ann Arbor, MI). Fluorescent microspheres (0.6-μm, FX, 112030-30) were obtained from Duke Scientific, (Palo Alto, CA). Minimal essential medium (MEM) (330-1435) and tricine (845-1398) were purchased from GIBCO Laboratories (Grand Island, NY). Powdered FA buffer was obtained from Difco laboratories (Detroit).

Mouse anti-human monoclonal antibodies and FITC-labeled goat-anti-mouse IgG were obtained from Coulter Corporation (Hialeah, FL).

Preparation of Cell Suspensions

Rat cells. Lymphocytes were obtained from the cervical and mesenteric nodes of Sprague-Dawley rats (female, 180–200 g) after killing by CO_2 anesthesia and cardiac puncture. Thymocytes were obtained from the thymus after dissection away from parathymic lymph nodes. Cells were gently teased free of connective tissue, collected into MEM buffered with 40 mmol/L tricine (pH 7.4) and supplemented with 1 mg/mL BSA or 5% fetal calf serum (FCS) (assay buffer), washed, and resuspended as described for each procedure. All steps were carried out at 4°C.

Human cells. Peripheral blood mononuclear cells (PBMCs) were fractionated from the peripheral blood of healthy volunteers using a discontinuous gradient of either Ficoll-Hypaque[17] or colloidal silica (Sepracell-MN; Sepratech, Oklahoma City). This procedure removed the bulk of granulocytes, RBCs, and platelets.

Because excessive contamination by platelets resulted in cell clumping during the in vitro binding assay, the cell suspensions were purified further using one of two methods: (a) sequential 200 g, 10 minutes, 4°C centrifugations in calcium, magnesium-free PBS (CMF-PBS), or (b) brief treatment with thrombin as follows. The mononuclear suspension prepared from 60 mL blood was diluted 1:1 with Hank's balanced salt solution (HBS) and centrifuged (~400 g, 15 minutes). The pellet was resuspended in 2 mL of HBS; 10 μL of thrombin solution [1:20 to 1:100 dilution of frozen stock (100 U/mL) in HBS] were then added to 1-mL aliquots of the cell suspension at room temperature. The suspensions were gently agitated (~30 seconds) and centrifuged briefly at 13,000 g to pellet the platelet–fibrin clumps. The mononuclear cells remaining in suspension were pelleted (400 g, 2 minutes, 4°C), the supernatant was discarded, and the cells were resuspended in buffer containing 5% heat-inactivated FCS. Indirect immunofluorescence with T11 (pan-T cell), B1 (pan-B cell), and M01 (monocyte and granulocyte specific) mouse–anti-human monoclonals indicated that PBMC suspensions prepared with either method contained >90% lymphocytes, predominantly mature T cells (data not shown).

T cell lines, isolated after allogeneic stimulation of PBMCs, were provided by Dr Bruce Richardson (Department of Internal Medicine, University of Michigan). Lines were maintained in RPMI 1640 supplemented with 10% calf serum and interleukin 2 (IL 2), pH 7.4, with restimulation by irradiated allogenic PBMCs at 2-week intervals. Cells were harvested during log-phase growth, washed, and resuspended in assay buffer.

HEV binding assay. The binding of lymphocytes to the HEVs of rat lymph nodes was determined essentially as described previously.[12] In brief, suspensions of rat or human lymphocytes were preincubated (15 minutes, 4°C) in the presence of test substances or buffer alone. The suspensions (10×10^6 cells/mL unless otherwise specified) were then applied to paraformaldehyde-fixed, frozen sections of rat cervical lymph nodes and gyrated (60 rpm) at 7 to 10°C for 30 minutes. The cell suspensions were then gently decanted, and the sections were fixed in glutaraldehyde (3% in PBS, 20 minutes, 4°C) and stained with toluidine blue. In some experiments, sections were dipped in PBS several times prior to staining to remove unattached cells. The affinity of lymphocytes for HEVs was determined by measuring the average number of lymphocytes bound to HEVs per 200× microscopic field. The binding after experimental treatment is expressed as the percentage of binding relative to that in the control (cells exposed to buffer alone). This method of analysis facilitated the pooling of data from independent experiments conducted under the same conditions. SEM for this procedure varied from 10% to 30%.

The binding of human lymphocytes to the HEV of human lymph nodes was determined as above except that PBMCs were routinely preincubated with neuraminidase (0.005 U, 30 minutes, 37°C) before binding assays were conducted. This treatment enhanced the adhesive interaction between human lymphocytes and human HEVs without altering specificity (described in the Results section). Human peripheral lymph nodes were snap-frozen in OCT and stored at −70°C until use (2 weeks to 2 months). Only surgical biopsy specimens showing normal or hyperplastic histology were used in the binding assay.

PPME-bead assay. The conjugation of PPME, the polyphosphomonoester core polysaccharide derived from the yeast *Hansenula holstii,* to fluorescent microspheres and the procedure for measuring the attachment of conjugated beads to lymphocytes has been presented in detail elsewhere.[18] In brief, 3 to 7 mg PPME was reacted with cyanogen bromide (100 mg/mL) in distilled water. The pH of the reaction was monitored and maintained at ~11 by the dropwise addition of NaOH (0.5 mol/L). The cyanogen-bromide–activated PPME was separated from free cyanogen bromide over a G50 Sephadex column in borate buffer (0.2 mol/L, pH 8.0, room temperature). The 2 to 3 1-mL fractions with the highest concentration of carbohydrate (determined by the phenol-sulfuric assay) were pooled, diluted 1:10 with borate buffer, and added to 0.6 μm microspheres (100 μL/1 mL PPME solution). After two-24 hour incubations at room temperature, the conjugated beads were washed in distilled water, aliquoted, snap-frozen in liquid nitrogen, and stored at −70°C until use. Conjugated beads prepared in this manner may not withstand long-term storage. Some preparations lost cell binding activity completely within 2 weeks. Therefore, experiments were conducted with freshly thawed aliquots within 7 to 10 days of preparation.

Prior to use, the beads were sonicated to disrupt clumps, washed, and resuspended in assay buffer. The binding assay was initiated by adding 50 μL PPME-beads to 5×10^5 cells in flat-bottomed, 96-well microtiter plates (200 μL final volume; beads diluted 1:32 relative to stock solution). The plates were centrifuged and then allowed to incubate undisturbed for 60 minutes on ice. Cells with attached beads were resuspended, separated from free beads by centrifugation through a 6% BSA solution, and fixed in 1% paraformaldehyde.

Cell-associated fluorescence was quantified on a Coulter Epics V flow cytometer. A narrow low-angle light-scatter gate, set on a control population of cells without attached beads, excluded both cell clumps and free beads from the analysis. A wide 90° light-scatter gate was set to assure that cells with large numbers of attached beads would not be excluded from the analysis. Fluorescence histograms of 5 to 10,000 cells, exposed to either PPME-conjugated or nonconjugated beads, were collected. The fluorescent signal in the latter population was taken as a measure of nonspecific bead attachment and subtracted from the signal measured with PPME-beads (EASY analytic software, Coulter Corp, Hialeah, FL).

The binding of beads to lymphocytes was characterized by measuring both the percentage of fluorescing cells (those with one or more beads attached) and the amount of fluorescence per cell (a measure of the number of beads per cell). Perturbation of the adhesive interaction altered one or both of these parameters. Therefore, a unitless measure of specific bead binding—the product of the percentage of fluorescing cells and the mean fluorescence channel number for the entire population (SBI)—was calculated for each experimental condition. The degree of bead binding in experimental samples was expressed relative to that in control samples (cells exposed to conjugated beads in the absence of additives).

Cell Treatments

Trypsin. Cells were harvested, washed, and resuspended in Dulbecco's PBS. The trypsin digestion was conducted in PBS (10 minutes at 37°C). The reaction was terminated by the addition of excess cold assay buffer. The cells were washed and resuspended in assay buffer and used immediately in binding assays.

EDTA. Prior to the HEV and bead binding assays, cells and beads were washed and resuspended in MEM containing 2 mmol/L disodium EDTA with or without an additional 3 mmol/L calcium or magnesium chloride. The HEV binding assays were initiated by adding cell suspensions directly to tissue sections. The bead-binding assay was initiated by combining cells and beads as described above.

Carbohydrates. Cell suspensions were incubated (15 minutes, 4°C) with carbohydrates prior to the start of the HEV or bead-binding assays. The HEV assays were initiated as described above. Carbohydrates were present throughout the incubation period at the concentrations specified for each experiment.

Neuraminidase. Gradient-purified human PBMCs were incubated (1×10^7 cells/mL, 30 minutes, 37°C) with neuraminidase (0.005 U final concentration in CMF-PBS). The suspensions were subsequently washed in cold assay buffer, resuspended at 5 to 10×10^6 cells/mL, incubated 15 minutes on ice, and then used in lymphocyte-HEV binding experiments. Enzyme treatments were conducted immediately after gradient separation and before exposure to potential inhibitors of the lymphocyte binding interactions (eg, carbohydrates or EDTA).

RESULTS

The adhesive interaction between human lymphocytes and the HEVs of lymph nodes from humans and rats were examined using an in vitro assay adapted from the work of Stamper and Woodruff.[19,20] We used rat PNs as the routine source of HEVs since previous reports indicated that rodent tissues can substitute for analogous human tissues in the in

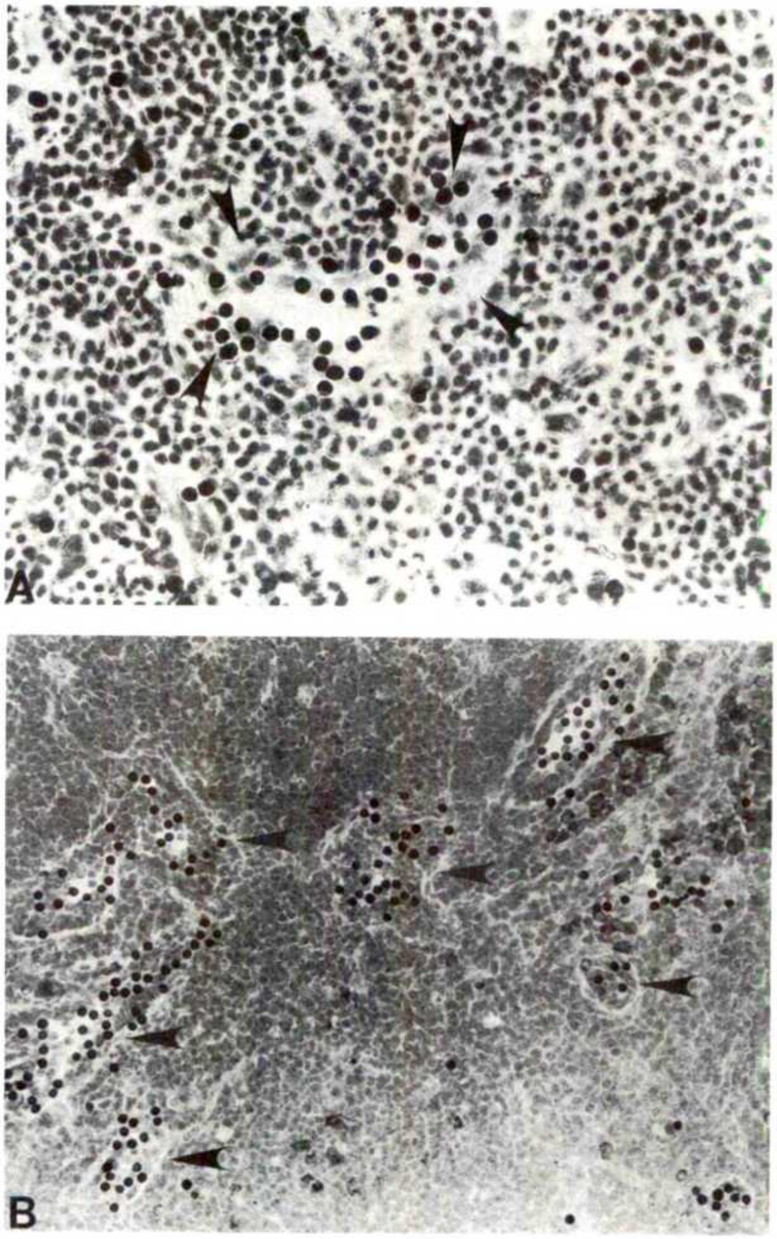

Fig 1. Human PBMCs adhering to the HEVs of human (A) and rat (B) peripheral lymph nodes. Exogenous PBMCs (dark cells 7 to 10 μm in diameter) bind to HEVs (vascular structures with defined lumena and prominent lining cells). In contrast to the HEVs, rat sinusoids (not shown) bind significant numbers of both erythrocytes and lymphocytes, indicating that adhesion to this structure is less specific.

vitro adhesion assay.[21,22] Nonetheless, critical experiments were performed with both human and rat lymph nodes as targets.

Human lymphocytes bound avidly and specifically to the HEVs of paraformaldehyde-fixed, frozen sections of both human and rat lymph nodes (Fig 1A and B). The density of binding over the HEVs was at least 50-fold greater than that to most other regions. This binding interaction could be enhanced by pretreating PBMCs with neuraminidase (Table 1). Such pretreatment did not alter the specificity of inhibitors such as mannose-6-phosphate (M6P) or EDTA (data not shown); it simply increased the baseline density of lymphocyte binding to the HEV.

When tested in parallel at the same cell concentrations, human PBMCs bound 50% to 70% as well as rat nodal lymphocytes to rat HEVs. The magnitude and reproducibility of the binding to rat HEVs far exceeded that to human material, however, and may reflect the lability of the binding sites on HEVs. Rat lymph nodes were snap frozen immediately on removal from the animal and used within hours. Human material could not be frozen as expeditiously, and several weeks generally elapsed before tissues were available for experimental use.

As previously described for rodent lymphocytes, the binding of human lymphocytes to rat HEVs was calcium dependent and trypsin sensitive (Fig 2). Chelation of divalent cations with 2 mmol/L EDTA reduced binding by 70%, the addition of 3 mmol/L Mg^{2+} increased attachment to a slight degree whereas the same concentration of Ca^{2+} returned binding to control levels. A 10-minute preincubation of lymphoid cells with 20 μg/mL trypsin reduced binding by 70% whereas 40 μg/mL eliminated binding completely.

The capacity to attach to rat HEVs was not a characteristic of all human lymphocytes examined. Two IL 2-dependent, T4-positive lymphoid lines failed to bind (Fig 2). In contrast, Navarro et al reported that IL 2-dependent T cell lines bound to human PN-HEVs.[23] This discrepancy may reflect the fact that we examined interspecies rather than intraspecies adhesion. Alternatively, the lines we used may be at a stage of differentiation or proliferation at which the homing receptors were not expressed. Such a relationship has been demonstrated in the murine system. Specifically, immature lymphocytes isolated from the thymus,[24] B lymphoblastoid cells isolated from germinal centers of lymph nodes,[25] and a variety of IL 2-dependent lymphoblastoid cell lines[26] failed to express the Mel 14 antigen, bind to HEVs in vitro, or recirculate in vivo. Therefore, the expression of murine homing receptors appears to be regulated. The nature and extent of such regulation in the human requires further study. Nonetheless, the two human lines were useful negative controls in subsequent experiments.

Table 1. Binding of Human Lymphocytes to Human HEVs

Additive	Neuraminidase Treatment	
	(−)	(+)
None	0.7	2.9
Mannose 1 P	0.3	3.5
Mannose 6 P	0.035	0.8

Human PBMC were isolated from peripheral blood as described in the Materials and Methods section. After preincubation (with or without 0.005 U *Clostridium perfringens* neuraminidase as described in the text), 5 × 10^6 cells/mL were layered on fixed, frozen sections of human peripheral lymph nodes. The mannose-phosphates were present at a concentration of 5 mmol/L. Cell binding to HEVs is reported as the number of cells attached to HEVs per 200× microscopic field. Neuraminidase treatment also enhances the binding of human PBMCs to HEVs of rat lymph nodes (data not shown).

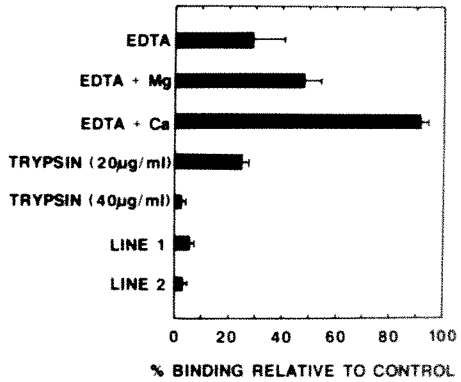

Fig 2. Binding of human PBMCs to rat HEV–divalent cation requirements, trypsin sensitivity, and the interaction with two T cell lines. Three independent experiments are shown. The first three bars show the effects of EDTA (2 mmol/L in assay buffer) with or without additional magnesium or calcium chloride. The next two bars demonstrate the effect that brief trypsinization of the lymphocyte has on their binding activity. The last two bars show the binding activity of two T4-positive T cell lines collected during log phase growth. Data in each of these experiments are expressed as binding relative to untreated PBMC in assay buffer alone. Mean and SEM for each data point were based on four replicate samples.

We next examined the effects of various monosaccharides and polysaccharides on the human PBMC-HEV binding

Table 2. Binding of Human Lymphocytes to HEVs: Inhibition by Carbohydrates

Carbohydrate	Binding Relative to Control	
	Human	Rat
Monosaccharides		
Mannose 6 P	36 (9.5)	14 (5)
Mannose 1 P	84 (8.5)	40 (10)
Fructose 6 P	—	101 (22)
Fructose 1 P	—	15 (5)
Glucose 6 P	—	64 (7)
Glucose 1 P	—	51 (24)
Polysaccharides		
PPME	11 (3.4)	0.5 (0.25)
Fucoidin	15 (4)	2 (1)
Heparin	89 (20)	85 (22)
Chondroitin sulfate	91 (18)	94 (9)
Hyaluronic acid	—	72 (15)

Human PBMCs were prepared as described in the Materials and Methods section; 1 × 10^7 cells/mL were incubated over sections of either human or rat peripheral lymph nodes, with or without added carbohydrates. All monosaccharides were present at 5 mmol/L concentration. Polysaccharides were at 0.1 μg/mL in experiments with human tissue sections and 1.0 μg/mL in experiments with rat tissue sections. The means and SEM (in parentheses) for binding relative to the buffer control were based on a minimum of four replicates.

interaction using both rat and human HEV as targets. In keeping with previous observations in both the rat and mouse systems,[12,18] the attachment of human lymphocytes was inhibited by M6P, the M6P-rich mannan PPME and the sulfated, fucose-rich polysaccharide fucoidin (Table 2). Mannose-1-phosphate (M1P) and a variety of anionic polysaccharides that contain neither fucose nor mannose residues showed significantly less activity. In addition, fructose-1-phosphate, a structural homologue of M6P, inhibited attachment to rat HEVs whereas fructose-6-phosphate and the glucose-phosphates had minimal activity. Thus, human and rodent lymphocytes appeared to use similar carbohydrate binding receptor(s) to attach to HEVs.

The presence of this receptor was confirmed with fluorescent microspheres covalently linked to PPME (PPME-beads). As shown in Fig 3, PPME-beads bound avidly and specifically to human PBMCs. In general, 45% to 75% of the PBMCs bound to PPME-conjugated beads whereas <5% bound to the nonconjugated beads. The percentages of cells that bound PPME-beads (% POS) and the average number of PPME-beads/cell (MCN) varied considerably from one experiment to the next. This variability may reflect batch-to-batch inconsistencies in the conjugation process, leaching of PPME from the bead surface during storage, or modulation of the receptor on the PBMC surface. Physiologic parameters that may alter the expression of the carbohydrate binding receptor(s) are currently under investigation.

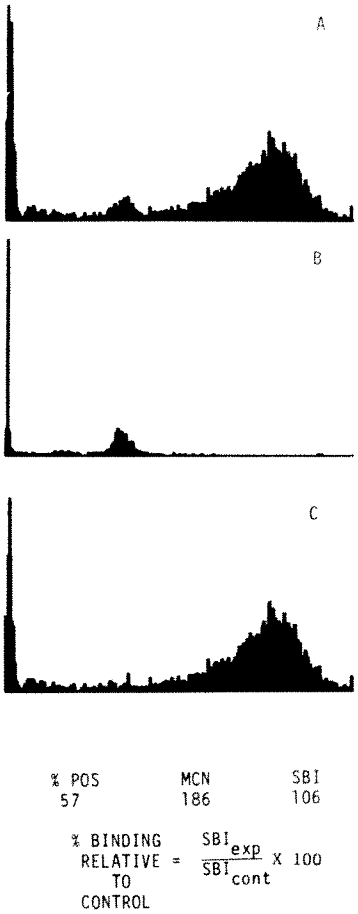

Fig 3. Binding of PPME-conjugated and nonconjugated fluorescent beads to PBMC. (A through C) Fluorescence intensity (256 channels; three-decade log scale) is plotted on the *x*-axis, and the number of cells at each intensity level is registered on the *y*-axis. (A) Distribution of cell-associated fluorescence with PPME-conjugated beads. (B) Distribution of fluorescence with nonconjugated beads. (C) Subtraction histogram (A and B) generated by the IMMUNO analytic software (described in Materials and Methods section). The percentage of the cell population with attached beads (% POS), the mean channel number of the fluorescence distribution (MCN) and the specific binding index (SBI) are calculated from the subtraction histogram; % binding relative to control is the measure used to compare the effects of the various experimental conditions.

The binding of human PBMCs to PPME-beads paralleled the PBMC-HEV adhesive interaction in several respects. First, PPME-bead attachment was calcium dependent and trypsin sensitive (Fig 4). Second, the two T cell lines that failed to attach to rat HEV also failed to express receptors for PPME-beads (Fig 4). Third, the monosaccharide and polysaccharides that inhibited binding to HEV were also effective against PPME-beads (Table 3). Finally, the dose–response curves for the mannose-phosphates, PPME, and fucoidin revealed identical relative potencies in the two adhesion assays. Specifically, M6P was four to fivefold more potent than M1P as an inhibitor of attachment to both HEV and PPME-beads (Fig 5), whereas fucoidin and PPME were equally potent in both assays (Fig 6).

These results parallel those reported by us in mouse[18] and, in Table 4, we report similar findings in the rat. Specifically, the attachment of PPME-beads to rat cervical lymph node lymphocytes was calcium dependent, trypsin sensitive, and inhibited to a greater extent by M6P than M1P. Thymocytes, a nonrecirculating population of cells that do not bind to the HEVs,[26] showed minimal binding to the PPME-beads.

DISCUSSION

In summary, the attachment of normal human PBMCs to PN-HEVs involves a carbohydrate-binding receptor with affinity for M6P and related compounds. Direct analysis, using fluorescent microspheres derivatized with a high-

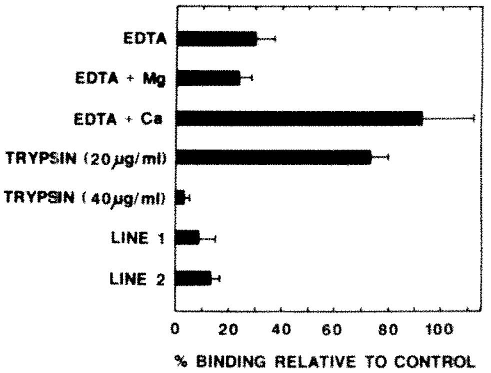

Fig 4. Binding of PBMCs to PPME-conjugated beads–divalent cation requirements, trypsin sensitivity, and the interaction with two T cell lines. The assay was conducted as described in the Materials and Methods section and the legend to Fig 2. Means and SEM were based on a minimum of four replicate samples.

Table 3. Binding of Human Lymphocytes to PPME-Beads: Inhibition by Carbohydrates

Carbohydrate	Binding Relative to Control
Monosaccharides	
Mannose 6 P	19 (5)
Mannose 1 P	97 (22)
Fructose 6 P	96 (3)
Fructose 1 P	35 (7)
Glucose 6 P	91 (5)
Glucose 1 P	86 (6)
Polysaccharides	
PPME	15 (8)
Fucoidin	2 (1)
Heparin	74 (10)
Hyaluronic acid	81 (7)
Chondroitin sulfate	92 (7)

Effects of carbohydrates on the binding of human PBMCs to PPME-conjugated beads. All monosaccharides were present at 5 mmol/L; PPME and fucoidin at 1 μg/mL; heparin at 10 μg/mL; chondroitin sulfate and hyaluronic acid at 100 μg/mL. Means and SEM (in parentheses) were based on a minimum of four replicate samples.

affinity polysaccharide ligand (PPME), reveals that the receptor is functionally similar to those on rat and mouse lymphocytes. Therefore, the attachment of human, rat, and mouse lymphocytes to lymph node HEVs involves a lectinlike receptor on the lymphocyte surface in each species.

Jalkanen et al recently reported antigenic crossreactivity between murine and human PN-homing receptors.[27] In addition, Mel 14 (a monoclonal antibody specific for the PN-homing receptor of murine lymphocytes)[6] blocked the attachment of human PBMCs to the HEVs of both human and murine lymph nodes but not to the HEVs of GALTs. In addition, we recently showed that the MEL 14 antigen is closely linked or identical to the carbohydrate-binding receptor on murine lymphocytes and lymphomas.[14] Therefore, the activity of MEL-14 in the human system further supports the proposal that PN-homing receptors are highly conserved cell-surface lectins.

The fact that the same spectrum of carbohydrates inhibits the attachment of human PBMCs to HEVs from either human or rat peripheral lymph nodes suggests that the ligand for the PN-homing receptor on the HEVs is similarly conserved during evolution. Previous studies have reached similar conclusions. Jalkanen et al isolated EBV-transformed human lymphoblastoid lines that show identical tissue binding specificities toward human and mouse HEVs.[21] Woodruff et al reported a polyclonal rabbit anti-human lymphocyte antibody that blocks the attachment of human PBMCs to the HEVs of human tonsil and rat cervical lymph node.[22] This antibody failed to inhibit the attachment of human PBMCs to rodent mesenteric lymph nodes. Thus, several independent investigations indicate that the organ selective determinants on HEVs are preserved across species lines.

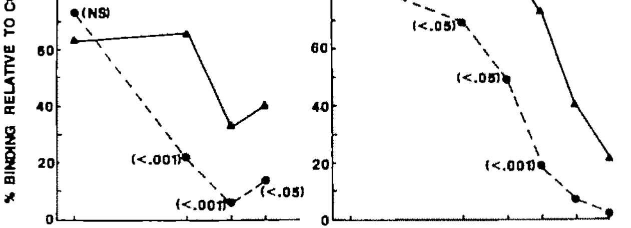

Fig 5. Dose–response curves for mannose phosphates effects on human PBMCs attachment to HEVs (A) and to PPME-conjugated beads (B). Each data point is pooled from 8 to 14 replicates collected from two to four independent experiments. The level of significance (based on Student's distribution) for the differences between M1P (▲) and M6P (●) is recorded in parentheses adjacent to the data points for the latter.

Neuraminidase-treated PBMCs were used to enhance the sensitivity and reproducibility of the human lymphocyte-human HEV binding assay. Although not used extensively in the current study, this treatment similarly accentuated specific binding to both rat HEVs and PPME-beads (data not shown). Therefore, it has become our standard method for conducting all binding assays with human PBMCs.

Mild neuraminidase treatment appeared to enhance adhesion without altering the interaction of the PN-homing receptor with carbohydrate ligands. This is in keeping with the work of Samlowski et al showing that the murine PN-homing receptor functions normally in vivo after neuraminidase treatment ex vivo if one inhibits the sequestration of infused lymphocytes in the liver.[28] Desialation of cell-surface structures may enhance their interactions with specific ligands,[29] as documented in the homotypic interaction of purified neural cell adhesion molecules (N-CAMs) with endogenous N-CAMs on intact cells.[30] In addition, generalized removal of sialic acid residues from the cell surface reduces the net negative charge, resulting in nonspecific accentuation of adhesive phenomena. Therefore, neuraminidase treatment in vitro may directly alter the activity of the lymphocyte homing receptor or indirectly enhance adhesion by reducing surface charge.

The accentuation of lymphocyte binding to HEVs after treatment of the lymphocytes contrasts sharply with the complete inhibition of the binding interaction after neuraminidase treatment of the HEVs.[15] The latter result indicates that sialic acid may be part of the lymphocyte-binding site on the HEVs. Thus, sialic acid moeities on both the lymphocyte and the HEVs can influence their adhesive interaction in vitro. Control of intercellular adhesion through modulation of receptor-associated sialic acid has been proposed for N-CAM[31] based on the correlation between neural cell adhesion and polysialation of N-CAM in brain tissues.[32,33] Whether a similar mechanism regulates the lymphocyte–HEVs interaction in vivo remains to be determined.

The precise relationship of the lymphocyte lectin to adhesive structures such as the Hermes 1 antigen[21] and LFA-1[34] remains to be determined. The Hermes 1 monoclonal appears to recognize an epitope common to the binding sites on lymphocytes for the HEVs of both peripheral lymph nodes and GALTs. The PN-homing receptor precipitated by

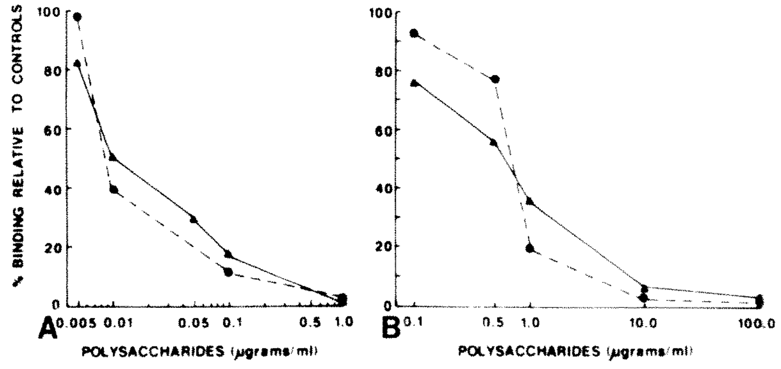

Fig 6. Dose-response curves for PPME and fucoidin effects on human PBMC attachment to HEVs (A) and to PPME-conjugated beads (B). The means of three to six replicate samples are plotted. There was no significant difference between PPME (▲) and fucoidin (●).

Hermes 1 crossreacts with MEL-14 and consists of a single, 90-kd polypeptide, suggesting structural homology between the human and murine structures. In light of the relationship between gp 90 Mel-14 and the murine lectin, we are currently examining the possibility that the Hermes 1 antigen is similarly linked to the human carbohydrate-binding receptor.

LFA-1 participates in a variety of adhesive interactions involving lymphocytes including T cell-mediated cytotoxicity,[35] NK-mediated cytotoxicity,[36] and binding to human umbilical vein endothelium.[37,38] This latter observation has led to speculation that LFA-1 contributes to lymphocyte recirculation and/or migration into chronic inflammatory lesions. Several lines of evidence indicate that LFA-1 is distinct from the cell-surface lectin involved in binding to PN-HEVs. First, binding of lymphocytes to HEVs in vitro is most efficient at 8°C; LFA-1-mediated adhesion is markedly reduced at low temperature.[39] Second, the binding of lymphocytes to PN-HEVs requires calcium, whereas LFA-1-mediated processes are magnesium dependent.[30,39] Third, most murine thymocytes express LFA-1 but neither express the cell-surface lectin nor bind to HEVs. Finally, in S49 murine lymphoma lines, LFA-1 is expressed equally on cell lines with high and low HEV-binding activities.[14] Only the expression of PPME-bead binding sites and Mel-14 antigen correlate with affinity for PN-HEVs. Thus, LFA-1 appears to be distinct from the family of carbohydrate-binding molecules we have described in rodents and humans. Concerted action of the PN-homing receptor and LFA-1 in situ, however, remains an intriguing possibility.

Table 4. Binding of Rat Lymphocytes to PPME-Beads

Cells	Treatment	PPME-Bead Binding
Lymphocytes	Control	100 (28)
	EDTA	18 (1)
	EDTA + Ca^{2+}	70 (12)
	EDTA + Mg^{2+}	24 (5)
Lymphocytes	Control	100 (15)
	M1P	73 (2)
	M6P	17 (6)
Lymphocytes	—	100 (10)
Thymocytes	—	5 (3)
Lymphocytes	Control	100 (5)
	Trypsin	4 (2)
	Trypsin + trypsin inhibitor	94 (14)

Binding of rat lymphocytes to PPME-conjugated beads. The assays were conducted as described in the Materials and Methods section. The analytic procedure for measuring bead attachment differed slightly from the technique used in the above experiments and is described in detail elsewhere.[18] Means and SEM (in parentheses) are based on a minimum of four replicates.

The interactions of PBMCs with PPME-beads and HEVs require Ca^{2+} and show a relatively modest difference in the inhibitory potencies of M6P *v* M1P. These observations contrast with the characteristics of both the high and low molecular weight phosphomannosyl receptors (PMRs) that have been implicated in the intracellular transport of acid hydrolases to the lysosome.[40-44] Recently, both PMRs have been detected in human lymphoid cells and may be expressed at the cell surface.[45] The relationship between these receptors and the PN-homing receptor is currently under study.

The nonspecific inhibition by the glucose phosphates in the HEV-binding assay has been observed with rodent cells[18] and reflects the role of ionic forces in the adhesive interaction. In rodents, increasing the ionic strength above physiologic levels resulted in progressive inhibition of lymphocyte attachment whether the ionic species was sodium chloride or anionic carbohydrates.[11] Furthermore, desulfation of fucoidin and dephosphorylation of PPME eliminated inhibitory activity (L.M. Stoolman and S.D. Rosen, unpublished observations).[12] Inhibition by PPME, fucoidin, M6P, and F1P consistently exceeded that expected on a charge basis alone, however.[12] Thus, biologic activity requires more than the mere presence of negatively charged groups. Perhaps, as has been suggested for the cell-binding domain of fibronectin,[46] the spatial orientation of such groups will prove to be a key factor.

The relationship between the exogenous carbohydrate inhibitors and the endogenous HEV attachment site remains to be defined. Investigation of the murine HEVs indicates that terminal sialic acid residues are critical to the activity of the PN-HEVs attachment site.[15] A more detailed analysis of the PN-HEVs attachment site will be required to determine whether it shares key structural features with either PPME or fucoidin. Such an analysis will also help determine whether the carbohydrate-binding receptor on the lymphocyte attaches directly to the HEVs or, as suggested for ligatin,[47] acts as a membrane attachment site for a ligand that forms an intercellular bridge.

The present study amplifies the work of Butcher et al,[48] who proposed that evolutionary mutations in the interacting adhesive molecules on lymphocytes and HEVs resulted in progressive interspecies incompatibility. They also observed a baseline level of compatibility between widely separated species, however, thus suggesting the persistence of certain essential structural features in the adhesive interaction. The current study indicates that a carbohydrate-binding receptor at the lymphocyte surface is a conserved essential determinant for recognition of PN-HEVs.

ACKNOWLEDGMENTS

We wish to thank Mary Burton and Hazel Ebling for their expert technical assistance. In addition, this study would not have been possible without the staff of the Flow Cytometry Laboratory, Department of Pathology, University of Michigan. We are indebted to Dr M.E. Slodki and his staff at the US Department of Agriculture, Northern Regional Research Center, Peoria, IL, for their generous gift of PPME.

Spontaneous Production of Interleukin 1 Activity by Chronic Lymphocytic Leukemic Cells

By Charlotte Uggla, Miguel Aguilar-Santelises, Anders Rosén, Håkan Mellstedt, and Mikael Jondal

Chronic lymphocytic leukemic B cells (B-CLL) were found to produce an IL 1-like growth factor spontaneously in vitro for mouse thymocytes. This factor was comitogenic with concanavalin A (Con A) and nonmitogenic combinations of phorbol ester and calcium ionophore but not with phytohemagglutinin (PHA). Growth factor production was dose-related to the number of in vitro cultured cells and detectable at 6 hours using high cell concentrations. A small number of admixed normal T cells was not important for factor production. No growth of autologous B-CLL or allogeneic thymocytes was induced by the factor. A chromatographic high-performance liquid chromatography (HPLC) analysis and inhibition experiments with a polyclonal rabbit anti interleukin 1 (IL 1) antiserum indicated that the B-CLL–derived growth factor belonged to the IL 1 family. This was supported by the direct demonstration of IL 1 β in supernatants from B-CLL by radioimmunoassay. Possible biologic implications for B-CLL–derived IL 1 are discussed in relation to tumor cell growth in different clinical stages.

© 1987 by Grune & Stratton, Inc.

CHRONIC lymphocytic leukemia of B cell type (B-CLL) is characterized by a clonal proliferation of cells that can differ substantially with regard to malignant behavior.[1-3] Rai et al proposed a clinical staging system (0 through IV) in which stage 0 is characterized by a blood lymphocytosis but no other disease-related findings. In stage IV, the disease is progressive with thrombocytopenia and anemia. The median survival for stage 0 is >8 years whereas stage IV patients survive for 9 months only.[4] The reasons for this wide variability in malignant behavior are not well understood but could be related to both an aberrant T cell control[5,6] as well as to inherent growth characteristics of individual cell populations.[7,8]

Regulation of B cell growth is highly complex and dependent on the combined effect of different factors for initiation and continued maintenance of cell cycling.[9,10] Melchers et al defined three different restriction points in the B cell cycle.[11] The first of these is triggered by antigen through interaction with specific Ig receptors and enters the cell into the G1 phase. The second is located in late G1 and is dependent on monokine factors such as IL 1 (α factors). The third one is positioned in G2 and is triggered by T cell products such as BCGF (β factors). Differences in growth potential between different B-CLL clones could thus be related to both an aberrant growth factor production and an increased tendency of the tumor cells to pass certain restriction points.

Interleukin 1 (IL 1) was originally described as a monokine but has recently been shown to be produced by a number of different cell types.[12] Two different monocyte-derived IL 1 genes have been cloned which code for IL 1α (pI 5.0 and 17 kd) and IL 1β (pI 7.0 and 17 kd) with distinct molecular properties.[13,14] Biologic IL 1 activity has also been found in polypeptides ranging from 2 to 75 kd,[15] the larger being an aggregate form and the smaller cleavage product from a 31-kd precursor molecule. IL 1 induces a multitude of biologic activities such as fever, production of acute phase reactants, coactivation of lymphocytes, chemotaxis of polymorphonuclear (PMN) leukocytes, proliferation of fibroblasts and endothelial cells, and different forms of antitumor cell defense mechanisms.[16]

In the immune response, macrophage-derived IL 1 induces the upregulation of IL 2 receptors on T cells and also acts as a growth factor for B cells. In addition, clonal B cells produce IL 1 in line with their macrophagelike capacity to process and present antigen.[12] Recently, Pistoia et al demonstrated that both normal B cells and some B chronic leukemic cells produce IL 1 in the absence of any apparent stimulus.[17] Some Epstein-Barr virus (EBV) transformed B cell lines produce both IL 1 and "contra IL 1."[18,19] This IL 1 activity may be mediated by factors that differ from monocyte-derived IL 1, as shown by protein sequencing and neutralization studies.[20]

When analyzing growth factors secreted by B CLL cells in vitro, we found no spontaneous production of B cell growth factor (BCGF); BCDF or IL 2 but evidence for IL 1-like factor activity (B-CLL–derived IL 1) in the standard mouse thymocyte assay. The present work further defines IL 1-like activity from a progressive stage IV patient with regard to comitogenicity with different inducers of proliferation, direct growth-inducing properties, and susceptibility to inhibition by polyclonal antibodies. In addition, the presence of IL 1β has been analyzed in supernatants from B-CLL cultures representing different clincial stages.

MATERIALS AND METHODS

Isolation and fractionation of leukemic cells. AD B-CLL were obtained by leukapheresis. Cells were then isolated using the Ficoll-Hypaque one-step density-gradient technique and frozen in 10% dimethylsulfoxide (DMSO) with 20% fetal calf serum (FCS) for later use. Normal lymphocytes present in B-CLL preparations were analyzed using monoclonal antibodies against CD3, CD16, and CD13 and by rosette formation for detection of CD2 receptors. Normal T cells were removed using sheep RBC (SRBC) sedimentation with AET-treated SRBC as described.[21] Additional leukemic

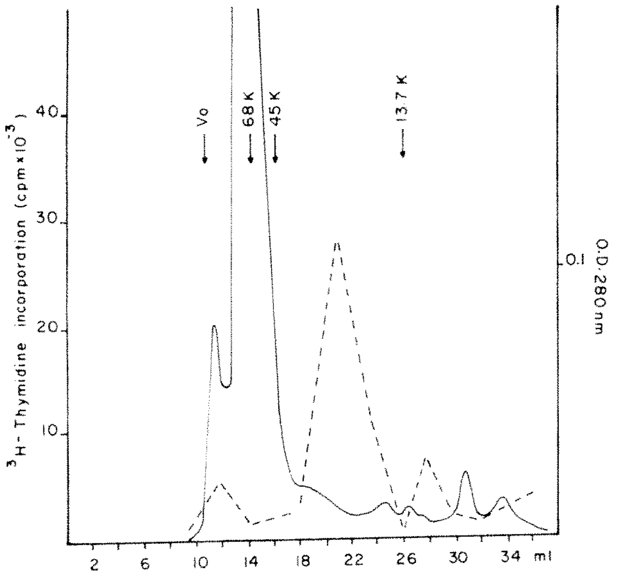

Fig 1. Supernatant material from AD B-CLL culture was concentrated and purified in a two-step HPLC procedure using a hydroxylapatite Biogel HPHT column and an Ultropac TSK-G2000 SW column as described in the Materials and Methods section. Fractions were tested for protein content (——) and induction of direct mitogenicity on mouse thymocytes (------).

cell populations were obtained from peripheral blood, isolated as above and used without further purification.

Supernatants from normal B cells and B cell lines. Peripheral blood samples from normal donors were depleted of T cells by repeated rosetting and Ficoll-Hypaque centrifugations. B cells with <1.0% T cells contamination were cultured at different concentrations, between 2 and 25 × 10^6/mL. Supernatants were collected after 24 hours and tested for direct mitogenic effect in the mouse thymocyte assay. B cell lines were cultured at a concentration of 1 × 10^6/mL, and supernatants were collected at 24 hours.

IL 1 assay and comitogenicity assays. IL 1 activity was measured in the standard mouse thymocyte proliferation assay.[22] In short, 1.5 × 10^6 thymocytes from C3H/HeJ mice were cultured for 72 hours in standard 96-well microplates and pulsed for the last 8-hour period with 1 μCi ^{3}H-thymidine. Supernatants to be tested were diluted twofold from a starting concentration of 50%. These were either tested alone or in the presence of phytohemagglutinin (PHA) (5 μg/mL) or a combination of phorbol ester TPA (30 ng/mL) and calcium ionophore A 23187 (0.1 μmol/mL) for a comitogenic response. All measurements were done in triplicate, and only representative experiments are given in which mean error deviations were <5%.

BCGF, BCDF, and IL 2 assays. BCGF activity was tested on purified and anti-IgM prestimulated normal tonsillar B cells as described.[23] BCDF activity was evaluated by secreted IgG in BCGF assays. IL 2 activity was measured on the IL 2-dependent mouse T cell line CTLL-2 as described.[24]

Radioimmunoassay. A commercial radioimmunoassay for determination of IL 1β was used. In brief, anti IL 1β was mixed with standard or test samples and incubated for 16 hours at room temperature before ^{125}I-IL 1β was added. After an additional 16 hours, antibody-bound–labeled IL 1β was separated by addition of polyethylene glycol 6000 in phosphate-buffered saline (PBS) containing anti-rabbit IgG serum, followed by centrifugation. Supernatants were then decanted and labeled antibody-bound IL 1β was counted in a γ counter (1282 Compugamma LKB). Duplicate controls for total counts (^{125}I-IL 1β alone) and nonspecific binding were also included. Calculations of the bound IL 1β were made according to a standard formula, and interpolations were made from a standard curve.

Preparation of B-CLL–derived IL 1-like factors (B-CLL IL 1). B-CLL were obtained by leukapheresis, washed several times in PBS with 5% FCS, and counted. Contaminating RBCs were removed by centrifugation on Ficoll-Hypaque if necessary. Cells were adjusted to the desired cell concentration in RPMI 1640 medium with antibiotics and 5% FCS and added to 24-well Costar plates in a total volume of 2 mL. Bulk preparations of B-CLL IL 1 were produced by culturing B-CLL at high concentrations (usually 30 × 10^6/mL) in tissue culture bottles. Serum-free preparations of B-CLL IL 1 were produced in adjusted Iscove's medium containing transferrin (12.5 μg/mL), bovine serum albumin (BSA) (400 μg/mL), and 2-mercaptoethanol (5 × 10^{-5} mol/L).

HPLC chromatography. B-CLL from patient AD were cultured for 2 days in Iscove's medium containing 400 μg/mL BSA (Boehringer, Darmstad, FRG) and 12.5 μg/mL human transferrin (Kabi, Stockholm) with penicillin, streptomycin, and L-glutamine as additives. The cells were seeded at 5 × 10^6/mL and kept in a humidified incubator at 37°C in 5% CO$_2$. To determine the biochemical properties and the mol wt of the B-CLL IL 1, released supernatants were concentrated and dialyzed against 10 mmol/L phosphate buffer pH 7.2 containing 1 mmol/L Ca Cl$_2$ on collodium bags with 10-kd mol wt cutoff (Schleicher and Schull, FRG). The concentrated material (2 mL) was purified in a two-step high-performance liquid chromatography (HPLC) procedure according to Köck and Lugger. First, a hydroxylapatite separation on a Biogel HPHT column was performed using a 10 to 500 mmol/L sodium phosphate gradient. The activity peak of IL 1 was concentrated and dialyzed against PBS + 0.1% polyethylene glycol (PEG) 4000 (Merck). The material (0.2 mL) was separated on an Ultro-pac TSK-G2000 SW (7.5 × 600 mm) column equilibrated with PBS + 0.1% PEG 4000, collecting 2-mL fractions (Fig 1). Fractions were tested at dilutions of 1:4 and 1:8 in the mouse thymocyte assay. Mol wt markers were blue dextran (2 × 10^3 kd) like the void volume, and BSA (68 kd), ovoalbumin (45 kd), and RNA (13.7 kd).

Reagents and antisera. PHA was purchased from Wellcome Diagnostics (Dartford, England). Phorbol ester TPA, 2-aminoethyl isotiouronium bromide hydrobromide, and Calcium ionophore A

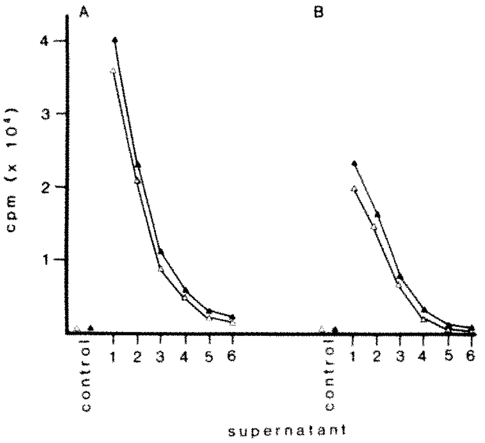

Fig 2. Supernatant from AD B-CLL culture was tested for IL 1-like activity on mouse thymocytes in a standard 72-hour assay. Supernatant was added at different concentrations (1 to 6) starting from 50% and using twofold dilutions. Mouse thymocytes were used at cell concentrations 8 × 10^5/well (A) and 4 × 10^5/well (B) with (△—△) and without (▲—▲) PHA at 5 μg/mL.

23187 were purchased from Sigma Chemical (St Louis). Blue dextran, BSA, ovoalbumin, RNA and concanavalin A (Con A) were purchased from Pharmacia Fine Chemicals (Uppsala, Sweden). Antisera against IL 1, purified IL 1, and IL 1β (^{125}I) radioimmunoassay (RIA) were purchased from Eurogenetics N. V. (Cistron, Biotechnology), Belgium.

RESULTS

B-CLL–derived IL 1-like growth factors in supernatants from tissue-cultured cells. B-CLL were isolated from a patient undergoing regular leukapheresis as part of the treatment schedule. The cells were tissue cultured at a concentration of 4 × 10^6/mL in RPMI 1640 with 5% FCS. Supernatants were analyzed for BCGF, BCDG, or IL 1 and IL 2 activity in standard biologic assays.[22-24] At no time (24, 48, and 72 hours) were any detectable levels of BCGF, BCDF, or IL 2 found (not shown) although an IL 1-like activity was already apparent at 24 hours (Table 1). An even higher factor activity was found if serum-free conditions were used. Among the B-CLL a small contamination of normal T cells was found, but no levels of CD 16 (NK) or CD 13 (monocytes)-positive cells were detectable. If the small fraction of normal T cells was removed by rosetting, similar levels of B-CLL IL 1 activity remained (Table 1).

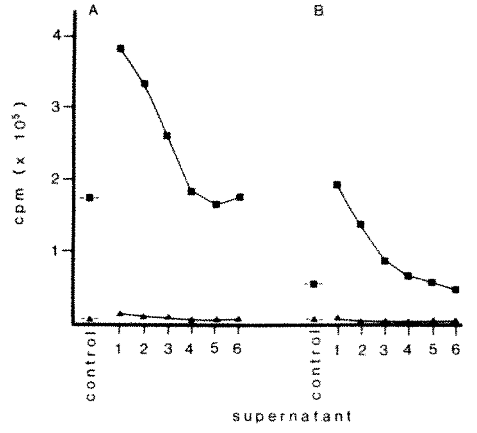

Fig 3. Supernatant from AD B-CLL culture was tested for IL 1-like activity on mouse thymocytes in a standard 72-hour assay. Supernatant was added at different concentrations (1 to 6) starting from 50% and using twofold dilutions. Mouse thymocytes were used at cell concentrations 4 × 10^5/well (A) and 2 × 10^5/well (B) with (■—■) and without (▲—▲) Con A at 5 μg/mL.

‡Phorbol ester TPA was used at a final concentration of 30 ng/mL and calcium ionophore A 23187 at 0.1 μmol/mL.

Comitogenic properties of B-CLL IL 1. To characterize B-CLL IL 1 functionally, the comitogenic properties were tested with PHA, Con A, and/or combinations of phorbol ester TPA and calcium ionophore A 23187. B-CLL IL 1 was directly mitogenic for mouse thymocytes, and the addition of PHA did not influence the results (Fig 2). With Con A instead of PHA, however, a direct mitogenic response to the lectin occurred that was markedly potentiated by B-CLL IL 1 (Fig 3). In comparison with B-CLL IL 1's direct mitogenicity at a final supernatant concentration of 50%, Con A-dependent comitogenicity gave approximately ten times

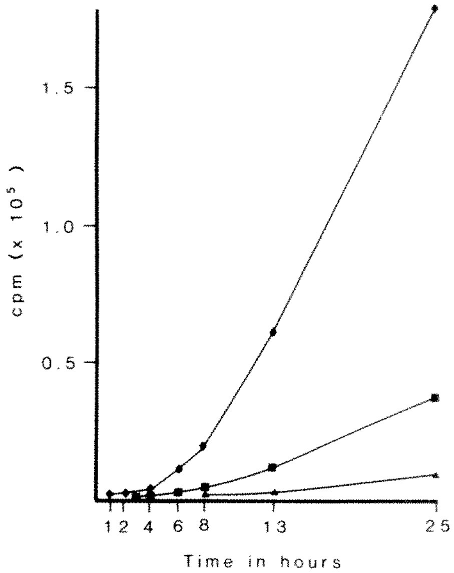

Fig 4. AD B-CLL were cultured at 4 × 10^6/mL. Supernatants were collected at different times and tested at final concentrations of 50% (♦—♦), 25% (■—■), and 12.5% (▲—▲) for a comitogenic response with TPA (30 ng/mL) and calcium ionophore A 23187 (0.1 μmol/mL). Background proliferations were <1 × 10^3 cpm.

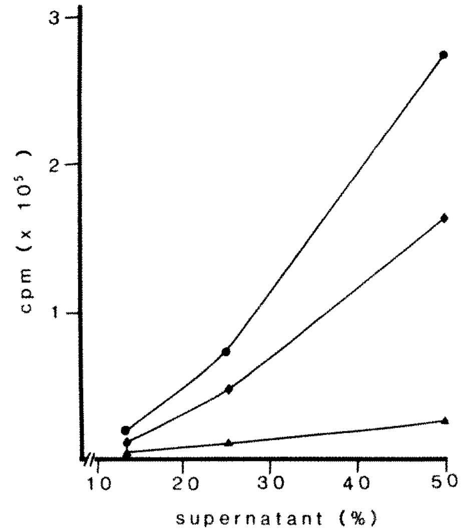

Fig 5. AD B-CLL were cultured at cell concentrations 8 × 10^6/mL (●—●), 4 × 10^6/mL (♦—♦), and 2 × 10^6/mL (▲—▲). Supernatants were collected at 24 hours and tested with calcium ionophore A 23187 and TPA (described in legend to Fig 4) for induction of mouse thymocyte proliferation. Background proliferation was 0.7 × 10^3 cpm.

more counts per minute per cell basis although the background was considerable. To optimize B-CLL IL 1 detection, combinations of TPA and calcium ionophore were tested for comitogenicity. TPA at 30 ng/mL and calcium ionophore A 23187 at 0.1 μmol/mL did not stimulate any background proliferation but allowed a sensitive detection of an IL 1-like comitogenic effect (Table 2).

Kinetics and dose dependency of B-CLL IL 1 formation. B-CLL cells were tissue cultured at 4 × 10^6/mL. Supernatants were collected at different times and tested at final concentrations of 50%, 25%, and 12.5% for a comitogenic response with TPA and calcium ionophore. With 50% supernatants, some B-CLL IL 1 activity was already detectable at 6 hours (Fig 4). Peak activity was obtained at 24 hours (not shown).

A dose-response relationship was established between the number of cultured B-CLL and B-CLL IL 1 activity in the TPA/calcium ionophore coresponse assay (Fig 5). At more than 4 × 10^6 B-CLL/mL there appeared to be a linear correlation, as 8 × 10^6/mL gave almost a doubling of the proliferative response.

Effect of B-CLL IL 1 on autologous cells and allogeneic thymocytes and lymphocytes. B-CLL IL 1 was tested for direct mitogenicity on mouse thymocytes, autologous B-CLL, and allogeneic thymocytes and lymphocytes. Although B-CLL IL 1 was directly mitogenic for mouse thymocytes, none of the other cell types responded in a 72-hour proliferation assay (Table 3). When B-CLL IL 1 was tested for comitogenicity with TPA/calcium ionophore on allogeneic thymocytes and lymphocytes, there was no response of the thymic cells but a clear low-grade response of the peripheral lymphocytes (not shown).

Inhibition of B-CLL IL 1 by anti-IL 1. Two different anti-IL 1 preparations were tested for inhibition of B-CLL IL 1-dependent direct mitogenicity on mouse thymocytes (Table 4). One antisera was an IL 1-neutralizing polyclonal rabbit antiserum; the other was a nonneutralizing monoclonal antibody. Purified IL 1 was also included in the assay. The neutralizing antiserum neutralized both IL 1 as well as B-CLL IL 1 to a similar degree.

Study of B-CLL IL 1 by HPLC chromatography and activity of the fractions. Supernatants were concentrated ten times, purified, and analyzed as described in the Materials and Methods section, after HPLC hydroxylapatite and gel filtration. As shown in Fig 1, the highest IL 1-like activity was related to the 17-kd region, which is in concordance with previously reported mol wt for human IL 1. The effect from B-CLL IL 1 on the mouse thymocyte proliferation assay was directly observed in the absence of PHA or Con A.

B-CLL IL 1 activity in unfractionated leukocyte preparations from different chronic leukemias. Whole leukocyte fractions from five additional chronic leukemic patients were cultured for 24 hours, and supernatants from cultures were tested for IL 1-like activity, measured as direct mitogenicity or comitogenicity with TPA/calcium ionophore on mouse thymocytes (Table 5). All three cases of B-CLL were positive in both systems, with a strong potentiation by the presence of TPA/calcium ionophore. With the other leukemias, a low-grade induction of direct mitogenicity, less amplified by TPA/calcium ionophore as compared with B-CLL, was found. WBC counts varied widely; however, >90% were leukemic cells.

Identification of IL 1β by RIA. IL 1-like activity in supernatants from leukemic, cultured cells was analyzed by means of an IL 1β (^{125}I) RIA. A comparison between the mouse thymocyte assay and IL 1β (^{125}I) RIA was done (Table 6). B cell line supernatants were negative in both

assays. Supernatants from normal cultured B cells were negative in the mouse thymocyte assay. There was no direct correlation between results from the different assays. Supernatants containing high concentrations of IL 1β did not correspond to higher responses in the mouse thymocyte assay. Particularly with the supernatants from patients AD and JÅ no such correlation was found.

DISCUSSION

Isolated B-CLL spontaneously produced IL 1-like factors in vitro but not BCGF, BCDF, or IL 2. Similarly to human monocyte IL 1, B-CLL IL 1 was directly mitogenic for mouse thymocytes and comitogenic with Con A.[25,26] The mouse thymocyte proliferation assay was not influenced by PHA in contrast to the effect of Con A. In absolute numbers of counts per minute, the comitogenicity with Con A gave approximately five to ten times more counts although supernatants titered to similar endpoints in both assays. Because Con A also is directly mitogenic for mouse thymocytes, we used a nonmitogenic combination of phorbol ester TPA and calcium ionophore. With this combination, the concentration of the ionophore (0.1 μmol/mL) was crucial to avoid background stimulation and to optimize comitogenicity.

B-CLL produced strong B-CLL IL 1 activity that was easily detected if tested for comitogenicity with TPA/calcium ionophore. Among the different leukemic cells there was no obvious relationship between disease activity and B-CLL IL 1 production. Only AD cells, however, were tested as purified B-CLL. Thus, normal cells were present among the leukemic cells, although they comprised <10%. These cells may contribute to the spontaneous production of IL 1.[17,25] Hence, a clear B-CLL origin of B-CLL IL 1 was only established with AD cells. This patient died 10 months after initiation of the study. Numerous cells from leukapheresis were obtained in numbers $>10^{11}$ and can thus serve as an abundant source for further isolation and characterization of B-CLL IL 1.

B-CLL IL 1 production in the present system was spontaneous and did not require stimulation with LPS as noted earlier.[17] Although an endotoxin contamination in FCS, present in culture medium, was not formally ruled out, B-CLL IL 1 production was even higher if serum-free conditions were used (data not shown) as described for IL 1. B-CLL IL 1 production did not require proliferation of B-CLL because these were essentially nonproliferative and factors production was detectable as early as after 6-hour culture at high cell concentration as noted earlier.[17] Although B-CLL cells did not proliferate spontaneously, either with endogenous or additional B-CLL IL 1, cells could be triggered to divide at 48 hours with TPA and calcium

ionophore (data not shown). Whether endogenous B-CLL IL 1 is important for this proliferation is unclear.

Inhibition of B-CLL IL 1 activity by an IL 1-neutralizing polyclonal rabbit antiserum, but not by a monoclonal antibody, strongly indicated a similarity to monocyte-derived IL 1. Additional neutralization studies with anti-IL 1α and β, should contribute to its further definition. Also the chromatographic behavior of B-CLL IL 1 on HPLC-HPHT (high performance hydroxylapatite) and TSK-G2000 SW columns suggested a similarity to monocyte-derived IL 1. The binding properties on a hydroxylapatite Biogel HPHT column with elution at 0.23 to 0.28 mol/L sodium phosphate are identical for B-CLL IL 1 and monocyte-derived IL 1. TSK-G2000 SW HPLC gel filtration also gives similar activity peaks for B-CLL IL 1 and monocyte IL 1 (10 to 20 kd with maximum at 17 kd). In addition, it is clear that IL 1β was spontaneously produced by the leukemic cells. Supernatants from normal B cells and B cell lines did not produce significant stimulation in the mouse thymocyte assay. B cell lines did not produce detectable levels of IL 1β.

The thymocyte assay and the IL 1β (^{125}I) RIA did not give identical results (Table 6). One supernatant with a high RIA level gave a poor thymocyte proliferative response (HM in Table 6), and several high responders in the thymocyte assay were low in RIA measurements. This indicates production of enhancing/suppressor factors by the B-CLL and/or the formation of different IL 1-like factors.

The biologic and clinical significance of B-CLL IL 1 is still unclear. The detection of IL 1-like factors in nonmonocytic cells is not surprising because both normal B cells and, indeed, most nucleated cells can produce similar factors.[16] A further characterization and analysis of B-CLL IL 1 should be done in accordance with the work by Wakasugi et al,[19,20] who demonstrated a novel type of IL 1 in an EBV-containing B cell line which functions as an autocrine growth factor. The described IL 1 was not neutralized by polyclonal antimonocytic IL 1 antibodies, however, and thus was distinct from our B-CLL-derived IL 1-like factor.

Pistoia et al analyzed B-CLL IL 1 production in purified B-CLL from 12 patients and found activity in nine but not obvious relationship to the stage of the disease.[17] In additional work, IL 1 activity should be measured in serum and urine in individual patients, and an effort should be made to analyze whether increased levels of IL 1 influence T cell immunity in these patients as the T cell system is clearly aberrant in B-CLL.[5,6] Another interesting question is whether increased IL 1 concentrations, either systemic or local, increase stem cell activity in bone marrow for the B-CLL clone as measured by colony formation in vitro.[27]

In summary, some B-CLL spontaneously produce factors in vitro that have characteristics of IL 1. Among them, IL 1β has been identified. A further characterization of B-CLL-derived factors should be facilitated by the availability of large numbers of clonal cells.

Dermatan Sulphate Induces Plasminogen Activator Release in the Perfused Rat Hindquarters

By Marzia Abbadini, Guang Jin Zhu, Antonio Maggi, Jerta Pangrazzi,
Maria Benedetta Donati, and Luciana Mussoni

Heparin or heparin-like substances have been described to induce the release of plasminogen activator (PA) activity in different animal perfusion models. In this paper we report that Dermatan Sulphate (DS) is able to induce PA activity release in the perfused rat hindquarters. Perfusion of different doses of DS (0.1 to 0.8 mg/mL) stimulates a release of PA activity that is maximum after the initial two minutes of perfusion. The amount of PA activity released rises progressively within a certain concentration range of DS (0.1 to 0.4 mg/mL) and declines thereafter (0.6 to 0.8 mg/mL). The type of PA activity increased during DS perfusion was characterized by SDS-PAGE and fibrin autography as tissue-type PA (t-PA) on the basis of its mol wt (67,000 d) and inhibition by a specific anti t-PA antiserum. This effect might be considered as potentially contributing to the antithrombotic activity of DS, at least at the local level.

© 1987 by Grune & Stratton, Inc.

PREVIOUS investigations have shown that heparin and heparin-like substances can interact with proteins of the fibrinolytic system, both in ex vivo and in vitro studies. In particular, Markwardt et al[1] demonstrated that perfusion of heparin and sulphated polyanions enhance PA release, in the isolated pig ear model, in a dose-dependent manner.[1] Moreover, high and low mol wt heparin preparations (HMW, LMW) induced fibrinolytic activity, both in vitro and in vivo in human volunteers.[2] The same investigators have shown that this effect partially depends on the degree of sulphation of the molecule, since a synthetic polysulphate polysaccharide (SP54) was more active than other heparin preparations tested.[2] The antithrombotic effect of HMW and LMW heparins was lost when antifibrinolytic drugs were administered along with the heparins in the rabbit Wessler model.[3] Further studies with SP54 indicated that this substance induced the release of t-PA if perfused in the rabbit ear and that this activity was involved in the drug's antithrombotic action.[4] Moreover in human volunteers SP54 activates the fibrinolytic system after both oral and subcutaneous administration.[5] Recently it has been hypothesized that a direct interaction of heparin or heparin-like substances with plasminogen and t-PA or urokinase (UK) induces an increase in plasmin formation.[6,7]

Dermatan Sulphate (DS), like heparin, has been shown to be a potent antithrombotic agent in different experimental models of venous thrombosis,[8,9] without affecting the coagulation tests. To clarify the possible mechanisms that may contribute to the antithrombotic efficacy of DS, we studied its interaction of this drug with the fibrinolytic system. In particular, we investigated if DS was able to modify the release of plasminogen activator (PA) from the vascular bed using the perfused rat hindquarters model. This model was proposed[10] as a useful tool to study the physiological and pharmacological modulation of PA release.

MATERIALS AND METHODS

Dermatan Sulphate (DS) MF 701, isolated from pig intestinal mucosa, was kindly supplied by Mediolanum Farmaceutici SRL, Milano, Italy. Heparin contamination was <1% as demonstrated by electrophoretic analysis and the in vitro anticoagulant activity was calculated to be around 5 U/mg USP.

Perfusion Model

The experimental model used was the perfused rat hindquarters described by Emeis.[10] Briefly, 200 to 250 g male CD-COBS rats (Charles River, Italy) were anaesthetized with sodium pentobarbital (50 mg/kg), administered intraperitoneally. After isolating both the aorta and vena cava, up to the ileofemoral bifurcation, a ligature was applied around each vessel. A 22 G needle was inserted, without stasis, into the aorta and perfusion was immediately started at a constant flow rate of 10 mL/min. A cannula was inserted into the vena cava to allow perfusate collection. Perfusion of the hindlimb vascular bed was performed using a Tyrode's solution pH 7.4, containing 0.1% BSA (Sigma Chemical Co, St Louis) and oxygenated with 95% O_2 and 5% CO_2, at 37°C. The perfusion pressure on entry was continuously monitored using a transducer and polygraph (Grass Instrument Co, Quincy, MA).

Experimental procedure. Each experiment started with a 30 minute, wash-out period of the rat hindquarters using only Tyrode's solution. After this initial period, the drug under investigation (dissolved in Tyrode's) was perfused for three minutes, followed by a second wash-out with Tyrode's solution. Samples (1 mL) were collected at regular intervals (five to ten minutes) from the cannulated vena cava during wash-out and every minute during drug perfusion. The samples, collected on ice, were centrifuged (12,000 g for 60 seconds) and analyzed for fibrinolytic activity. Each animal was perfused only once.

Fibrinolytic Activity

Fibrin plate assay. PA activity of the samples, collected during the perfusion period, was measured by a fibrin plate method using plasminogen-rich human fibrinogen (Grade L; Kabi, Stockolm).[11]

Thirty microliters of each sample were placed (in duplicate) on the fibrin film and the diameter of the lysis areas were measured after 18 hours incubation at 37°C. The PA concentration was expressed as PA mU/mL of perfusate in comparison to a reference curve obtained, for each set of experiments, using known concentrations of t-PA standard (WHO, London, coded 831517). The results were analyzed statistically by Duncan's test.[12]

Fibrin autography. The perfusion samples, collected as described in the experimental procedure, were kept at −20°C in 0.01% Tween 80 until tested. The molecular type of PA was evaluated by a fibrin autography technique[13] after SDS-PAGE. The apparent mol wt of PA was calculated by comparing the migration distance of the lysis area with those of marker proteins of known mol wt (Pharmacia, Uppsala, Sweden), run simultaneously. The immunological characterization was performed with home-made rabbit antibodies against human t-PA or UK incorporated in the fibrin agar plate.

RESULTS

Using the rat hindquarters perfusion model, we observed that DS was able to stimulate the release of PA activity in a dose dependent manner (in the range of 0.1 to 0.4 mg/mL). At higher DS concentrations (0.6 to 0.8 mg/mL) there followed a gradual decrease in the lysis of fibrin plates (Fig 1). Throughout the whole of these experiments no increase in basal perfusion pressure (50 to 60 mmHg) was recorded.

If we examine the profile of PA activity measured in the perfusate with the DS dose giving the highest PA activity release (0.4 mg/mL), we can observe (Table 1) that the maximum PA level was achieved during the first initial minutes of perfusion progressively declining thereafter to basal values 50 to 60 minutes from the beginning of the experiment.

Table 1 reports PA activity released from vascular cells during the perfusion of DS at doses of 0.1 to 0.4 mg/mL. The release of PA activity induced by DS (0.2 to 0.4 mg/mL) was maximal and significantly different from baseline levels during the first two minutes of DS perfusion and decreased thereafter. Above 0.4 mg/mL a reduction in PA was also seen, 0.6 mg/mL inducing a similar release of PA as the 0.1 mg/mL dose.

Different heparin preparations, tested at concentrations comparable with DS, were found ineffective (Fig 1); moreover, also lower concentrations of heparin (0.0001 to 0.01 mg/mL) were devoid of activity (data not shown).

The samples collected from the vena cava both during Tyrode's and DS perfusion were examined by fibrin autography after SDS-PAGE to determine the type of PA released. The perfusate contained two types of PA, which appeared on a fibrin-agar plate as lysis bands of 67,000 and 43,000 mol wt (Fig 2). It can clearly be seen, that both in control samples (collected during the first wash-out period) and in the stimulated samples (collected in the first minute of DS perfusion), both bands appeared and that perfusion of DS caused an increase only in the band corresponding to a 67,000 mol wt while the lower mol wt band was unaltered. The 67,000 mol wt band is blocked by an anti–PA antiserum and the 43,000 mol wt band partially inhibited by an anti-human UK antibody, as previously described.[14]

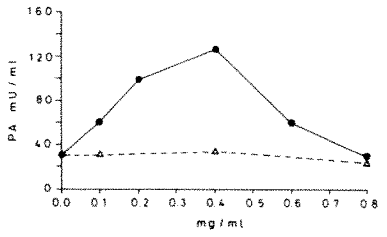

Fig 1. PA activity released as a function of DS (●) and heparin (△) concentrations perfused. The data reported here refer to the first minute of perfusion. Each value is the mean of five experiments performed on different animals (SD never exceeded 10% of the mean).

Table 1. PA Activity Released in Rat Hindquarters Perfused With Different DS Concentrations

Perfusion Time (min)		PA Released (mU/mL) After DS Perfusion*		
		0.1 mg/mL n = 5	0.2 mg/mL n = 7	0.4 mg/mL n = 9

To verify whether DS had a direct fibrinolytic activity on fibrin films or an in vitro interaction with PA molecules, DS

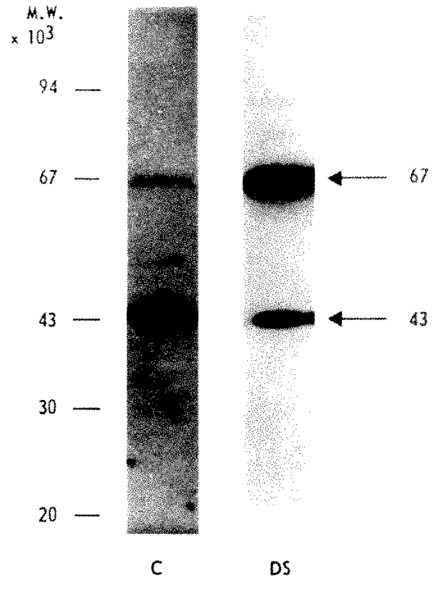

Fig 2. Fibrin autography of samples from perfused rat hindquarters. Line (C) corresponds to the perfusate collected after 25 minute wash-out with Tyrode's solution alone and line (DS) to the sample collected after the first minute of perfusion with 0.4 mg/mL of the drug. The arrows indicate the apparent mol wt corresponding to the lysis area.

(0.1 to 0.8 mg/mL) was dissolved in Tyrode's solution and placed directly on a fibrin plate, alone or together with different concentrations (10 to 100 mU/mL) of standard t-PA. DS alone did not lyse and did not potentiate the activity of standard t-PA. Moreover, no increased activity was observed when Tyrode's perfusion fluid was used as a source of PA instead of t-PA standard (data not shown).

DISCUSSION

DS is one of the components of the extracellular matrix; it is found alone or in association with other glycosaminoglycans in human coronaries, in bovine and Rhesus monkey aorta.[15,16] Unlike heparin, DS inhibits thrombin formation by interacting with only heparin cofactor II and not with antithrombin III.[17,18] Recently, it was shown that DS displays antithrombotic activity in models of experimental venous thrombosis.[8,9] In contrast to heparin, the antithrombotic activity was achieved at doses devoid of hemorrhagic effects.[9] These characteristics make DS a potentially interesting molecule for thrombosis prevention and call attention to the possible mechanisms of its peculiar antithrombotic effect. This paper reports the original observation that perfusion of DS induces an increase in fibrinolytic activity in the rat hindquarters model. The increase was dose-dependent, in a range of 0.1 to 0.4 mg/mL, but decreased following a further increase in the doses used. The rise in fibrinolytic activity was concomitant with the presence of DS in the microvasculature; maximum release was achieved during the initial minutes of perfusion followed by a slight decrease during the subsequent minutes (Table 1). The fibrinolytic activity induced by DS has been identified as t-PA–like molecules on the basis of the relative mobility in SDS-PAGE followed by fibrin autography (Fig 2). We have previously shown[14] that anti–PA antiserum could block the lytic activity of this molecule. This effect was peculiar for DS; indeed, in the same experimental conditions and at the same and lower dosages, different heparin preparations did not induce PA activity release. An in vitro effect of DS on plasminogen activation by t-PA and UK, recently described for heparin and DS,[6,7] was excluded by incubating both the standard t-PA preparation and Tyrode's perfusion fluid (as a source of PA activity) with DS (0.1 to 0.8 mg/mL) and measuring the fibrinolytic activity on fibrin films. We can thus conclude that a direct effect of DS on the vascular wall induces the release of t-PA–like molecules presumably from the endothelial cells.

On the basis of these data, we can thus put forward the hypothesis that part of the antithrombotic activity shown by DS[8,9] in experimental animals, might be due to its direct effect on endothelial cells. The PA released during intravenous (IV) administration of DS in the vicinity of the thrombus could thus bind to fibrin and express its thrombolytic action. On the other hand, the location of naturally occurring DS in subendothelial layers[15,16] could further contribute to the stimulation of PA release from surrounding endothelial cells in cases of vascular injury. Further in vivo studies are required to substantiate the role of endogenous and exogenous DS in thrombosis control.

ACKNOWLEDGMENT

Deoxygenation Inhibits the Volume-Stimulated, Cl^--Dependent K^+ Efflux in SS and Young AA Cells: A Cytosolic Mg^{2+} Modulation

By Mitzy Canessa, Mary E. Fabry, and Ronald L. Nagel

We recently reported that the Cl^--dependent K^+ (K:Cl) efflux, which can be stimulated by cell swelling in the presence of inhibitors of the Na^+ pump (ouabain) and of the Na-K-Cl cotransport (bumetanide), is highly active in young AA and SS RBCs. We report here that deoxygenation inhibits volume-stimulated K:Cl efflux in SS and reticulocyte-enriched density-separated SS and AA RBCs. In SS whole blood, the K:Cl efflux stimulated by hypotonic (220 mOsm) swelling was reduced from 9.2 ± 2 (mean ± SE) in oxygen to 2.7 ± 1.9 (mmol/L cell/h – flux units = FU) (n = 4) under deoxygenated conditions ($P < .005$). Deoxygenation also decreased the acid pH-stimulated K:Cl efflux from 5.9 ± 1.5 to 3.7 ± 1.1 FU (n = 3) ($P < .025$) but did not inhibit NEM-stimulated K:Cl transport. The effect of deoxygenation on density-separated SS cells is similar: When fraction SS2 (reversible discocytes) is deoxygenated under hypotonic conditions, the K:Cl efflux is reduced by 50%. In reticulocyte-enriched AA cells obtained from anemic patients, deoxygenation under hypotonic conditions also reduces K^+ efflux by 50%. In SS cells only, deoxygenation under isotonic conditions results in an increased Cl^--independent K^+ efflux. Because ionized Mg^{2+} in the cytosol increases during deoxygenation, we investigated the effect of external and internal Mg^{2+} on the volume-stimulated K:Cl efflux. Removal of external Mg^{2+} did not influence the rate of transport in oxygenated cells. When internal Mg^{2+} was clamped at 0.15 mmol/L with A23187 and EDTA at ionized cytosolic Ca^{2+} = 0, however, the inhibitory effect of deoxygenation on the K:Cl efflux was eliminated. We conclude that deoxygenation inhibits the volume-stimulated, Cl^--dependent K^+ efflux in AA and SS young red cells by concomitantly increasing ionized cytosolic Mg^{2+}.

© *1987 by Grune & Stratton, Inc.*

WE RECENTLY reported the existence of a Cl^--dependent K^+ (K:Cl) efflux in SS, SC, and CC cells that is involved in volume reduction secondary to cell swelling.[1] This pathway of K^+ transport is insensitive to ouabain and bumetanide and is stimulated by cell swelling induced by hypotonic and acid pH medium containing Cl^- but not NO_3.[1] Another important property of the K:Cl transport system is that it is stimulated by *N*-ethylmaleimide (NEM). The K:Cl efflux stimulated by cell swelling and NEM was elevated to a variable extent in HbS when compared with mature AA cells. The magnitude of this K^+ efflux varies from patient to patient with sickle cell anemia,[1,2] analogous to the heterogeneity in RBC density and volume distribution previously described.

More recently, we reported[2,3] that this K:Cl efflux is a characteristic of the young AA and SS RBCs; most cells in the blood of a sickle cell anemia patient are young cells due to the very short lifetime of SS cells.[4] Two important questions remain to be answered: the effect of deoxygenation on these fluxes, since it is deoxygenation that elicits the pathophysiologic responses of SS cells; and the relation of the K:Cl efflux to the deoxygenation-induced K^+ efflux first observed by Tosteson et al[5] in sickle cells. We report here that deoxygenation inhibits volume-stimulated K:Cl efflux and that this effect is mediated by cytosolic Mg^{2+}.

MATERIALS AND METHODS

Patient material. Normal controls (homozygous for hemoglobin A) and sickle cell anemia patients (homozygous for hemoglobin S), as ascertained by two types of electrophoresis, donated blood after informed consent at the Heredity Clinic of the Bronx Municipal Hospital. Reticulocyte-enriched blood was obtained from AA individuals recently treated for nutritional anemias. Blood was obtained in heparinized tubes and shipped on ice to Boston overnight under conditions previously described.[1] All experiments were performed within 24 hours of venipuncture.

Measurement of K^+ efflux. Since SS and AA cells contain variable amounts of Na^+ and K^+, all cells and fractions were loaded by a modified nystatin procedure[6] to have 11.5 ± 2 Na^+ and 95 ± 9 K^+ mmol/L cell. K^+ fluxes were determined as previously described[1,3] incubating cells at 2% (vol/vol) hematocrit in the following media (in mmol/L): A, 140 NaCl, pH 7.4; B, 140 $NaNO_3$, pH 7.4; C, 100 NaCl, pH 7.4; D, 100 $NaNO_3$, pH 7.4; E, 140 NaCl, pH 7, F, 140 $NaNO_3$, pH 7.0. All media contained 0.1 ouabain, 1.0 $MgCl_2$ (if not otherwise indicated), 0.1 bumetanide, 10 glucose, and Tris-MOPS of the pH indicated at 37 °C.

Cl^--dependent K^+ transport was estimated by subtracting the flux in isotonic nitrate media from that in isotonic chloride media (A – B), or hypotonic media (C – D), or acid pH media (F – E). The volume-dependent K^+ efflux was estimated from the differences between hypotonic and isotonic NaCl (C – A) medium. The Cl^- and volume dependent K^+ efflux was estimated from the difference between Cl^- and NO_3^- media (C – D). The NEM-stimulated K^+ efflux was estimated adding 1 mmol/L NEM to mediums A, B, C, and D. NEM-stimulated, Cl^--dependent K^+ efflux was estimated from the differences in K^+ efflux in chloride (A – B) and NO_3 (B – D) media. Time-course measurements of K^+ efflux every 10 minutes for 80 minutes indicated that initial rates were held for 30 minutes. For experiments under deoxy conditions, described below, NEM was added prior to deoxygenation.

To study the effect of ionized Mg^{2+} on K^+ efflux, the external Mg^{2+} concentration was varied between 0 and 0.5 mmol/L in the presence and in the absence of 1 mmol/L Tris EDTA pH 7.4 and 60 μmol/L/cells of A23187 as previously described.[7] In two separate experiments, ionized Ca^{2+} was buffered at zero and at 0.137 μ molar by use of 1.0 mmol/L EGTA and A23187, whereas Mg^{2+} was varied

between 0 and 0.5 mmol/L. Total Mg and Ca were determined by atomic absorption, and ionized Ca^{2+} was determined by a Ca^{2+} electrode.

Deoxygenation of RBCs for flux studies. For the purpose of deoxygenation, the chilled RBC suspensions were distributed in six 15-cc tubes for each flux medium. The rack, placed in a glove bag and on an ice bath, was evacuated and then flushed with nitrogen continuously and the tubes were agitated by hand for 1 minute/tube and were then capped with serum caps. A sample was removed by syringe and read on a Co-oximeter, and three tubes of each set of six were removed for a zero-time measurement of extracellular potassium. The remaining three tubes were then placed in a 37 °C water bath for 30 minutes; at the end of that time, the reaction was stopped by cooling in an ice bath for 2 minutes and then the whole tube was spun for 5 minutes at 6,000 g in a centrifuge at 5 °C. The supernatant was removed with a plastic pipette and transferred to a plastic tube for analysis by atomic absorption spectrophotometry. The final percentage deoxyhemoglobin was determined with a Co-oximeter (Instrumentation Laboratories, Sudbury, MA).

Density gradients. Percoll (colloidal silica coated with polyvinylpyrrolidone: Pharmacia Fine Chemicals, Piscataway, NJ) and Stractan (arabino-galactan polysaccharide, St Regis, West Nyack, NY) (prepared as described by Corash et al)[8] gradients were formed by centrifugation from a mixture of Percoll and Stractan as previously described.[9] Fraction SS2, the discocyte fraction with MCHCs between 33 and 37 g/dL, as previously described,[10] was aspirated by pipette after SS1 was removed. Fraction AA1, which is defined as cells with a MCHC <33 g/dL was similarly isolated. That this procedure results in a narrow range of densities can be seen from the density gradients shown in Fig 1.

If RBCs were to be exposed to deoxygenated conditions on density gradients, they were first deoxygenated by alternately flushing with humidified nitrogen and application of a moderate vacuum. Liganded controls were generated by equilibrating an aliquot of the cell suspension with carbon monoxide (CO). All samples were then incubated at 37°C for 30 minutes under the described conditions in the presence of 0.1 mmol/L ouabain and 10 mmol/L glucose. An aliquot was used to measure pH; another was used to measure percentage of deoxy hemoglobin with a CO-oximeter. A further aliquot of the cell suspension was then transferred in a nitrogen-filled glove bag to a centrifuge tube with 5.9 mL appropriate density gradient mix to which 50 µL 100 mmol/L sodium dithionite stock solution prepared under nitrogen had been added. The tubes with gradient mix and cell suspensions were then centrifuged as usual.

RESULTS

Effect of deoxygenation on K:Cl efflux stimulated by swelling in SS whole blood. Deoxygenation stimulates K^+ efflux from SS RBCs;[5] furthermore, we recently demonstrated that conditions that induce swelling also induce a Cl^--dependent potassium (K:Cl) efflux from SS whole blood (as well as young AA RBCs) under fully oxygenated conditions.[2,3] The following experiments deal with the question of the effect of deoxygenation on the portion of the K^+ efflux that is Cl^--dependent.

Under oxygenated and isotonic conditions, K^+ efflux is not Cl^--dependent (Fig 2). In whole blood of an individual with Hb SS, exposure to hypotonic oxygenated NaCl medium containing ouabain and bumetanide induced "volume-stimulated" increase in the K^+ efflux from 4.0 to 11.8 mmol/

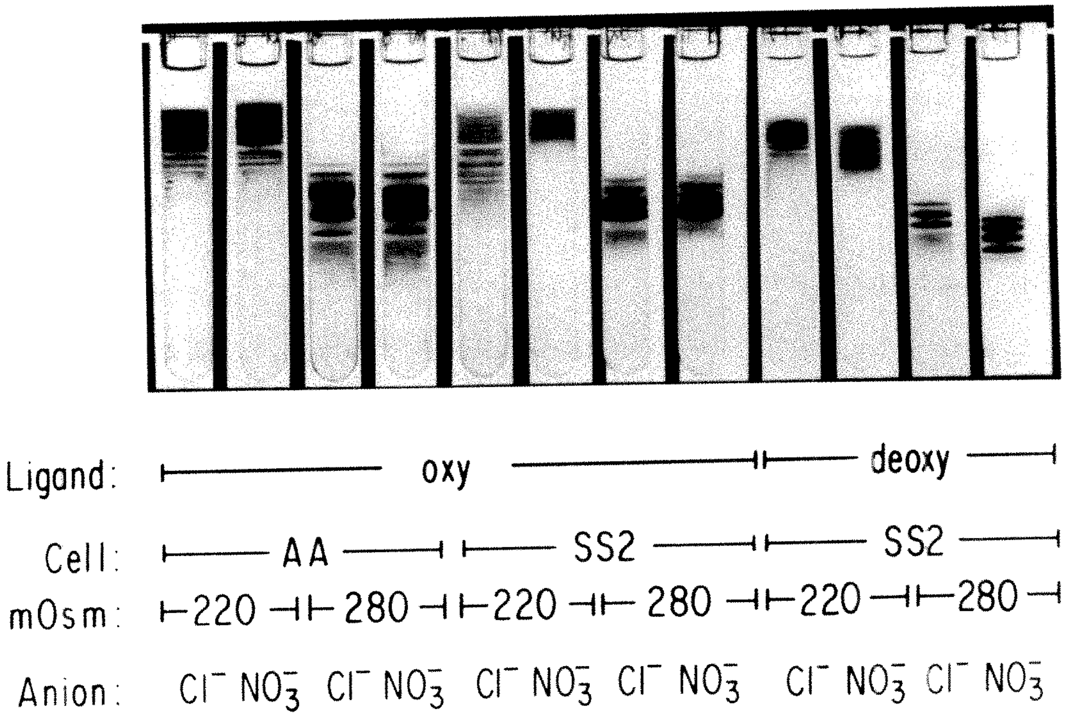

Fig 1. Effect of deoxygenation and hypotonic media containing Cl or NO_3^- on the density distribution of SS discocytes (SS2) and AA whole blood. Percoll-Stractan continuous density gradients were formulated with $C1^-$ or NO_3^- at 220 or 280 mOsm and centrifuged at 37°C. All tubes were at pH 7.4 and had 0.1 mmol/L ouabain. All were preincubated for 30 minutes at 37°C with 10 mmol/L glucose, 10 mmol/L hepes, 0.1 mmol/L ouabain, and osmolarity, anion, and ligand as described in the text. Oxy SS2 cells in hypotonic NO_3^- media have the same density as AA cells in hypotonic media for both the oxy and deoxy states. In contrast, in hypotonic Cl^- media, SS2 cells have a higher density (smaller decrease in MCHC) than do AA cells; however, deoxy SS2 cells have the same density in both Cl^- and NO_3^- media.

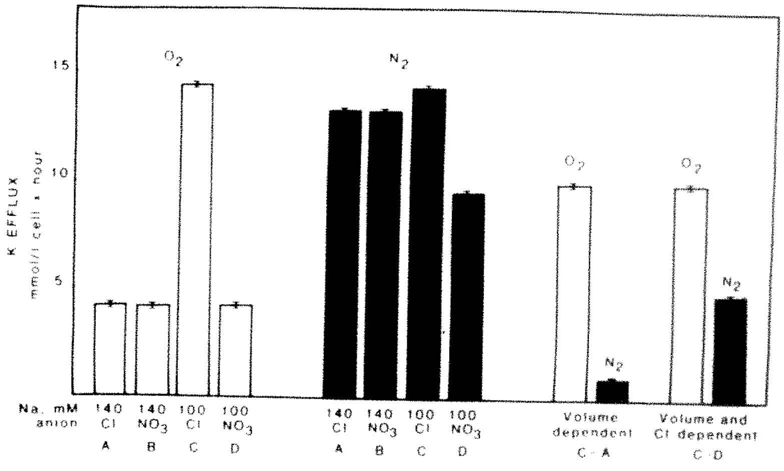

Fig 2. Effect of deoxygenation on initial rates of volume and Cl$^-$-dependent K$^+$ efflux from HbSS RBCs of a single individual. The volume and Cl$^-$-dependent K$^+$ efflux (B through C) is estimated from the differences between hypotonic chloride media (100 mmol/L NaCl = B) and hypotonic nitrate medium (100 mmol/L NaNO$_3$ = C). The volume-dependent K$^+$ efflux from the differences between (C through A) media. RBCs containing 95 mmol/L cell K$^+$ prepared as indicated in the Materials and Methods section were incubated at 2% (vol/vol) hematocrit in NaCl, or NaNO$_3$ as indicated. All media contained (in mmol/L): 1 MgCl$_2$, 10 glucose, 10 Tris-MOPS pH 7.4 at 37°C, 0.1 ouabain, and 0.1 bumetanide.

L/cell × hour (abbreviated FU for flux units) (Fig 2, columns A and C). No stimulation was observed in hypotonic nitrate medium (column D), as expected for a Cl$^-$-dependent phenomena, demonstrating that almost all the volume-stimulated (Fig 2, column C-A) K$^+$ efflux is Cl$^-$-dependent (Fig 2, column D-C). Under isotonic conditions, the increase in K$^+$ efflux produced by deoxygenation clearly is not Cl$^-$-dependent, since it also takes place in nitrate (medium B) medium (Fig 2, A and B dark columns). Deoxygenation did not further increase K$^+$ efflux into hypotonic medium; however, there is still a volume-stimulated, chloride-dependent (Fig 2, C-D) K$^+$ efflux under deoxygenated conditions that is smaller than in oxygenated media. The nearly constant flux into Cl$^-$ media under deoxy isotonic and deoxy hypotonic conditions is due to the large Cl$^-$-*in*dependent K$^+$ efflux into deoxy isotonic media. This can be deduced from the magnitude of K$^+$ efflux-flux into isotonic nitrate medium, which increases from 4.3 (Fig 2, B) to 14.0 (Fig 2, B dark) FU under deoxy conditions (Fig 2) (dark).

Table 1 presents the mean values for the volume-stimulated and Cl$^-$-dependent K$^+$ efflux for four patients with HbSS disease. This K:Cl efflux under deoxygenation was 30% of the flux in oxygen; hence, there was a 70% inhibition (Table 1), and the mean increase of K$^+$ efflux into isotonic nitrate medium in these four subjects was 9 ± .8 FU (data not shown). The negative value of volume-dependent K$^+$ efflux in column B is the result of high values in deoxygenated isotonic chloride media.

We previously showed that cell swelling induced by acid pH 7.0 in isotonic media[1] also stimulates K:Cl efflux. The effect of deoxygenation on the K:Cl efflux stimulated by pH 7 was studied in whole cells from three patients with Hb SS (bottom of Table 1). We found that the volume-stimulated, Cl$^-$-dependent K:Cl efflux decreased 62% upon deoxygenation, whereas the K$^+$ efflux into isotonic NaNO$_3$ medium at pH 7 increased from 4.3 to 13 FU (data not shown).

Previous studies have shown that the K:Cl efflux from HbSS RBCs can also be stimulated by NEM under isotonic conditions.[1] Table 1 also shows that the basal NEM-stimulated K:Cl efflux from whole HbSS RBCs is not significantly different in oxy and deoxy conditions.

Effect of deoxygenation on the volume-stimulated potassium efflux from density-separated SS cells. Since we previously reported that the activity of the volume-stimulated K:Cl efflux is found mostly in young RBCs,[2,3] we fractionated Hb SS RBCs by centrifugation in Stractan-

1 mmol/L NEM was used as an activator as described in the Materials and Methods section.

Percoll isopycnic continuous gradients to obtain SS2 containing mainly discocytes. Due to increased RBC destruction, these cells are quite young in SS patients. Table 2 (section A) shows the effect of deoxygenation on basal and on volume-stimulated K:Cl efflux in fraction SS2 RBCs from five subjects with SS disease. The volume-stimulated K^+ efflux under oxygenated conditions varied between 35.9 and 6 FU, whereas efflux from deoxygenated cells varied between 22.4 and 0.8 FU. The volume-stimulated K:Cl efflux decreased by a mean value of 8.4 FU, which represented a 48% inhibition of the values recorded under oxygenated conditions.

Effect of deoxygenation on K^+ efflux stimulated by swelling in AA cells. Although in subjects with SS disease a large fraction of the circulating cells are young cells, in subjects with Hb AA the proportion of reticulocytes is very small (1% to 2%). We have shown, however, that in subjects with recently treated nutritional anemias and a high percentage of circulating reticulocytes, the K:Cl efflux can be as high as that observed in young SS RBCs.[2,3] We report here the effect of deoxygenation on the volume-stimulated K:Cl efflux in reticulocytes (fraction AA1) of three normal subjects (Table 2, section B). As previously reported, all volume-stimulated K^+ efflux was Cl^--dependent in AA reticulocytes under oxygenated and hypotonic conditions. Deoxygenation decreased the magnitude of the volume-stimulated K:Cl efflux from 20.7 to 9.5 FU, which is a 54% inhibition relative to its activity under oxygenated conditions. In AA cells, the volume-stimulated K:Cl efflux is inhibited by deoxygenation without a significant increase in K^+ efflux into nitrate medium as is observed in the RBCs of patients with HbSS (data not shown).

Effect of deoxygenation on the density of SS RBCs in hypotonic medium. Density gradients formulated from Percoll and Stractan are linear for ~ 70% of their span.[11] We have previously demonstrated that when oxygenated SS cells are exposed to hypotonic medium with nitrate as the external anion, they swell, thereby reducing their density, and achieve a final density comparable to that of AA cells under the same conditions.[2,3] In contrast, in Cl^--containing medium, the response of some (30% of SS2, ref. 3), but not all SS cells to hypotonic medium is smaller than that of AA cells. This is due to activation of the volume-stimulated K:Cl efflux in the SS cells, which is accompanied by water loss and in turn results in a lower RBC volume (higher density) at equilibrium. One possible explanation for the inhibitory effect of deoxygenation on the volume-stimulated K^+ efflux is that red cells swell less in hypotonic media under deoxygenated conditions. To test this possibility, we examined AA whole blood and SS2 (density-separated SS discocytes) under oxy and deoxy conditions in isotonic and hypotonic media containing either Cl^- or nitrate as the anion (Fig 1). We found that SS2 cells in nitrate medium respond to hypotonic conditions with a volume increase under both oxy and deoxy conditions. Some,[3] but not all, oxygenated SS cells in hypotonic Cl^- media partially restore their MCHC (by a Cl^--dependent K^+ efflux) to isotonic values, however, and therefore exhibit higher density than cells under the same conditions in nitrate media. In contrast, under deoxy conditions SS2 cells in hypotonic chloride media do not increase their density. This indicates that the volume regulatory decrease response does occur in SS cells under oxygenated conditions and that it is inhibited under deoxygenated conditions.

Effect of Mg^{2+} on K^+ efflux. To study the mechanism of the deoxygenation-induced inhibition of the volume-stimulated K:Cl efflux, we studied the regulatory effect of cytosolic Mg^{2+}. Studies by Flatman and Lew[12] of Mg^{2+} buffering in human RBCs have indicated that at external Mg^{2+} concentration of 0.15 mmol/L (corresponding to our internal ionized concentration of 0.4 mmol/L), the addition of the ionophore A23187 does not produce changes in the Mg^{2+} content of the cells. As shown in Table 3, reduction of external Mg^{2+} did not modify the inhibitory effect of deoxygenation on K:Cl efflux in SS cells. In contrast, when the intracellular Mg^{2+} concentration is fixed at a level between 0 and 0.15 mmol/L with use of the ionophore A23187 and EDTA, deoxygenation no longer inhibited the K:Cl efflux. Furthermore, when the intracellular concentration was raised to 0.5 mmol/L the K:Cl efflux was inhibited even in the oxygenated state.

Because cytosolic calcium is an activator of some K^+ channels, experiments were performed with ionized cytosolic Ca^{2+} equal to zero. To exclude the possibility that it is the removal of cytosolic Ca^{2+} which inhibits the volume-dependent K:Cl transport under deoxy conditions, we also performed two experiments using A23187 + EGTA and varying cytosolic Mg^{2+} while ionized Ca^{2+} was buffered at 0 and

Table 2. Inhibition by Deoxygenation of Volume and Cl^--Dependent K^+ Efflux From HbS Discocytes (SS2) and HbA Reticulocytes (AA1)

	K+ Efflux, mmol/L cell/h (mean ± SE)

Incubation contained (in mmol/L) 100 NaCl, or 100 $NaNO_3$ 10 Tris-MOPS (pH 7.4) 60 mmol/L/cell of A21387, 1 mmol/L Tris-EDTA, 10 glucose, 0.1 ouabain, 0.1 bumetanide. The difference between Cl^- and NO_3^- media estimated the volume and chloride-dependent K^+ efflux. The standard deviation of the flux fluctuated between 0.2-0.3 units.

at 0.137 μmol/L, which is somewhat higher than the physiologic cytosolic Ca^{2+} levels of 0.04 μmol/L. These experiments indicate that the removal of Ca did not modify the response of the K:Cl system to deoxygenation.

DISCUSSION

The data demonstrate that the volume-stimulated, Cl^--dependent K^+ efflux (K:Cl efflux) characteristic of SS and young AA red cells[1-3,13] is drastically inhibited by the deoxygenation of these cells. The inhibition of the volume-stimulated K:Cl efflux in both AA and SS cells strongly argues against a specific effect of HbS in the regulation of this pathway. In SS cells only, deoxygenation stimulated a chloride- and volume-insensitive K^+ efflux. The data clearly establish that under hypotonic conditions the deoxygenation-induced K^+ efflux described by Tosteson and colleagues[5] takes place through two pathways which are separate and distinct and, within the conditions studied, noninteractive pathways. This aspect of our findings agree with the observation of Berkowitz and Orringer[14] that deoxygenation in isotonic media stimulates a Cl^--independent K^+ influx.

The study of the inhibition of the volume-stimulated K:Cl efflux by deoxygenation was extended to density-separated RBCs prepared from SS and AA blood. In SS blood, the reversible discocyte fraction with normal MCHC (SS2), which is largely composed of young cells due to the active cell destruction observed in these patients, exhibits approximately double the volume-stimulated K:Cl efflux when compared with whole SS blood; but the inhibitory effect of deoxygenation is similar (~ 50%). The same inhibitory effect is noted in the lightest fraction of AA RBCs (AA1), which contains reticulocytes and other normal RBCs. These results are in accordance with the K:Cl efflux residing largely in the population of young RBCs.

In contrast, the NEM-stimulated K:Cl efflux was not inhibited by deoxygenation. This difference is not surprising because K:Cl transport is also insensitive to ATP depletion whereas the NEM-stimulated flux is inhibited by it,[15] suggesting that different mechanisms of activation are involved.

Studies of the effect of divalent ions on the K:Cl transport in sheep RBCs have shown that high intracellular concentrations of Mg^{2+} inhibit this ion pathway.[15] For this reason, we explored the possibility that cytosolic Mg^{2+} concentrations could mediate the deoxygenation-induced inhibition of the K:Cl efflux. Although removal of external Mg^{2+} did not influence the K^+ efflux in oxygenated or deoxygenated RBCs, clamping of the internal Mg^{2+} by A23187 at 0 to 0.15 mmol/L drastically reduced the inhibitory effect of deoxygenation on the K:Cl efflux. Experiments under oxy and deoxy conditions with both zero and elevated cytosolic ionized Ca^{2+} indicated that Ca^{2+} was not involved in the response of the K:Cl system to deoxygenation. Higher cytosolic concentrations of Mg^{2+} inhibited K:Cl efflux both in oxy and deoxy conditions. Of interest are the recent studies by Bookchin et al[16] indicating that HbSS RBCs have a total Mg^{2+} content similar to that of AA cells.

The increase of free Mg^{2+} in deoxygenated RBCs is principally due to the elevated association constants of deoxygenated hemoglobin with ATP and 2,3-DPG as compared with Mg^{2+}-ATP and Mg^{2+}-2,3-DPG; hence, deoxygenation results in the displacement of Mg^{2+} from these complexes. Evidence that these are the dominant interactions in RBCs comes from the close agreement between the calculated values predicted by Berger et al[17] and the values observed in the intact RBC by P-31 NMR by Gupta et al.[18]

We conclude that the Cl^--dependent K^+ efflux characteristic of young AA and SS cells is inhibited by deoxygenation through the increase in the cytosolic concentration of Mg^{2+} that occurs secondary to the loss of ligand by hemoglobin and the binding to 2,3 DPG.

The presence of a deoxygenation-induced inhibition of K:Cl efflux has potential pathophysiologic importance in sickle cell anemia. Low pH can produce cell swelling and stimulate potassium efflux via this mechanism, which would tend to decrease cell volume. This is a prosickling event as previously discussed[1-3] and can explain, at least partially, the negative effects generated by the infusion of acid solutions in sickle cell anemia patients.[19] Nevertheless, a simultaneous decrease in pH and deoxygenation, as may occur in the microcirculation, would be negated by the inhibition of the K:Cl efflux and the cells would benefit from an increase in cell volume and a reduction of MCHC, a situation that decreases the tendency of HbS to polymerize. Interindividual variability in the expression of these fluxes (reported by us previously[2,3]) could be a contributor to the interpatient variability in severity observed in this disease.

Evidence for Direct Action of Human Biosynthetic (Recombinant) GM-CSF on Erythroid Progenitors in Serum-Free Culture

By Anna Rita Migliaccio, Milena Bruno, and Giovanni Migliaccio

The biologic activity of human biosynthetic granulocyte-monocyte colony stimulating factor (GM-CSF) was investigated in serum-free culture of erythroid progenitors derived from adult peripheral blood. The/morphology of erythroid bursts and the cloning efficiency of BFU-E under serum-free conditions were similar to those observed in dishes with fetal bovine serum (FBS). For these experiments, progenitor cells were partially purified by Ficoll-Paque density centrifugation, adherence to a plastic surface, and complement-mediated cytotoxicity of Leu-1$^+$ elements. For some studies, blastlike cells were harvested directly from 6-day-old semisolid cultures. In serum-free culture of the light-density cell fraction, biosynthetic erythropoietin (Ep) was sufficient for formation of pure and mixed erythroid colonies whereas GM-CSF was required for granulocyte-monocytic colonies. When adherent and Leu-1$^+$ cells were removed, or when in vitro differentiated blast cells were used as a source of progenitors, neither Ep or GM-CSF alone induced colony formation. In dishes supplemented with both growth factors, erythroid bursts were detected. Although the presence of GM-CSF alone did not induce formation of any colony or clusters, BFU-E were recorded when Ep was added 8 days later, suggesting that BFU-E could be maintained. Terminal maturation of the resulting erythroid bursts was delayed by 8 days. These results provide evidence that GM-CSF acts directly on early erythroid progenitors. Furthermore, they suggest that both Ep and GM-CSF are necessary to start the differentiation process.

HUMAN granulocyte-monocyte colony-stimulating factor (GM-CSF) has been identified in the conditioned medium of T lymphocytes responding to lectin and of some tumor cells[1] on the basis of its capacity to induce the formation of colonies composed of granulocytic and monocytic elements in cultures of progenitor cells from human marrow or blood.[2] A 22,000 dalton GM-CSF was purified from medium conditioned by the Mo-T lymphoblastoid line (Mo).[3] Recently, complementary DNA clones have been isolated,[4] and GM-CSF has been obtained following transient cDNA expression in monkey kidney COS cells.[4] The availability of biosynthetic and pure GM-CSF allows in vivo and in vitro analysis of the biologic activity of GM-CSF preparations free from contamination by other growth factors.[5-8]

Previous studies have suggested that biosynthetic GM-CSF preparations have burst-promoting activity (BPA) because they stimulate the formation of erythroid bursts in the presence of erythropoietin (Ep).[5-7] These results have been confirmed with highly purified progenitor cells from adult bone marrow in standard fetal bovine serum (FBS)-supplemented semisolid cultures.[8]

We recently developed serum-free culture conditions that allow optimal growth of human erythroid progenitors in terms of cloning efficiency, colony size and degree of cell differentiation.[9] We used this system to investigate the biologic activity of biosynthetic GM-CSF under circumstances in which serum factors could not play a role.

MATERIALS AND METHODS

Cell preparation. Heparinized peripheral blood from five appropriately informed adult (aged 30 to 35 years) volunteers was diluted 1:1 in Iscove's modified Dulbecco's medium (IMDM) and the light-density cell (LDC) fraction was separated by Ficoll-Paque gradient centrifugation (Pharmacia, Uppsala, Sweden). Removal of adherent cells was achieved by 2×20-minute adherence to a plastic surface where indicated (mean cellular recovery = 70% to 75%). The final monocyte concentration in nonadherent LDC (LDC-Ad$^-$) was 4% as evaluated by AD acetate esterase staining. Removal of T lymphocytes (LDC-Ad$^-$T$^-$) was accomplished by complement-mediated cytotoxicity after incubation of the LDC-Ad$^-$cells with the anti-human pan-T cytotoxic antibody Leu-1 (Becton Dickinson, Mountain View, CA). In this case, the mean cell recovery was 20% to 30%, and the residual concentration of Leu-1$^+$ cells, evaluated by indirect immunofluorescence, was 5% to 10%.

Hemopoietic growth factors. Either partially purified human Ep (step I, specific activity 1,000 IU/mg protein, Terry Fox Laboratories, Vancouver, Canada) or pure biosynthetic human Ep (specific activity 70,000 IU/mg, Amgen, Thousand Oaks, CA) was used. BPA activity was provided by medium conditioned by the Mo line[3] or by pure biosynthetic GM-CSF obtained from serum-free medium conditioned by COS monkey kidney cells transfected with the GM-CSF cDNA clone in the expression vector p91023 as described.[3,4,6,8]

Control cell culture. Each 1-mL plate contained the following components in IMDM[10]: methylcellulose (0.8%, final concentration), β-mercaptoethanol (7.5×10^{-5} mol/L), a selected heat-inactivated lot of FBS (No. 2919130, Flow laboratories, Glasgow, Scotland) (40%, vol/vol) and nucleated cells (3×10^5 peripheral blood LDC). In some experiments, the LDC-Ad$^-$ or LDC-Ad$^-$T$^-$ cells derived from 3×10^5 peripheral blood LDCs, were plated. An aliquot was counted, and the residual number of adherent and Leu-1$^+$ cells was evaluated (described above). Ep (1.5 to 2 IU/mL) was added where indicated.

Serum-free culture. FBS was substituted by deionized bovine serum albumin (BSA) and BSA-adsorbed cholesterol (final concentrations, 2×10^{-4} mol/L in both cases), iron-saturated transferrin (5×10^{-7} mol/L), insulin (1.7×10^{-6} mol/L), nucleosides (10 μg/mL each), sodium pyruvate (10^{-4} mol/L) and L-glutamine (2×10^{-3} mol/L) as previously described.[9]

Cultures were established in duplicate. Plates were incubated at

37°C in a fully humidified incubator with 5% CO_2 in air, and erythroid bursts were scored at 12 to 14 days according to standard criteria. The number of erythroblasts in each colony and their degree of maturation (ie, the ratio between immature and mature erythroblasts per dish) was evaluated as described.[9] In some experiments, CFU-GM colonies were also counted. Mean values ± SD from at least three separate experiments are presented.

Colony replating experiments. Clusters of 10 to 20 cells were individually removed in a small culture volume (3 μL) with a thin Pasteur pipette from 6-day-old serum-free cultures of LDC-Ad$^-$ peripheral blood cells stimulated with GM-CSF (10^{-10} mol/L) and Ep (1.5 IU/mL). Each cluster was transferred to a separate microwell containing 200 μL FBS-free culture media supplemented or not with Ep and/or GM-CSF. Some clusters were transferred to Ep-supplemented FBS-rich cultures as a control. The microwells were then scored at 14 days. Colonies containing >500 erythroid cells were considered BFU-E–derived colonies.

RESULTS

Cloning of human BFU-E in serum-free culture. The cloning efficiencies of erythroid progenitors from adult peripheral blood in FBS-rich and serum-free cultures are compared in Table 1. BFU-E cloning was strictly dependent on the presence of Ep. Semipurified urinary (uEp) (data not shown) and biosynthetic (rEp) Ep (Table 1) induced a comparable number of BFU-E–derived colonies in both FBS-rich and serum-free cultures in the absence of an external source of BPA. Addition of Mo-CM or GM-CSF did not increase the number of erythroid bursts (Table 1). This apparent BPA-independent growth of adult erythroid progenitors was not simply due to BPA contamination of some nutrients (ie, BSA), because removal of adherent cells completely abolished this effect (see below).

Effect of GM-CSF and/or Ep on the cloning of human BFU-E from LDC-Ad$^-$ and LDC-Ad$^-$T$^-$ fractions. When the adherent cells were removed, BFU-E cloning under serum-free conditions was dependent on the simultaneous presence of Mo-CM (a source of BPA) and Ep (Fig 1A and B). Some of the BFU-E clones (10% to 20%) were mixed colonies. GM-CSF could also be used as a source of BPA and induced erythroid colony formation in the presence of Ep in a concentration/dependent fashion (Fig 1A). The maximal frequency of erythroid bursts was observed at a GM-CSF concentration of 10^{-10} mol/L and was generally lower than the frequency of bursts detected in cultures supplemented with Mo-CM (Fig 1A). This was not due to a nonspecific effect of the elution buffer used during the GM-CSF purification because its addition to control dishes at a volume corresponding to the maximal GM-CSF concentration used did not affect the BFU-E cloning efficiency (data not shown).

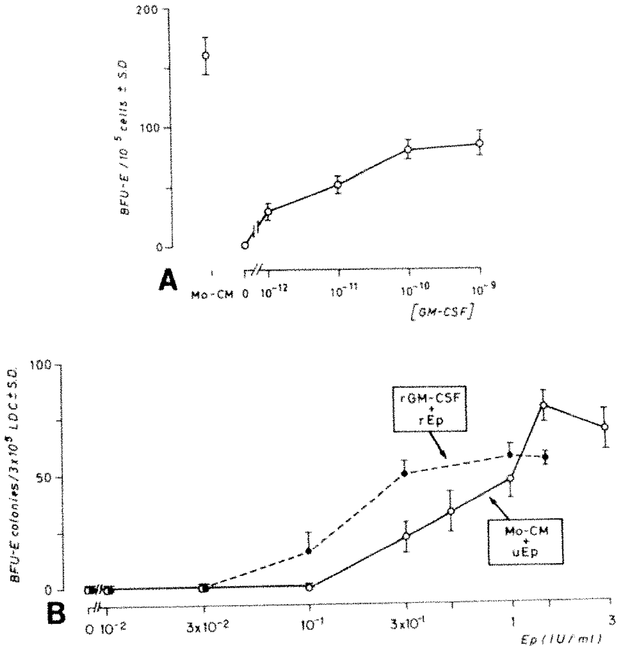

Fig 1. **(A) GM-CSF dose/response of BFU-E–derived colonies from the LDC-Ad$^-$ fraction in the presence of saturating amounts of recombinant Ep (1.5 IU/mL). Mo-CM–supplemented cultures (1%, vol/vol) are presented as controls. The CFU-GM colonies were also scored, and their maximal number per dish was 9.2 ± 4 (GM-CSF, 10^{-9} mol/L + Ep, 1.5 IU/mL), under these serum-free conditions. (B) Natural v biosynthetic Ep dose/response curve on adult BFU-E–derived colonies from LDC-Ad$^-$ fraction of peripheral blood in serum-free cultures supplemented with Mo-CM (10% vol/vol) or GM-CSF (10^{-10} mol/L), respectively. The colony numbers are expressed per 3 × 10^5 LDC.**

The colonies induced by GM-CSF were smaller than the

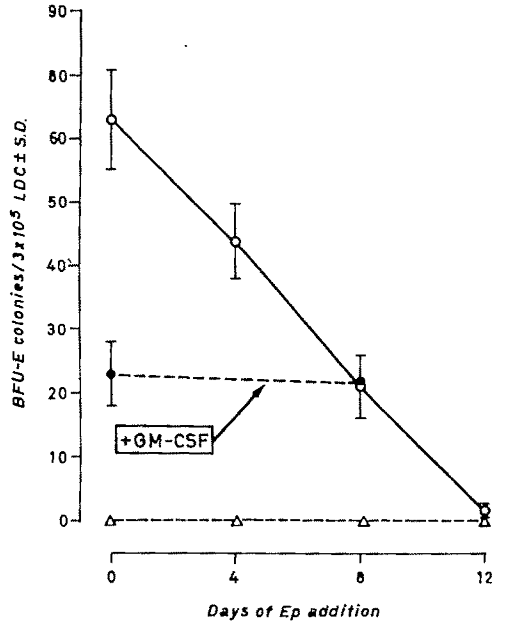

Fig 2. Survival of BFU-E progenitors from the LDC (—O—) or from the LDC-Ad$^-$ (—△—) fraction of peripheral blood upon sequential addition of recombinant Ep (1.5 IU/mL). Ep was added at day 0, 4, 8, or 12 of cultures, and maximal numbers of pink-red erythroid colonies were detected at days 12, 16, 20, and 24, respectively. GM-CSF (10^{-10} mol/L) was added at day 0 in some of the LDC-Ad$^-$ cultures (—●—).

colonies in Mo-CM–stimulated cultures (the mean cellular number per colony was 7 × 10^3 and 10^4, respectively), GM-CSF–induced colonies contained only erythroid cells, and their mean maturation time was 2 days shorter than observed for Mo-CM (the ratio between mature and immature erythroblasts was maximal at 14 to 15 and 16 to 17 days of culture, respectively).

The Ep dose/response curves on progenitor cells derived from the LDC-Ad$^-$ fraction of peripheral blood and stimulated either with Mo-CM or GM-CSF are shown in Fig 1B. uEp was used in Mo-CM–supplemented cultures, and rEp was used in GM-CSF–supplemented cultures. Preliminary experiments did not show significant differences in the dose/response curve of uEp and rEp in FBS–supplemented cultures (data not shown). Similarly, no difference was observed in the recombinant Ep dose/response curve in serum-free culture when adherent cells[9] or GM-CSF (Fig 1B) were used as a source of BPA. The Ep concentration required for 50% of the maximal cloning efficiency in GM-CSF–stimulated LDC-Ad$^-$ cultures, however, appeared slightly lower than the dose required in Mo-CM–stimulated cultures.

The BPA activity of GM-CSF persisted when the Leu-1$^+$ cells were removed (Table 1). Erythroid bursts derived from these LDC-Ad$^-$T$^-$ cells were morphologically equivalent to those obtained from the LDC fraction.

Survival of BFU-E progenitors in serum-free cultures in delayed Ep addition experiments. When Ep was added after 4 or 8 days in culture of the LDC fraction of peripheral blood, more than one third of the original number of BFU-E–derived colonies were observed (Fig 2). Maximal numbers of erythroid colonies were always observed 12 days after the time of Ep addition, however (ie, at 16 or 20 days of culture, respectively) whereas the morphology and the size of the colonies were not affected. The decreased BFU-E cloning efficiency after delayed Ep addition could be due to evolving suboptimal culture conditions with time.

Removal of adherent cells completely abolished the BFU-E survival (Fig 2), suggesting that this effect was mediated by factors produced by macrophages. The addition to the culture at day 0 of GM-CSF (10^{-10} mol/L) partially restored the maintenance of BFU-E in LDC-Ad$^-$ cell cultures (Fig 2).

Formation of erythroid bursts from single clusters under serum-deprived conditions. To clarify whether GM-CSF promoted the growth of erythroid progenitors directly or indirectly by activating contaminating cells to release BPA in vitro, erythroid progenitor cells were purified by collecting clusters of blastlike cells (10 to 20 cells/cluster) from 6-day-old serum-free cultures supplemented with Ep and GM-CSF. No such clusters were seen in dishes supplemented with only GM-CSF or Ep. Each cluster was transferred to a separate microwell and cultured for another 8 days. The results are summarized in Table 2. In FBS-rich cultures, 82% of the transferred clusters gave rise to erythroid colonies. Under serum-deprived conditions, no or very few clusters differentiated without addition of growth factors or in the presence of Ep or GM-CSF alone. The combination of both growth factors gave rise to erythroid colonies with 65% of recloning efficiency.

Effect of GM-CSF on the cloning of human CFU-GM. Under serum-free conditions, the nutrients required to grow murine erythroid progenitors are similar to those required by granulocyte-monocytic progenitors (ref. 11; Magliaccio, Bruno, Magliaccio, unpublished observations). Furthermore, the survival of human erythroid progenitors is dependent on culture conditions more complex than those

required by human CFU-GM.[12] For these reasons, we used the serum-free conditions that we developed for human BFU-E to culture human CFU-GM.

When the LDC fraction of peripheral blood was used as source of progenitor cells, the cloning of CFU-GM under serum-free conditions was strictly dependent on addition of GM-CSF (Fig 3). Maximal number of granulocyte-monocytic colonies were observed at a GM-CSF concentration of 10^{-12} mol/L (Fig 3), which has very low BPA (Fig 1A). Both monocyte and/or granulocyte colonies (5×10^2 cells/colony), morphologically identical to those obtained in cultures supplemented with FBS were detected.

When adherent and Leu-1^+ cells were removed, GM-CSF was sufficient to induce CFU-GM colony formation in FBS-rich but not in serum-free cultures (legend to Fig 1A and Table 1).

DISCUSSION

Biosynthetic GM-CSF has multilineage stimulatory activities because it supports the formation of colonies along the macrophage, granulocyte, and erythroid differentiation pathways in FBS-supplemented culture.[8] Some of the erythroid colonies also contain granulocytic and macrophagic elements and this led to the conclusion that human GM-CSF has an effect on the proliferation and/or differentiation of multipotential progenitor cells.[8]

Formation of hematopoietic colonies in culture depends on the interplay of several factors. These factors may derive from accessory cells or be present in FBS. For these reasons, we investigated the BPA of biosynthetic GM-CSF in serum-free cultures of progenitor cells obtained from adult peripheral blood.

Under serum-free conditions, the LDC fraction of adult peripheral blood (as well as the unfractionated bone marrow, unpublished observations) produced sufficient BPA endogenously to sustain maximal BFU-E cloning in the presence of Ep (Table 1). These systems were therefore not suitable to investigate BPA. When adherent and Leu-1^+ cells were removed, however, no BFU-E-derived colonies were observed in serum-free cultures of peripheral blood (Fig 1A and Table 1), although such colonies persisted in cultures of marrow cells (data not shown; also ref. 13). For this reason, blood was chosen as source of progenitor cells to investigate the BPA of recombinant GM-CSF.

In serum-free cultures of Ad^-T^- blood cells, GM-CSF alone did not induce the formation of colonies or clusters, although Ep and GM-CSF together induced the formation of *pure* erythroid bursts. The number of erythroid bursts was dependent on the concentrations of both Ep and GM-CSF. The lack of CFU-GM-derived colonies in GM-CSF-supplemented serum-free cultures of partially purified progenitor cells is difficult to interpret. It may reflect either culture conditions nonoptimal in terms of nutrients or growth factor(s) or the presence of inhibitory factor(s) released from residual accessory cells. As shown in Table 1 and Fig 1A, the maximal number of erythroid bursts induced by GM-CSF in the presence of Ep was less than the number observed in serum-free cultures supplemented with Mo-CM and Ep. Similarly, under FBS-rich conditions, fewer bursts have been reported in cultures of human[8] or murine[14] cells stimulated with Ep and GM-CSF than in cultures stimulated with Ep and conditioned media. Because GM-CSF-induced colonies were smaller and matured 2 days earlier than colonies induced by Mo-CM, they may represent only a fraction of the total BFU-E population in human peripheral blood, perhaps the most differentiated one.

Progenitor cells represented 0.1% of the LDC-Ad^-T^- cell fraction and 5% of the monocytes, and 5% to 10% of the T lymphocytes were not removed by the purification procedure. The effects on BFU-E observed in the presence of GM-CSF may have been indirectly mediated through stimulation of BPA production by accessory cells. GM-CSF sustained the differentiation of erythroid colonies from single clusters of blast cells in the presence of Ep, however, suggesting a direct effect.

No colony or cluster was observed in cultures of LDC-Ad^- cells in the presence of GM-CSF. Experiments with delayed Ep addition indicate, however, that the erythroid progenitors were maintained for at least 8 days in these dishes (Fig 3). When Ep was added in these GM-CSF-supplemented cultures, erythroid colonies were detectable 12 days later. This last result suggests that the process of erythroid differentiation in its early phases requires the presence of both factors.

ACKNOWLEDGMENT

We gratefully acknowledge the generous gift of Drs J.C. Gasson (pure recombinant human GM-CSF) and J. Egrie, Amgen (pure recombinant erythropoietin). Dr D.W. Golde is also acknowledged for critical revision of the manuscript.

Human Blood Basophils Display a Unique Phenotype Including Activation Linked Membrane Structures

By Christoph Stain, Hannes Stockinger, Michael Scharf, Ulrich Jäger, Heinz Gössinger,
Klaus Lechner, and Peter Bettelheim

To evaluate the membrane marker profile of human basophils a panel of well-established monoclonal antibodies (MoAbs, $n = 60$) was used for a combined toluidine/immunofluorescence staining procedure. Myeloid-associated MoAbs (particularly MoAbs against the LFA-1 family (CD11, CD$_w$18), MoAbs directed against lactosylceramide (CD$_w$17), anti-glycoprotein (gp) 150 MoAbs MCS 2 and MY 7 (CD$_w$13), anti-gp 67 MoAb MY 9, anti Fcγ-receptor (mol wt 40 kd) MoAb CIKM5, anti-CR 1 MoAb E 11, and the antiglycolipid MoAb VIM-2) were reactive with basophils, indicating a close relationship to other mature myeloid cells. Under normal conditions, basophils surprisingly express at least three activation-linked structures not detectable on mature neutrophils, ie, the p45 structure defined by MoAbs OKT-10 and VIP-2b, the p24 structure identified by the CD9 MoAb BA-2, and the receptor for interleukin 2 (IL 2) recognized by three different MoAbs (anti-TAC, IL2RI, anti-IL 2). Moreover, under short-term culture conditions basophils both in mononuclear cell (MNC) suspension and as purified fractions display the HLA-DR and T4 antigens. The neutrophilic/eosinophilic structure 3-fucosyl-*N*-acetyllactosamine is expressed on basophils only after neuraminidase treatment. Basophils were not stained at all by CD16 MoAbs directed against the Fc γ-receptor (mol wt 50 to 70 kd) of neutrophils, by the MoAb 63D3 (CD$_w$12) recognizing the monocyte/granulocyte-associated p 200 antigen, and by the CD$_w$14 antibodies (VIM-13, Mo 2) defining the monocyte-specific structure p 55. Enriched basophils freshly obtained from chronic granulocytic leukemia (CGL) patients yielded identical results in FACS analyses. In summary, these data indicate that basophils generate a unique combination of surface determinants and possibly represent an activated cell population.

© *1987 by Grune & Stratton, Inc.*

HUMAN BASOPHILS represent a distinct minority of peripheral blood cells with a prevalence of 0.5% of total leukocytes.[1] Mature basophilic cells have to be distinctly differentiated from neutrophils and eosinophils in terms of their physiologic role. So far, evidence of basophil differentiation was mostly restricted to the identification of morphological characteristics and biochemical activities.[2-7] In contrast to neutrophils and eosinophils, the expression of membrane antigens has hitherto not been investigated in detail.[8-11] This is due to the small amount of basophils in the peripheral blood and to the fact that basophils, which unlike neutrophils and eosinophils remain in mononuclear cell (MNC) preparations, cannot be distinguished from other cells in MNC analyses unless additional cytochemical staining procedures are performed. Using a combined cytochemical (toluidine) and immunologic (monoclonal antibodies, MoAbs) staining procedure, we were able to analyze the antigenic membrane profile of this cell type.

MATERIALS AND METHODS

Cell Preparation

MNC were isolated by gradient centrifugation on Ficoll-Hypaque (Pharmacia, Uppsala, Sweden) and were then subjected to staining with MoAbs. Neutrophils obtained from healthy controls ($n = 3$) were prepared by standard techniques as previously described.[12] Eosinophils were isolated from two patients with hypereosinophilia and from two patients suffering from transient drug allergy. Purity of these cell fractions was >90%.

MoAbs

The MoAbs used in this study and referred to as belonging to a cluster of differentiation (CD) or for being reactive with a well-defined structure were: Leu 1 (CD5), Leu 2a (CD8), Leu 3a (CD4), Leu 4 (CD3), Leu 7 [human natural killer (NK) cells], Leu 11a (CD16), and anti-HLA-DR (Becton Dickinson, Sunnyvale, CA); MY 7 (CD$_w$13), MY 9 (anti-p67), Mo 2 (CD$_w$14), T4 (CD4), T8 (CD8), T11 (CD2), B1 (CD20), B2 (CD21), B4 (CD19), and IL 2 R1 (CD25) (Coulter Immunology, Hialeah, FL); BA-1 (CD24), and BA-2 (CD9) (Hybritech, San Diego); OKT-1 (CD5), OKT-9 (antitransferrin receptor), OKT-10 (p45), OKM-1 (CD11), and OKB-2 (CD24) (Ortho Pharmaceuticals, Raritan, NJ); and 63D3 (CD$_w$12) (BRL; Gaithersburg, MD); anti-Il 2 (Eurogenetics, Agoralaan, Belgium); BMA-022 (HLA-DR) and BMA-0111 (PanT-ERFC receptor) (Behringwerke AG, Marburg, FRG).

The MoAbs VIP-1 (antitransferrin receptor),[13] VIP-2b (p45),[13] VID-1 (anti-HLA-DR),[14] VIL-A1 (CD10),[15] VIM-12 (CD11),[16] VIM-13 (CD$_w$14),[16] VIM-D5 (CD15),[12] VIM-2 (not clustered),[17] VIM-C6 (CD15),[18] VIB-C5 (CD24),[19] VIT-3b (CD3),[20] VIT-4 (CD4),[19] VIT-6 (CD1),[21] VIT-8 (CD8),[19] VIT-12 (CD6),[19] ViFcR2 (CD16), and VIE-G4 (anti-glycophorin A)[22] were produced at the Institute of Immunology, University of Vienna. The MoAb Na1/34 (CD1) was kindly provided by Dr A. J. McMichael. WT-1 (CD7) antibody was sent by Dr W. I. M. Tax, and MCS-2 (CD$_w$13) antibody was donated by Dr J. Minowada. VEP-13 (CD16) was supplied by Dr Rumpold (Vienna). Anti-TAC (CD25) was kindly

provided by Dr T. A. Waldmann. CLBery3 was sent by P. T. Tetteroo. MoAbs L4F3, 1G10 (CD15), KiM5 (CD11), T5A7 and (G)035 (CD17), TSI/18.11 and MHM 23 (CD$_w$18, LFA-1-β-chain; McMichael, personal communication, 1984, 1986), CIKM5 (40 kd Fcγ-receptor) were selected from the myeloid panel of the Second International Workshop on Human Leukocyte Differentiation Antigens. MoAb E 11 (anti-CR 1 receptor) was taken from the myeloid panel of the Third International Workshop on Human Leukocyte Differentiation Antigens.

Supernatant from the IgE-producing human myeloma cell line U-266 and a mouse anti-human IgE MoAb (E124 2-8, Immunotech, Marseille, France) was used for detection of membrane-bound IgE (positive control). Monoclonal antibodies of either IgG 1, IgG 2a, IgG 2b, and IgM subclass with irrelevant specificity were used as negative controls.

Immunologic Characterization With MoAbs

As previously described,[12] the binding of the various antibodies to isolated MNCs was assessed by indirect immunofluorescence with fluoresceinated goat F(ab')$_2$ anti-mouse IgG and IgM antibodies. Fluorescence of MNCs was evaluated by means of a Leitz Ortholux microscope (Leitz, Wetzlar, FRG). Purified basophils of CGL patients and enriched neutrophils of one healthy donor were analyzed with a FACS 440 (Becton Dickinson).

Combined Immunologic/Toluidine Staining Procedure

Blood samples from 15 volunteers were drawn for testing the entire panel three times. After the indirect immunofluorescence staining procedure, cells (6×10^5 for each MoAb) were fixed in glutaraldehyde at room temperature (RT) for 1 minute (0.025% glutaraldehyde in fixation buffer: 0.1 mol/L Tris buffer in 1 vol% glucose, pH 7.8). After three washings with phosphate-buffered saline (PBS, pH 7.2) cells were incubated with toluidine blue (Sigma, St Louis) (0.0125% wt/vol in PBS) at RT for 15 minutes. Subsequently, cells were washed three times in PBS and subjected to analysis as follows: Toluidine-stained cells were first identified in bright field and then examined for antibody binding under fluorescence light.

The antibodies we used either stained practically all cells examined or did not stain basophils at all. For FACS analyses, a reactivity of >20% was considered positive.

Neuraminidase Treatment of Cells

MNCs (4×10^6/mL) were incubated with *Vibrio cholerae* neuraminidase 0.2 U/mL (Behringwerke AG) in a shaking water bath at 37°C for 30 minutes. The reaction was terminated by washing the mixture three times with RPMI 1640 medium supplemented with 10% fetal calf serum (FCS).

Enrichment of Basophils

To compare the phenotype of normal basophils with that of CGL patients (two patients in stable phase, one patient in accelerated phase), the combined immunofluorescence technique and an analysis of enriched basophils was used. Enrichment of basophils was achieved by incubating MNC with a mixture of antibodies and subsequent rabbit complement lysis. After informed consent was obtained from each patient, heparinized peripheral blood of three CGL patients (5%, 11%, and 15% basophils, respectively) underwent MNC isolation as described above; 5×10^8 cells were incubated with 1 mL RPMI at 4°C for 45 minutes, the milliliter of RPMI containing 100 μg of MoAB VIM-D5. After being washed, cells were exposed to 5 mL rabbit complement (Behringwerke AG) at 37°C for 90 minutes. Monocyte depletion of washed cells was achieved with scrubbed nylon wool (37°C for 45'). Cells were then incubated with a mixture of antibodies consisting of 25 μg VIT-3, 25 μg VIB-C5, 25 μg Leu 1, 50 μg Leu 7, 25 μg VIE-G4, 25 μg anti-HLA-DR, CLBery3 (ascites, 1:500 diluted), 25 μg VIM-D5 at 4°C for 45 minutes, and subsequently incubated with 4 mL rabbit complement at 37°C for 90 minutes. Cells were again centrifuged on Ficoll-Hypaque and washed twice. Cytospin preparation of this cell fraction revealed >95% basophils (Fig 1).

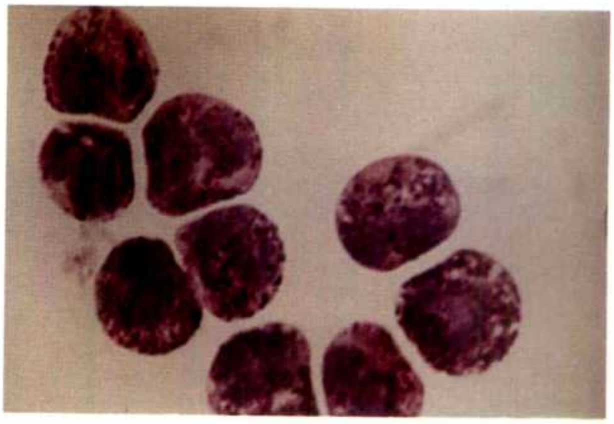

Fig 1. Purified CGL basophils obtained by MoAb + complement lysis.

Culture Studies

Activation of neutrophils and basophils by formyl-methionyl-leucyl-phenylalanine (fMLP). As reported previously,[23] PMNs (1×10^7/mL) or MNCs (1×10^7/mL) were incubated at 37°C for 10 minutes, the medium (RPMI 1640, 5 g/L human albumin, pH 7.2) containing 1 μmol/L fMLP and cytochalasin B 10 μg/mL as well as dimethylsulfoxide (DMSO) (final concentration 0.01%) as a solvent. The reactivity of stimulated MNCs was evaluated by means of the combined immunofluorescence/toluidine staining procedure.

Activation of basophils from two healthy donors (in MNC suspension) with the Ca-ionophore A23187. Cells (1×10^7) were incubated with the Ca-ionophore A23187 (1 μg/mL, Sigma) at 37°C for 30 minutes. After this procedure degranulation of basophils was evident.

Short-term cultures with biologic factors. Basophils were cultured either in MNC suspension (five healthy controls) or as purified fractions (CGL basophils from two patients) after lysis with a mixture of antibodies (>95% purity as determined by Wright staining of cytospin preparations) for 5 days in RPMI 1640 (Flow Laboratories, McLean, VA) plus 10% FCS, supplemented with either 20 U/mL human recombinant IL 2 (Boehringer Mannheim), 100 U/mL human recombinant γ-interferon (hr-γ-IFN, Interferon Sciences, New Brunswick, NJ), supernatant of the HTB-9 cell line[24] (9:1 vol/vol), or supernatant of the T cell hybridoma producing basophil-like promoting activity factor (BaPA, 4:1 vol/vol) kindly provided by Dr B. Stadler.[25,26] Phenotyping (normal basophils in MNC fractions: combined toluidine immunofluorescence technique; purified CGL basophils: FACS analyses) of cultured cells was performed on days 0, 2, and 5.

^{3}H-incorporation. Incorporation of ^{3}H-thymidine was carried out as described previously.[27] In brief, purified basophils from two CGL patients (10^5 cells/well) were incubated with factor-conditioned media (γ-IFN, BaPA, HTB-9-supernatant, and IL 2) at 37°C for up to 5 days in a humidified atmosphere with 5% CO$_2$. One

microcurie per well ^{3}H-thymidine (New England Nuclear) was added 12 hours before harvest. The incorporated radioactivity was collected on glass-fiber filters and counted in a liquid scintillation counter. Values are given as cpm $\times 10^{-3} \pm$ SD of triplicate cultures.

Enrichment of neutrophils by MoAb + complement lysis. Heparinized blood drawn from a normal donor was first centrifuged on Ficoll-Hypaque. The sedimented cell pellet containing erythrocytes, neutrophils, and residual MNCs, subsequently underwent dextran sedimentation. Neutrophils (1×10^8) obtained by this method were incubated with a mixture of MoAbs comprising 25 μg anti-HLA-DR, 25 μg BMAO111, 25 μg B1, 25 μg VIM-13, and CLBery3 (ascites, 1:500 diluted) at 4°C for 45 minutes. Cells were then exposed to 1 mL rabbit complement at 37°C for 90 minutes. After two washings, cytospin examination revealed >95% neutrophils.

RESULTS

By means of a toluidine staining procedure in suspension, basophils are easily identified by their purple cytoplasmic granules. This procedure, combined with the simultaneous application of the immunofluorescence technique allowed determination of the basophil marker profile (Fig 2A and B).

A panel of 60 MoAbs was used to delineate the phenotype of basophils from that of neutrophils and eosinophils. Thirty MoAbs reacted with at least one type of mature granulocytes and showed a homogeneous staining for positive subsets in all samples tested. Table 1 shows that 20 MoAbs stained basophils. MoAbs giving positive results and identifying common granulocytic membrane structures were, in particular, anti-CR1 MoAbs (220 kd), anti-Fcγ-receptor (40 kd) MoAbs, anti-C3bi-receptor antibodies (OKM-1, VIM-12, and Ki M5/CD 11), anti-LFA-1-β chain MoAbs (CD_w18), anti-gp 150 MoAbs (CD_w13), and MoAb VIM-2, which recognizes a glycolipid structure. Of all MoAbs tested in this study, antilactosylceramide MoAbs (CD17) showed the strongest reactivity with basophils (Fig 2A and B). MoAbs detecting the p 67 membrane determinant bound to basophils moderately and, in our hands, gave a very weak reactivity with neutrophils as well.

In contrast to eosinophils and/or neutrophils, the structure 3-fucosyl-*N*-acetyllactosamine (identified by MoAbs clustered as CD15) and the 50- to 70-kd Fcγ-receptor (recognized by CD16 MoAbs) were not detectable on the surface membrane of circulating basophils. The CD_w12 and CD_w14 anti–monocyte-associated MoAbs tested also failed to react with basophils.

We furthermore tested nonmyeloid-associated MoAbs of clusters CD1-10, 19 through 21, 24, 25, MoAbs directed against the T10 antigen and an antitransferrin receptor MoAb. A constant and reproducible finding was the reactivity of various activation-linked markers with basophils. All three anti-IL 2 receptor MoAbs (CD25) tested, both anti-T10 MoAbs, and the anti-p24 MoAb BA-2 (CD9) gave positive results. HLA-DR antigens and the transferrin receptor, also activation-linked structures, were not detectable on freshly obtained basophils. MoAbs directed against lymphocyte-associated structures (CD 1 through 8, 10, 19 through 21, 24, anti-human NK cell MoAb Leu7) failed to stain basophils at all. They included anti-common acute lymphocytic leukemia (cALLA) MoAb VIL-A1 (CD10) and CD24 MoAbs known to bind to neutrophils.

Neuraminidase Treatment of MNCs

Seven MoAbs (VIM-D5, BA-2, T5A7, VEP-13, VID-1, VIP-1, and anti-TAC) were tested after neuraminidase

treatment of cells. When pretreated with neuraminidase basophils, which are normally VIM-D5 (anti–3-FAL) negative, reacted strongly with this very MoAb. All other MoAbs tested displayed the same reactivity pattern with basophils both before and after neuraminidase treatment.

Purification and Phenotypic Analysis of CGL Basophils

After MoAb plus complement lysis, purity of basophils was >95% (Fig 1). Purified cells underwent indirect immunofluorescence staining with MoAbs of major significance and were evaluated by FACS analyses (Fig 3A and B). Identical results were obtained with all three CGL patients on day 0. These FACS data therefore confirmed the results obtained with normal basophils by use of the combined toluidine staining procedure.

Phenotypic Analysis of Purified Neutrophils

The phenotype of neutrophils has already been well defined. To examine whether the MoAb + complement lysis may cause an alteration of surface structures, purified neutrophils were stained with a panel of MoAbs and measured on a FACS. The phenotype of neutrophils appeared to remain unchanged by this procedure and was identical to the neutrophil reactivity pattern obtained by indirect immunofluorescence microscopy (data not given).

Culture Studies

fMLP effect on basophils and neutrophils. The binding of MoAbs (VIM-D5/CD15, T5A7/CD$_w$17, BA-2/CD9, VID-1/HLA-DR, VIP-1/transferrin receptor, and anti-TAC/IL 2 receptor) was tested before and after fMLP activation of basophils and neutrophils (two healthy controls). Neutrophils displayed a distinct increase of the fluorescence intensity with MoAb VIM-D5, whereas T5A7 bound neutrophils to a lower extent after this procedure. With regard to basophils, no change of fluorescence intensity was evident with any MoAb tested.

Effect of Ca-ionophore A 23187 on basophils. When basophils, in MNC preparations, were exposed to the Ca-ionophore A23187, the reactivity of the MoAbs studied remained unchanged (same MoAbs were tested as are listed in the fMLP experiment).

CGL basophils cultured in factor-conditioned media. Purity of 5-day-cultured basophils still was >95% in all samples tested (as determined by morphological criteria). Trypan blue staining revealed a viability of at least 98% of cells. FACS analyses of basophils obtained from two CGL patients were performed on days 0, 2, and 5. The reactivity of anti-TAC, already detectable on unstimulated cells, was increased on days 2 and 5 and was not dependent on the addition of biologic factors. An example of this reactivity pattern is given in Fig 3C. The HLA-DR and T4 antigens, expressed neither on basophils obtained from healthy donors nor on CGL basophils on day 0, became detectable on days 2 and 5. All three surface structures in question were also identified on cells in the control medium. Table 2 shows a comparison of the anti-TAC, anti–HLA-DR, and T4 reactivities of basophils cultured in the control medium (as determined by FACS analyses on days 0, 2, and 5). The expression of HLA-DR was stronger on BaPA and γ-IFN–stimulated basophils than on those in the other factor-conditioned media and the control medium, respectively (Fig 3D). Moreover, a moderate reactivity of the three anti-T4 antibodies (VIT-4, T4, Leu 3a) was noted in all culture samples, which is shown in Fig 3E. The reactivity of all other MoAbs tested remained unchanged (data not shown).

Normal basophils cultured in factor-conditioned media. Phenotypic analyses (combined toluidine/immunologic staining procedure) of normal basophils from all but one donor (in MNC preparations) cultured for 5 days in

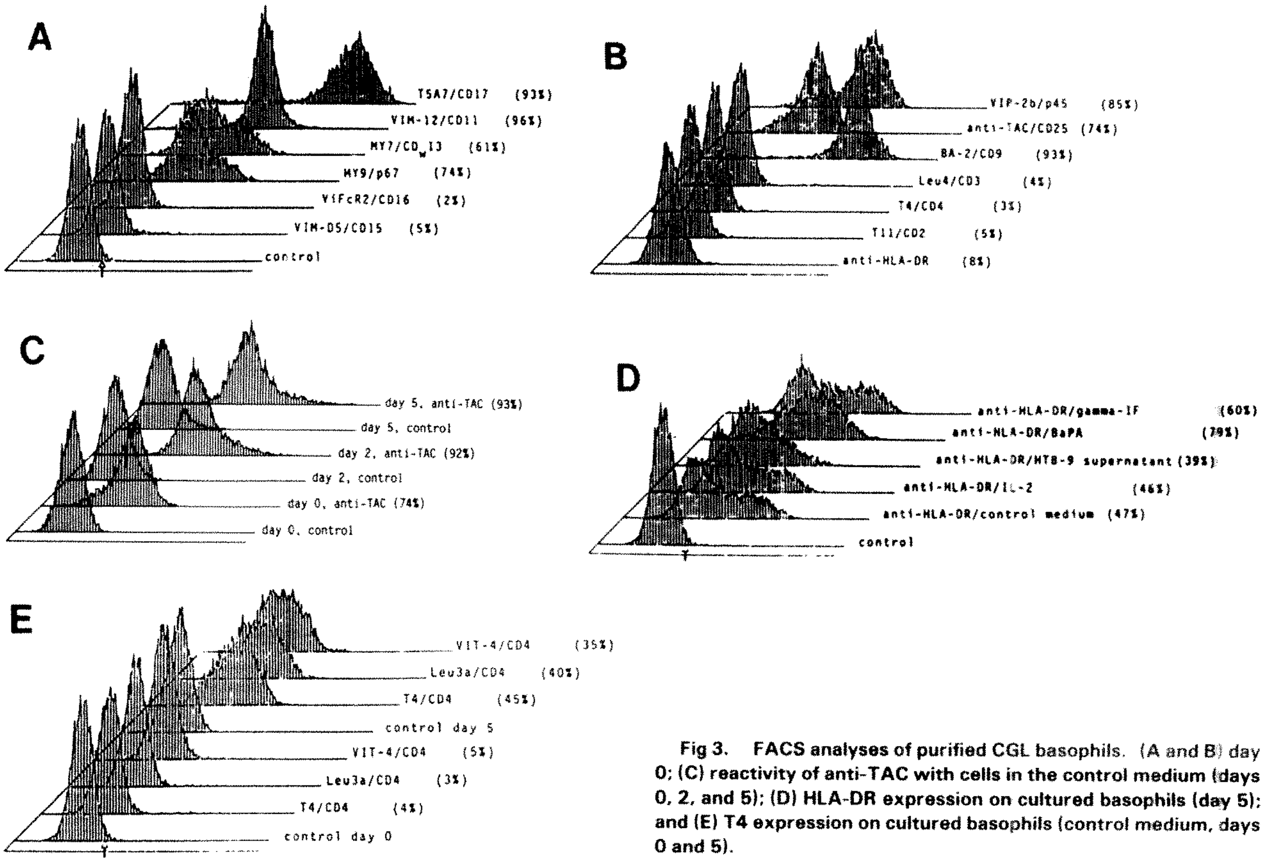

Fig 3. FACS analyses of purified CGL basophils. (A and B) day 0; (C) reactivity of anti-TAC with cells in the control medium (days 0, 2, and 5); (D) HLA-DR expression on cultured basophils (day 5); and (E) T4 expression on cultured basophils (control medium, days 0 and 5).

factor-conditioned media gave identical results (HLA-DR$^+$, T4$^+$) as compared with purified CGL-basophils.

^{3}H-Incorporation studies. Table 3 shows the proliferation kinetics as measured by ^{3}H-thymidine uptake on days 0, 2, and 5. It is evident that the ^{3}H-thymidine incorporation was higher on day 2 than on day 5. A distinct increase of the ^{3}H-thymidine incorporation was noted in the HTB-9–conditioned medium. As compared with the control medium, all other samples revealed no significantly elevated ^{3}H-uptake over a period of 5 days.

DISCUSSION

In this study, toluidine-stained cells were phenotyped with a panel of MoAbs to evaluate the antigenic membrane profile of peripheral blood basophils. The results clearly indicate that basophils express a unique pattern of membrane determinants.

The most conspicuous finding was the detection of three activation-linked structures on the surface membrane of basophils. The presence of the structures in question, ie, the IL 2 receptor, the T10 antigen, and the structure p 24, is consistent with the common idea of basophils representing an activated cell type and/or a population responding immediately to certain stimuli.

So far, reactivity of MoAbs directed against the IL 2 receptor was observed with activated T and B lymphocytes as well as monocytes stimulated by γ-IFN.[28-30] With the exception of the recently established eosinophilic cell line EoL[31] and a subset of myeloid blast cells,[32,33] no granulocytic cells

have yet been reported to be reactive with anti-IL 2 receptor antibodies.

Basophils also reacted with MoAb BA-2 (CD9), recognizing the p 24 structure. This antibody, which in our hands fails to react with neutrophils, was initially reported to identify a lymphohematopoietic cell surface structure.[34] Recently, the structure p 24 has also been detected on activated T cells,[35] and from affinity-purified antigen preparations it is now evident that the p 24 molecule is responsible for a protein kinase and for growth-promoting properties.[36]

Moreover, basophils were stained by MoAbs detecting the T10 antigen, which represents a new and quite unexpected observation. Whereas this structure was reported to be expressed on immature precursor cells as well as on activated lymphocytes, maturing myeloid cells have so far been considered unreactive with anti-T10 antibodies.[37,38]

Based on the assumption that basophils represent cells in an activated state or that these cells rapidly respond to stimuli, we also studied the basophil phenotype after in vitro culture. To this end, normal basophils in MNC suspension and CGL basophils as purified fractions were exposed to fMLP/cytochalasin B and Ca-ionophore and cultured for 5 days in medium containing either hrIL 2, hr-γ-IFN, supernatant of the HTB-9 cell line (which is reported to enhance blast colony formation),[24] or BaPA synthesized by a T cell hybridoma.[25,26] As compared with freshly obtained normal basophils and CGL basophils, the phenotype of cells in short-term cultures differed in three respects: First, after 2 days of culture, the reactivity of anti-TAC was significantly increased in all samples tested and remained unchanged until day 5. Second, the expression of HLA-DR was detectable on days 2 and 5. Third, the T4 antigen became demonstrable with three different MoAbs directed against this structure. At this point, we cannot definitely say whether the expression of HLA-DR and T4 on basophils is a phenomenon restricted to culture conditions or whether this may also occur in vivo. A differentiation to a "late" HLA-DR–positive state may be conceivable with regard to the other activation-linked structures. Whether the expression of differentiation structures or the susceptibility of receptors corresponds with mediator release requires further investigation.

The expression of various activation-linked structures and the T4 antigen on basophils again raises the question of a possible relationship of T lymphocytes and metachromatically stained cells.[39] The detection of the surface structures in question suggests that the functional properties and/or the differentiation of basophils are influenced by T cells or T cell modulating factors. Despite the occurrence of the T4 antigen on cultured basophils, the existence of a common precursor cell, as proposed by Burnet,[40] seems unlikely with regard to the numerous myeloid-associated determinants. The detection of the T4 antigen on cultured basophils does not represent a novel finding concerning myelomonocytic cells, nor does the presence of this antigen provide evidence for a common precursor since monocytes and γ-IFN–stimulated HL-60 cells were reported to display the T4 antigen as well.[41,42]

The myeloid determinants we detected on basophils were in particular the CR3 receptor recognized by CD11 MoAbs, the structure p150 (CD_w13 MoAbs), the β chain of LFA-1 (CD_w18 MoAbs), lactosylceramide (CD17 MoAbs), the CR1 receptor (MoAb E11), the 40-kd Fcγ-receptor (MoAb CIKM5), and the glycolipid structure identified by MoAb VIM-2, present on all granulocytic cells beyond the stage of promyelocytes. Moreover, basophils clearly displayed the structure p67 (MoAbs MY9, L4F3), which had so far been known to be generated only by myeloid progenitors and monocytic cells.[43]

The p67 determinant was reported to be lost gradually with ongoing granulocyte differentiation.[43] Because staining of basophils was evident in our study, the decrease of antibody binding seems to be restricted to neutrophil and eosinophil differentiation. Basophils we obtained from healthy adults therefore showed a different reactivity with MY9, as did in vitro-cultured fetal basophilic cells which were reported to be MY9 negative.[44]

Certain well-defined neutrophil-associated structures were missing: The structure 3-fucosyl-*N*-acetyllactosamine identified by CD15 MoAbs (VIM-D5, 1G10, VIM-C6) was not detectable. After neuraminidase treatment, however, 3-FAL is expressed on basophils, which represents a phenomenon we already observed with myeloid and lymphatic blast cells.[18] An observation of apparent functional importance was that basophils lack the 50- to 70-kd Fcγ-receptor (recognized by MoAbs VEP-13, Leulla, ViFcR2). This receptor is of major importance for the phagocytotic capacity of neutrophils. Antibodies against this structure completely block the binding and ingestion of IgG-coated sheep erythrocytes.[45] Because basophils are known to bind aggregated human IgG,[46] minor differences of the receptor's molecular structure on the different types of granulocytes could be an explanation for the nonreactivity of the CD16 MoAbs with basophils. An alternative possibility which cannot yet be excluded either is that the 40-kd Fcγ-receptor (recognized by MoAb CIKM5) is the sole IgG binding site of basophils.

CR 1 and the LFA-1 structures, which are further receptors contributing to the functional process of phagocytosis mainly by providing attachment to target particles, were identified by corresponding MoAbs on all types of mature granulocytes. These data confirm previous findings of the CR 1 receptor on basophils, obtained by use of complement-coated particles,[47] and are consistent with the role assigned to basophils in the immune response.

So far, basophils have been explored mostly by morphological,[2,3,48,49] histochemical,[4,7,48] and functional[5,6,50,51] analyses. These studies were laborious and, with a few exceptions, could not be performed simultaneously. The knowledge of the basophil phenotype and the technique used in this study offers a new possibility for the simultaneous determination of differentiation and function and provides the opportunity to influence this cell type specifically through its different surface structures.

ACKNOWLEDGMENT

We are indebted to Professor Dr W. Knapp for his suggestions for this manuscript. We also wish to thank Dr O. Majdic for his helpful technical advice, Susanne Frank and Roswitha Gabriel for their skillful technical assistance, Mag. Alexandra M. Jantscher-Karlhuber for her help in translating, and Johanna Moser for typing this manuscript.

Experimental Transmission and Pathogenesis of Immunodeficiency Syndrome in Cats

By Edward A. Hoover, James I. Mullins, Sandra L. Quackenbush, and Peter W. Gasper

We describe the identification, experimental transmission, and pathogenesis of a naturally occurring powerfully immunosuppressive isolate of feline leukemia virus (designated here as FeLV-FAIDS) which induces fatal acquired immunodeficiency syndrome (AIDS) in 100% (25 of 25) of persistently viremic experimentally infected specific pathogen-free (SPF) cats after predictable survival periods ranging from <3 months (*acute immunodeficiency syndrome*) to > one year (*chronic immunodeficiency syndrome*), depending on the age of the cat at time of virus exposure. The pathogenesis of FeLV-FAIDS–induced feline immunodeficiency disease is characterized by: a prodromal period of largely asymptomatic viremia; progressive weight loss, lymphoid hyperplasia associated with viral replication in lymphoid follicles, lymphoid depletion associated with extinction of viral replication in lymphoid follicles, intractable diarrhea associated with necrosis of intestinal crypt epithelium, lymphopenia, suppressed lymphocyte blastogenesis, impaired cutaneous allograft rejection, hypogammaglobulinemia, and opportunistic infections such as bacterial respiratory disease and necrotizing stomatitis. The clinical onset of immunodeficiency syndrome correlates with the replication of a specific FeLV-FAIDS viral variant, detected principally as unintegrated viral DNA, in bone marrow, lymphoid tissues, and intestine. Two of seven cats with chronic immunodeficiency disease that survived >1 year after inoculation developed lymphoma affecting the marrow, intestine, spleen, and mesenteric nodes. Experimentally induced feline immunodeficiency syndrome, therefore, is a rapid and consistent in vivo model for prospective studies of the viral genetic determinants, pathogenesis, prevention, and therapy of retrovirus-induced immunodeficiency disease.

THE HUMAN immunodeficiency virus (HIV)[1-7] has infected several million people worldwide, at least 50,000 of whom have contracted AIDS.[8-11] More than 36,000 cases of AIDS have been reported in the United States; >56% of these people, including 79% of those infected with HIV for ≥23 months, have died.[9,10] If 10% to 30% of the 1 to 1.5 million persons currently infected with HIV in the United States develop disease, 270,000 cases will occur by 1991,[10] the most serious epidemic of the past 50 years.[11]

Retrovirus-induced AIDS has long-standing precedent in feline leukemia virus (FeLV)-associated immunosuppression, a naturally occurring syndrome recognized for >15 years in cats infected with some isolates of FeLV.[12-18] The contagious transmission of FeLV was first recognized among dense urban animal populations of cats with high degrees of social contact and high incidences of leukemia and other infectious diseases.[18-19] It has subsequently become clear that many more cats die from the cytosuppressive consequences of FeLV infections (immunodeficiency syndrome and bone marrow aplasia) than from leukemia[12,16-22], a paradigm perceived by Gallo and colleagues[23,24] in seeking a contagious exogenous retrovirus as a cause of immunodeficiency disease. Although HIV and FeLV infections clearly represent distinct retrovirus/host relationships, both infections involve horizontal transmission requiring close contact and transfer of secretions, sequential stages in the progression of infection and disease,[27-29] virus strain-related variations in tissue tropism and pathogenicity,[29-35] and viral latency and activation.[36]

Whether retrovirus-associated immunodeficiency is determined principally by specific viral genotypes (variants) or whether, alternatively, disease is triggered principally by cofactors such as genetic background or frequent viral or other intercurrent infections is an issue important to the understanding of retrovirus pathogenesis. We provide evidence for the former tenet in describing the identification, transmission, and pathogenesis of a naturally occurring, intensely immunosuppressive isolate of feline leukemia virus (designated here as FeLV-FAIDS) which consistently induces lethal immunodeficiency syndrome, the onset of which is associated with replication of a disease-specific variant virus genome in bone marrow, lymphoid tissue, and intestine of experimentally infected animals.

MATERIALS AND METHODS

Animals

The specific pathogen-free (SPF) cats used in the transmission studies we report were from a breeding colony of cesarian-derived SPF cats maintained in the Department of Pathology, Colorado State University. These animals are free of infection with and immunity to horizontally transmitted feline viruses, including FeLV. Age-matched, noninoculated, noncontact control SPF cats were obtained from the same source, for which there is a substantial database of normal age-adjusted hematologic data.

Virus, Inoculation, and Sample Collection

The original FeLV-FAIDS inoculum consisted of a 20% (wt/vol) viable-cell-free extract of thymic lymphoma tissue from an FeLV-infected pet cat in which the lymphoma had regrown after regression induced by radiotherapy. In most inoculation experiments, virus was administered intraperitoneally (IP); in two series of inoculations, the

intranasal route was used (both routes induced infection and disease) (Table 1). Inocula for serial passage experiments were prepared as 20% (wt/vol) extracts of bone marrow, spleen, or lymph node from animals that had developed fatal immunodeficiency disease in the first virus passage (Table 1). All inocula contained between 1 and 2×10^5 focus forming units (ffu) of infectious FeLV. One group of two weanling animals was inoculated with virus harvested from a feline fibroblast cell line inoculated with the original stock of FeLV-FAIDS. Likewise, FeLV-FAIDS was characterized morphologically by electronmicroscopic examination of glutaraldehyde-fixed, osmium tetroxide-postfixed inoculated feline fibroblast cell cultures.

Blood samples were collected from each inoculated cat prior to infection and at weekly intervals for the first 6 weeks postinoculation and biweekly thereafter. Bone marrow samples were collected at various intervals (most often biweekly) by needle aspiration from the femur or humerus of inoculated cats. For all inoculation, blood collection, and bone marrow sampling procedures, animals were anesthetized with ketamine hydrochloride.

Assays to Monitor FeLV-FAIDS Infection in Cats

Immunofluorescence for FeLV p27 group-specific antigen in blood cells and tissues. FeLV-FAIDS group-specific antigen (gag gene-coded major viral structural protein p27) was detected by indirect immunofluorescence staining of methanol-fixed blood films[32-37] and on methanol-fixed paraffin-embedded tissues.[38] The goat anti-FeLV p27 antiserum used was extensively absorbed with feline blood and bone marrow cells to eliminate non-specific reactivity due to natural anti-feline tissue antibody in goat or rabbit sera.[32,37] The persistent presence of FeLV p27 antigen in blood cells (neutrophils, platelets, lymphocytes) correlates >95% of all instances with the presence of infectious virus in blood.[39,40]

Enzyme-linked immunosorbent assay (ELISA) for FeLV antibody. FeLV antibody was determined by an ELISA using sucrose density-gradient purified whole FeLV (KT isolated from the FL74 lymphoblast cell line) as antigen, feline test serum, and peroxidase-conjugated goat-anti-feline IgG as the secondary reagent (Miles Scientific, Naperville, IL).[41]

Quantitation of infectious virus in inocula. Infectious FeLV in tissue extracts was determined by the clone 81 focus induction assay described by Fischinger et al[42] Particle-associated reverse transcriptase was also demonstrated as described for FeLV by Nicolson et al.[43]

Detection of viral DNA in tissues. FeLV-FAIDS integrated and unintegrated viral DNA was detected in tissues of infected cats by Southern blotting[44] using Kpnl endonuclease digestion and hybridization to an exogenous FeLV-specific DNA probe that identifies a 250-base pair (bp) sequence in the unique region of the long terminal repeat of exogenous feline retroviruses only, as detailed by Mullins et al.[45,46] In brief, total cellular DNA (7.5 μg) was purified, digested with Kpnl, electrophoresed in 1.2% agarose gels, transferred to nitrocellulose, hybridized with the exogenous FeLV-specific probe (exU3) with 10% dextran sulphate and 50% formamide, washed, then exposed to x-ray film as described previously.[45-47]

Hematologic assays. Complete blood cell counts were performed at biweekly intervals (Coulter S-plus calibrated for feline blood). In some cats with terminal immunodeficiency disease, bone marrow cell clonogenic colony-forming assays of erythroid and granulocyte/macrophage progenitor cells were performed in methylcellulose semisolid medium using techniques described by Abkowitz et al[48] and modified by Gasper et al[49] Albumin and globulin classes in terminal sera from some cats were determined by electrophoresis using standard procedures.

Lymphocyte Blastogenesis and Skin Grafting

Mitogen-driven, feline T lymphocyte blastogenesis was determined as previously described originally by Cockerell et al[50] and extended by Rojko et al[51] for feline blood lymphocytes. Blastogenesis assays were performed by incubating Ficoll-metrizoite-separated blood mononuclear cells with either concanavalin A (1 μg/ 2×10^5 cells, a feline T cell mitogen)[51]; staphylococcus protein A (20 formalin-fixed bacteria per cell, a feline T and B cell mitogen)[51]; or pokeweed mitogen (10 μg/ 2×10^5 cells, a feline T and B cell mitogen).[51] Net cell DNA-associated uptake of ^{3}H thymidine in cells pulse-labeled for 18 hours before harvest with 0.5 μCi of ^{3}H thymidine/ 2×10^5 cells was then quantitated by liquid scintillation. Allogeneic cutaneous allographs (1.5 cm^2) from a single unrelated donor cat were applied and rejection intervals were assessed as described previously in SPF cats by Perryman et al.[14]

Histologic Examination

Necropsies were performed and macroscopic lesions were recorded for all cats that died or were killed due to symptoms of severe immunodeficiency disease. Duplicate tissue sections were collected in absolute methanol for immunofluorescence and in either formalin or Bouin's fixative for conventional histologic section preparation. The following tissues from each of 20 animals were examined histopathologically; mandibular, pharyngeal, mesenteric, and colonic lymph nodes, spleen, bone marrow, thymus, liver, kidney, adrenal, lung, heart, and small intestine (duodenum, jejunum, ileum) colon, urinary bladder, trachea, esophagus, thyroid, nostril, and brain.

RESULTS

Virus Isolation and Characteristics

The lymphocytopathic FeLV we describe was identified by intrathymic inoculation of newborn kittens with an extract of thymic lymphoma tissue from an FeLV-infected pet cat in which the lymphoma had regrown after regression induced by radiotherapy. Five of six inoculated kittens died with severe lymphoid depletion and enteritis within 2 months postinoculation (Table 1). The viral isolate (designated here as FeLV-FAIDS) was identified as a feline leukemia retrovirus[52] by the following criteria: type C morphology by electronmicroscopy; immunoreactive FeLV group-specific (gag) and envelope proteins as determined by immunofluorescence and immunoelectrophoresis, respectively; virus particle-associated reverse transcriptase activity[53,54]; and FeLV interference inducing activity characteristic of FeLV subgroup A and B viruses[55-58] (performed in the laboratory of Drs Oswald Jarrett and David Onions, University of Glasgow, Glasgow, Scotland).

Experimental Transmission and Disease Induction

To determine whether the lymphocytopathic activity of the FeLV-FAIDS isolate was restricted to or dependent on infection during the neonatal period, we inoculated groups of SPF cats aged 8, 15, and 24 weeks with the original virus stock. We then performed two serial virus subpassages in 8-week-old SPF cats using marrow, spleen, and lymph node inocula containing between 1 and 2×10^5 (infectious) ffu[42] of FeLV (Table 1).

Cats were inoculated with between 1 and 2 × 10^5 ffu FeLV-FAIDS as determined by clone 81 assay.[42]

*Number affected/total tested.

†Prolonged rejection = >16 days ($p < 0.05$ by Student's *t* test) (mean for normal SPF cats 13.1 = +1.5 days, n = 20). A single unrelated donor was used for all cats.

Twenty-five of 35 cats of various ages (71%) inoculated with FeLV-FAIDS developed persistent viremia within 2 to 4 weeks after inoculation. All the viremic cats (25 of 25) died of immunodeficiency disease from 25 to 524 days after inoculation (mean 171 ± 156 days) (Table 1). None of 10 cats that developed transient, regressive infection after virus inoculation developed any sign of disease after observation periods as long as 600 days. ELISA antibody titers against FeLV-FAIDS developed in both progressively and regressively infected cats; however, titers of 25 viremic cats destined to develop immunodeficiency syndrome declined to minimal levels (geometric mean 1:4.3 ± 3.6) 3 to >40 weeks before clinical disease developed. The terminal mean viral antibody titer of ten regressively infected cats was 1:58 ± 5.6.

The susceptibility of SPF cats to induction of persistent FeLV-FAIDS viremia, the latent period for clinical immunodeficiency disease induction, and the incubation period for disease induction all were related to age of cat at time of inoculation (Table 1); 85% of animals <8 weeks old at inoculation developed persistent viremia and survived for an average of 80 ± 58 days postinoculation (DPI). In contrast, 56% of cats >15 weeks old at inoculation developed persistent viremia and survived for an average of 311 ± 173 DPI. Therefore, relative to other characterized FeLV isolates so studied,[30] FeLV-FAIDS exhibited considerable virulence and was capable of producing persistent viremia and disease in young adult cats after a single intranasal or intraperitoneal inoculation and without the concurrent administration of adrenal corticosteroids,[59] a cofactor required to induce >50% incidence of progressive infection in adult cats with many FeLV isolates.[30]

Clinical Courses of Disease

Two clinical courses of feline immunodeficiency syndrome were recognized. The first clinical course, acute or early onset immunodeficiency disease, was characterized by a survival period of <180 DPI (mean 86 ± 42; range 25 to 160) and developed in 72% (18 of 25) of all viremic cats and 94% (15 of 16) of viremic cats that were 8 weeks or less at inoculation. A short (2 to 10 weeks) asymptomatic period was followed by progressive lymphocytopenia, suppressed lymphocyte blastogenesis, failure to gain weight and/or progressive loss of weight leading to emaciation (Fig 1A), persistent diarrhea, and opportunistic infections including bacterial rhinitis, pneumonia, and necrotizing stomatitis (Fig 1B).

The second clinical course, chronic or late-onset feline AIDS, was characterized by a survival period of >180 DPI (mean 396 ± 113, 4.6 times that of cats with acute AIDS) and occurred in 28% (7 of 25) of all viremic cats but in 67% (6 of 9) of cats aged ≥15 weeks at inoculation. The chronic disease course was marked by a relatively long (6 months to >1 year) and largely asymptomatic period of viremia, subnormal weight gain, and progressive lymphocytopenia. This prodromal period was followed by an accelerated symptomatic phase characterized by relentless diarrhea and accelerated weight loss leading to terminal debilitation. Thus, the chronic clinical course of experimental feline AIDS more closely simulated the protracted natural evolution of most cases in immunodeficiency disease in humans.[8]

Hematologic and Immunologic Features of FeLV-FAIDS Infection

The mean lymphocyte count for all symptomatic and presymptomatic FeLV-FAIDS inoculated cats over the course of all sampling periods postinoculation (2 to 67 weeks) was significantly below that of age-matched controls (Fig 2, Table 2). Lymphocyte mitogen-driven blastogenesis characteristically was depressed in symptomatic cats as compared with uninoculated controls (Figs 2 and 3 and Table 2). Skin allograft rejection time was significantly prolonged in four of five symptomatic FeLV-FAIDS–infected cats *v* normal controls (Table 2). Gamma-globulin levels in terminal sera from ten AIDS cats assayed were 44% of those of controls (Table 2). Thus, evidence for severe deficits in both T and B lymphocyte function were present in cats with immunodeficiency syndrome.

Nonlymphocytic hematologic deficits also were detected in FeLV-FAIDS–inoculated cats. Circulating granulocytes and monocytes in virus-inoculated cats were significantly less than controls over the course of all sampling periods (Table 2). Terminal hematocrits of inoculated cats also were less than controls and evidence of erythropoietic regeneration was absent (reticulocyte counts were <50,000 in infected cats *v* >150,000 in controls). Clonogenic colony-forming assays of bone marrow cells from each of four cats with immunodeficiency syndrome tested revealed suppression of erythroid progenitor cells without discernible impairment of myeloid progenitor cell growth (Table 2).

Lesions

A consistent array of lesions was present in cats with acute feline AIDS. These were: (a) thymic atrophy in all (13 of 13) cats examined histologically (thymic remnants were detectable only by microscopy); (b) lymphoid depletion involving follicular and parafollicular lymphocytes in lymph nodes, spleen, and Peyer's patches, resulting in ablation of entire follicles (9 of 13 animals) (Fig 1B and D); (c) follicular lymphoid hyperplasia in some cats (6 of 13) characterized by large, sometimes irregularly shaped follicles with prominent germinal centers comprised of lymphoblasts (Fig 1C); and (4) necrotizing enterocolitis (13 of 13) marked by necrosis and partial regeneration of the mucosal germinal epithelium, neutrophil and macrophage infiltration, and atrophy of mucosal villi (Fig 1F). The histopathogenesis of the lymphoid lesions in FeLV-FAIDS–infected cats, therefore, resembles that in human AIDS, ie, an apparent sequence of follicular lymphoid hyperplasia of variable duration followed by progressive follicular ablation and ultimately extensive parafollicular and medullary lymphoid depletion.[60-63]

Lesions of lymphoid depletion in cats with chronic course of disease were more pronounced than in animals with the acute syndrome. Bone marrow cellularity in terminal immunodeficiency cats was significantly reduced *v* uninfected, age-matched SPF control cats. Four of seven animals with chronic disease that survived >400 DPI developed terminal

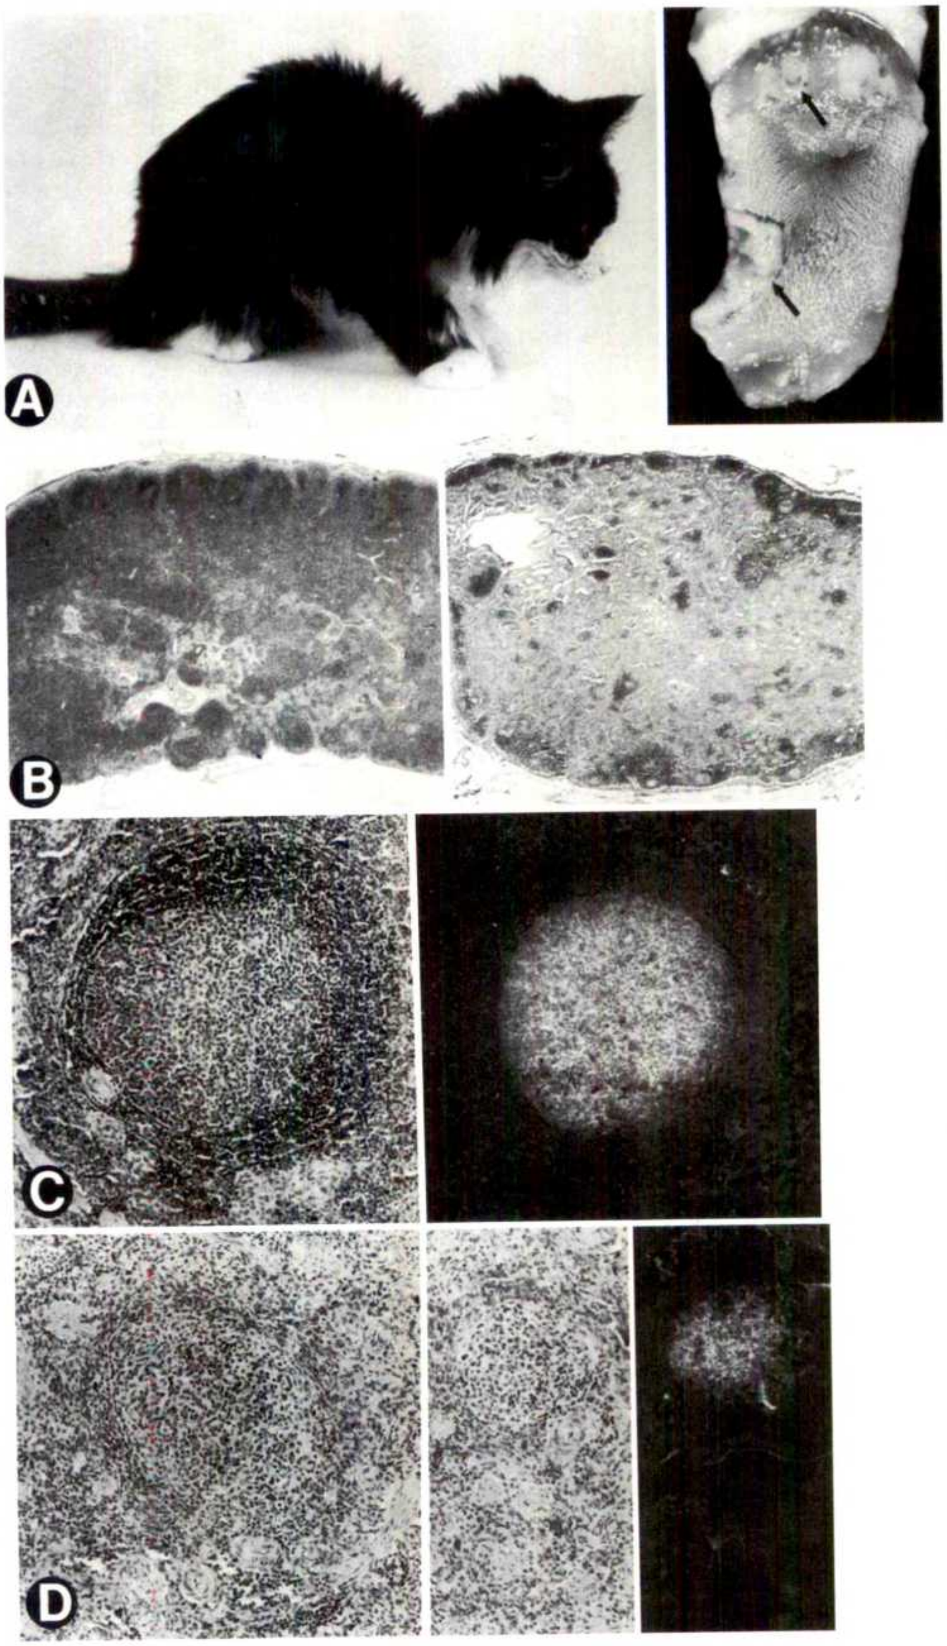

Fig 1. Pathogenesis of experimentally induced feline immunodeficiency disease. (A) Clinical appearance of a cat with advanced AIDS; chronic diarrhea, severe weight loss and debilitation are typical (left); opportunistic infection: necrotizing oral lesions (arrows) involving the tongue (right). (B) Normal lymph node from a control SPF cat; dense cortical and paracortical populations of lymphocytes are apparent (left). Comparable lymph node from a cat with terminal immunodeficiency syndrome; extensive depletion of lymphocytes in the cortical (follicular), paracortical, and medullary areas is evident (right). (C) Prodromal follicular lymphoid hyperplasia in a formalin-fixed, conventionally (H&E)-stained section of spleen from a cat infected with FeLV-FAIDS (left). FeLV-FAIDS replication in splenic follicle from the cat at left demonstrated by immunofluorescence in a methanol-fixed tissue section (right). (D) FeLV-FAIDS–induced lymphoid depletion, severely depleted splenic follicles in hematoxylin and eosin (H&E)-stained histologic sections (left and middle); corresponding immunofluorescence section (right) demonstrates concomitant depletion in viral replication.

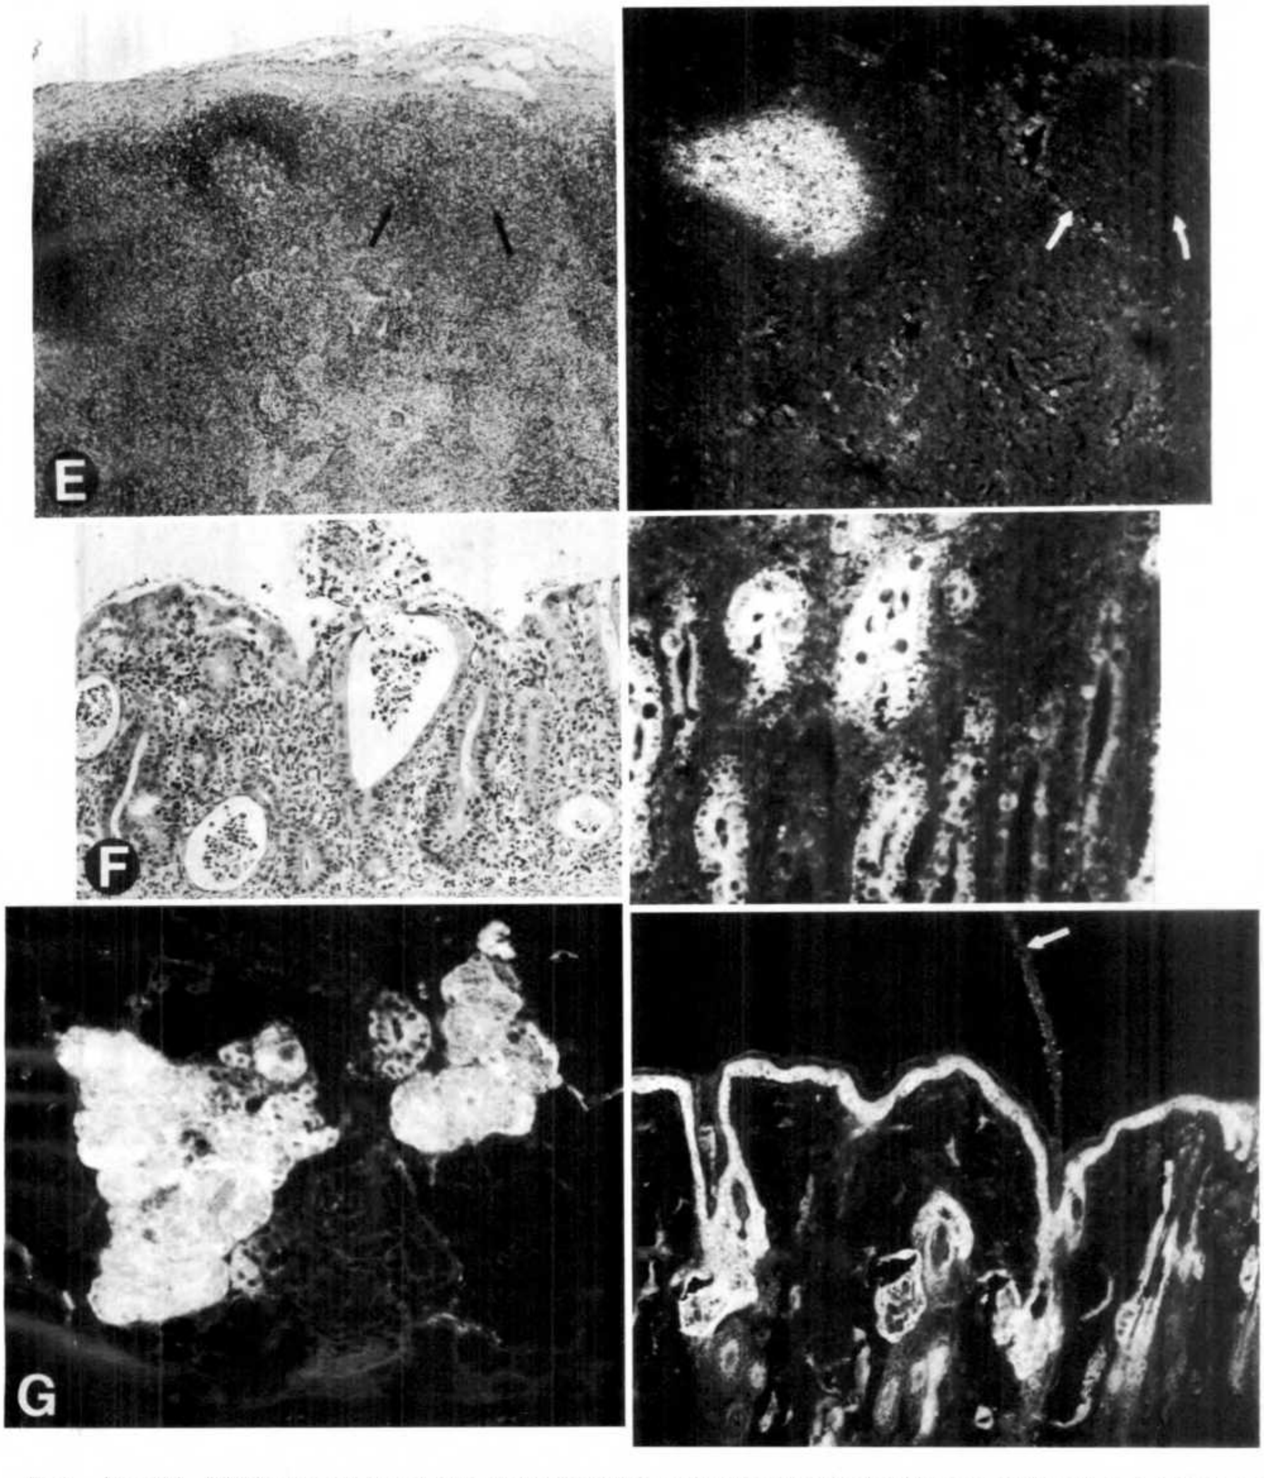

Fig 1. (Cont'd.) (E) Ablation of the cortical lymphoid follicles (left, arrows) correlated with extinction of viral replication in the same areas (right, arrows), whereas viral replication remained evident in the adjacent nondepleted follicle. (F) Necrotizing enteritis induced by FeLV-FAIDS, with depletion and regeneration of germinal epithelium in the colon (H&E section, left); replication of FeLV in colonic germinal epithelium of (immunofluorescence, right). (G) Replication of feline AIDS virus in salivary gland epithelium (left) and in the epidermis, hair follicles, and sebaceous glands of the nostril of an infected cat (right). Arrowhead = hair shaft (immunofluorescence as above).

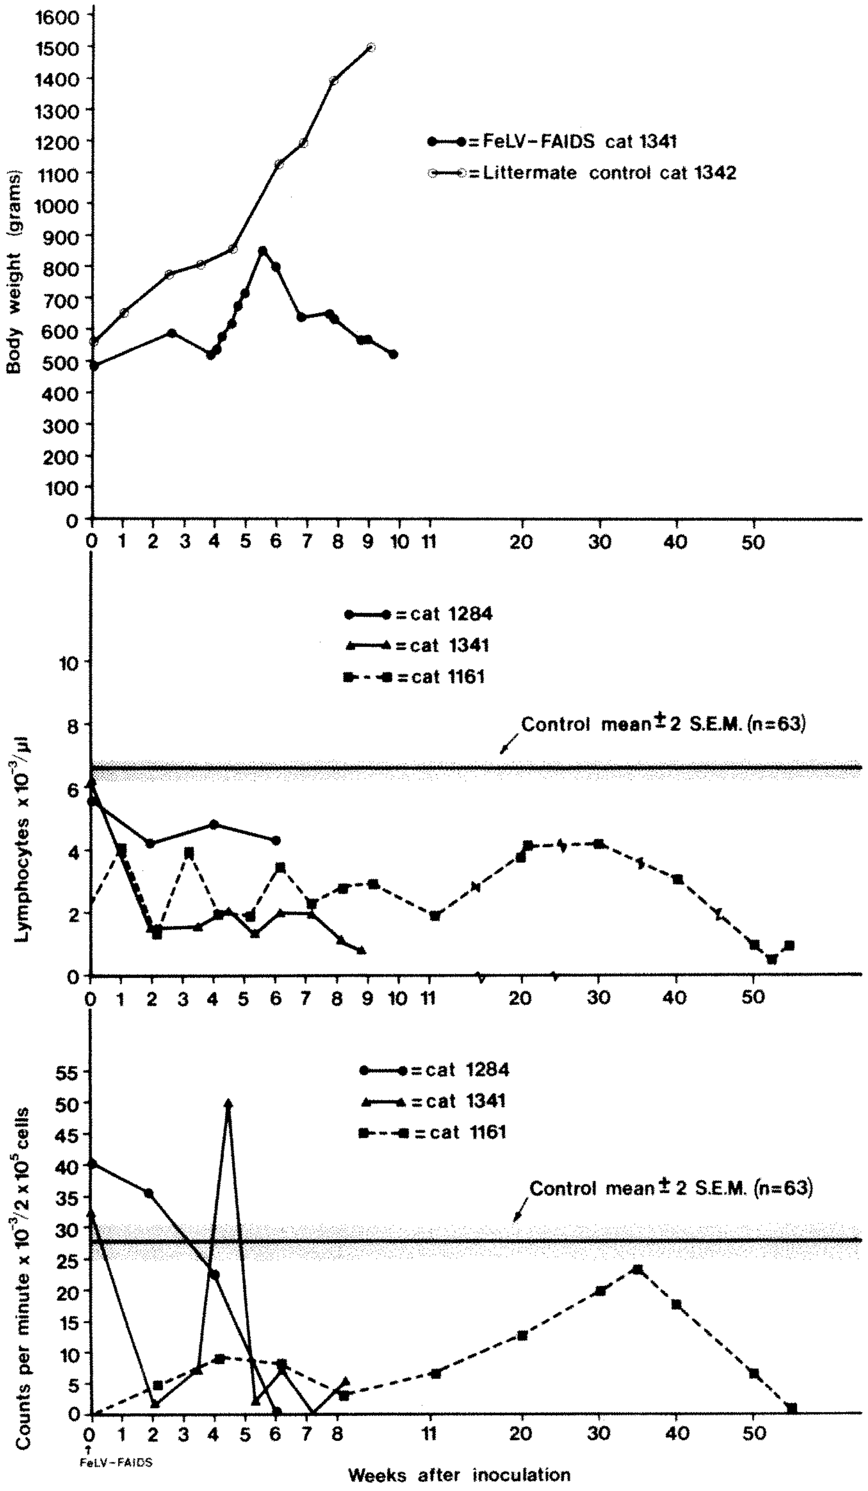

Fig 2. Sequential changes in body weight (top), lymphocyte numbers (middle), and lymphocyte mitogenic response to *Staphylococcus* protein A (bottom) in three cats inoculated with FeLV-FAIDS and representing the *acute* (cats 1284 and 1341) and *chronic* (cat 1161) courses of feline immunodeficiency disease.

lymphoblastic lymphoma superimposed on lymphoid depletion and affecting the marrow, intestine, and mesenteric nodes (see below).[64,65]

Virus Tissue Tropism

Immunofluorescence analysis of lymph node sections from cats inoculated with FeLV-FAIDS revealed intense viral replication (FeLV p27 gag protein) in nodes with many hyperplastic follicles but minimal viral replication in nodes with depleted follicles (Fig 1C through E). The extinction of viral replication in lymphoid tissues, therefore, correlated with extinction of lymphoid follicles. Viral replication in intestinal crypt epithelium also was correlated with evidence of antecedent necrosis of crypt epithelium (Fig 1F).

FeLV-FAIDS replication not associated with discernible cytopathic effect was detected in several cell types: ie,

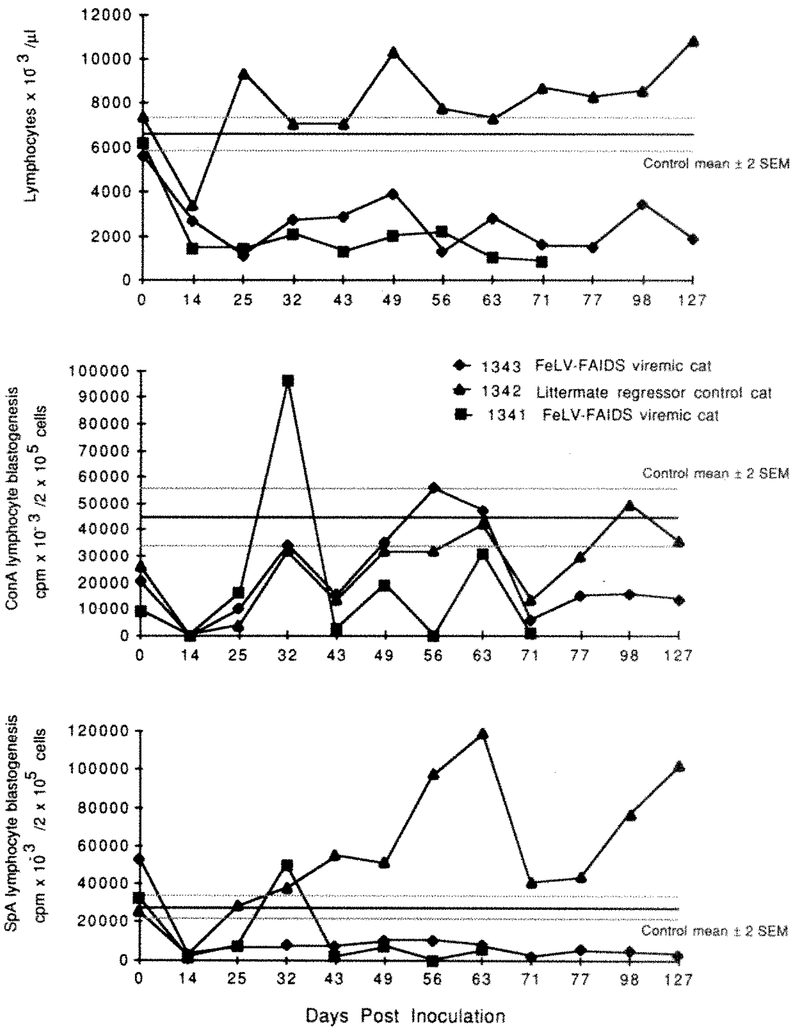

Fig 3. Sequential changes in blood lymphocyte numbers and blastogenic responses from representative cats inoculated with the mitogens concanavalin A and *Staphylococcus* protein A in representative FeLV-FAIDS–inoculated SPF cats that developed either persistent viremia (1341) or transient infection and regressive infection (1342) as compared with an uninoculated littermate control.

Table 2. Summary of Hematologic and Immunologic Data in Cats With Immunodeficiency Syndrome Induced by FeLV-FAIDS

Parameter Measured	FeLV-FAIDS Viremic Cats	Cats (n)	FeLV-FAIDS Regressors*	Cats (n)	Control SPF Cats	Cats (n)

Marrow CFU-GM (no. of CFU/10(5) cells seeded)	38 ± 8†	—	ND		37 ± 1	

*No disease developed after observation periods up to 600 days postinoculation.

†Hematopoietic colony-forming units–erythroid (CFU-e, BFU-e) or granulocyte macrophage (CFU-GM) generated by feline bone marrow cells assayed in a methylcellulose medium culture system.[80] For FAIDS cats, n = 4; for control cats, n = 320.

circulating neutrophils and platelets, salivary gland acinar and duct epithelium, mucosal epithelium of the esophagus, nasal passages, and bronchioles, and the glandular and hair follicle epithelium of the nostrils (Fig 1g). Neither viral antigen nor lesions were found in the testes, ovary, uterus, kidney, liver, adrenal, thyroid, heart, or brain. Thus, the feline AIDS-inducing virus replicated in a range of hemolymphatic and epithelial tissues but appeared to be cytopathic only in bone marrow, intestine, and lymphoid tissue.

The intestinal lesions in cats infected with FeLV-FAIDS resembled those produced by the feline and canine parvoviruses. Therefore, we assayed both original viral inocula and intestinal mucosal extracts from three cats with fatal immunodeficiency syndrome for feline parvoviral antigen by an ELISA sensitive to 2 pg viral antigen. Each was negative. Moreover, six of six SPF cats immunized with commercial feline panleukopenia parvovirus vaccine developed immunodeficiency disease featuring chronic diarrhea and enteritis after FeLV-FAIDS inoculation.

Southern Blot Analysis of Viral DNA in Tissues

Southern blot analyses of purified cellular DNA demonstrated viral DNA in all (90 of 90) virus-antigen–positive tissue and bone marrow samples from all 25 viremic cats examined (Table 1). Highest levels of FeLV-FAIDS DNA were in bone marrow, intestine, and lymphoid tissues. As initially reported,[47] two significant viral genomes were detected in the tissues of infected cats: (a) a ubiquitous "common" or "early" form virus genome recognized as a 3.65-kb internal viral DNA fragment (Fig 4) in all virus-antigen–positive tissues of all viremic asymptomatic and symptomatic cats examined at all postinoculation intervals; and (b) a variant genome (designated variant A) characterized by an additional KpnI site in the extracellular glycoprotein gene (gp70) region of the viral envelope gene and generating a signature 2.1-kb 3′ KpnI fragment (variant A), which was detected in large amounts (15 to 50 copies/cell), predominately as unintegrated viral DNA (Fig 4) in the bone marrow, intestine, and nonseverely-depleted lymphoid tissues only of animals with symptomatic immunodeficiency syndrome. In tissues of animals with severe lymphoid depletion, minimal amounts of viral DNA were discernible by Southern blotting and minimal viral antigen was demonstrable by immunofluorescence (Fig 1C through E). Thus, FeLV-FAIDS common-form virus was demonstrated in all viremic cats both before and after the onset of disease, whereas the appearance and amplification of variant A virus genome in marrow, intestine, and lymphoid tissues was correlated strongly with the development of symptomatic, ultimately fatal immunodeficiency disease.

Late-Onset Neoplasia in Some Animals Infected With FeLV-FAIDS

Two of the seven animals that developed chronic immunodeficiency syndrome, both of which survived for >400 days after inoculation (471 and 524 days, respectively), also developed terminal T cell or null cell lymphoma affecting the bone marrow, small intestine, and to a lesser degree, mesenteric lymph nodes. Histologic examination of the mesenteric lymph nodes indicated that proliferation of neoplastic lymphoblasts was superimposed on lymphoid involution. Other nodes contained only the lymphoid depletion typical of advanced immunodeficiency syndrome. Southern blot analysis of lymphoma tissues revealed clonal viral integration

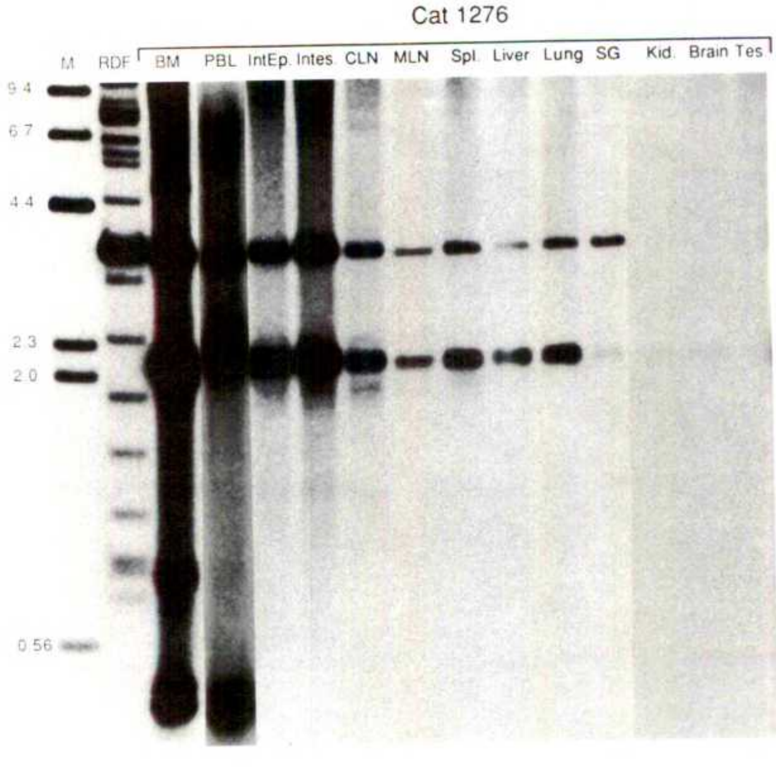

Fig 4. Tissue distribution of FeLV-FAIDS DNA in an animal with acute feline immunodeficiency syndrome; 7.5 μg total cellular DNA was purified from frozen postmortem samples of the tissues indicated and digested with the restriction endonuclease KpnI. M, mol wt markers (kb scale); RDF, a cloned cell line infected with FeLV-B-GA[43]; BM, bone marrow; PBL, peripheral blood lymphocytes; IntEp., intestinal epithelium, Intes., intestine; CLN and MLN, colonic and mesenteric lymph nodes, respectively; Spl., spleen; SG, salivary gland; Kid., kidney; Tes., testis. The FeLV-FAIDS common form (CF) internal virus band migrates at 3.65 kb, whereas the AIDS-specific variant A (VA) band migrates at 2.1 kb. The bands at 0.35 and 0.45 kb in the BM and PBL lanes correspond to 5′-LTR sequences detected as a consequence of the presence of unintegrated DNA, derived from linear and circular DNA, respectively.

patterns confirming the presence of a clonal proliferation of virus-genome–bearing cells (data not shown). Thus, prolonged FeLV-FAIDS viremia and/or chronic immunosuppression may result in long-latency lymphomagenesis, as has been observed in some HIV-infected patients.[66-68]

DISCUSSION

Although a lymphoid depletion/immunodeficiency syndrome has been recognized for >15 years in cats infected with feline leukemia virus,[12-18] the disease has neither been consistently reproduced with FeLV inocula nor has its relationship to virus genotype *v* other cofactors been elucidated. Cats infected with the most ubiquitous naturally occurring feline leukemia viruses—interference subgroup A (FeLV-A)[55-58]—commonly remain persistently viremic and asymptomatic for long periods. Viruses of subgroups B or C occur naturally only in combination with FeLV-A[57-58] and probably have evolved from the FeLV-A either through mutation or through recombination with silent multicopy endogenous FeLV sequences in the feline genome (Mullins JI et al, manuscript in preparation, and refs 52 and 58). It is plausible, therefore, that the acute pathogenicity associated with some FeLV field isolates reflects the presence of cytopathic virus variants in these inocula. Further definition of the molecular and biologic properties of FeLV variant genomes should aid in elucidating the mechanisms of disease induction by feline leukemia viruses. The studies we report define the biologic and virologic properties of a naturally occurring intensely immunosuppressive isolate of FeLV which consistently induces fatal immunodeficiency syndrome after incubation periods as short as 3 months to as long as 43 months, an interval governed principally by the age of the cat at time of infection. The onset of clinical immunodeficiency syndrome coincides with the appearance of a characteristic variant viral genome which replicates in bone marrow, lymphoid tissues, and intestine, predominantly as unintegrated viral DNA (UVD). The association of unintegrated retroviral replication with cytopathicity has been demonstrated for reticuloendotheliosis virus,[69] visna virus,[70] avian osteopetrosis virus,[71] and HIV.[33] In FeLV-FAIDS–associated immunodeficiency disease, the replication of UVD in target tissues is notable in its magnitude, persistence, and correlation with disease onset and lesions in vivo.

The consistent experimental induction of immunodeficiency disease by a specific type C retrovirus isolate in outbred animals free of intercurrent infection with other pathogens supports the tenet that viral genome rather than host or environmental factors plays the major role in induction of immunodeficiency disease. These results also suggest that neither D type morphology nor a complement of supranumery genes is essential for induction of immunodeficiency syndrome by retroviruses. Our continuing work with FeLV-FAIDS and another feline leukemia virus variant that induces aplastic anemia (FeLV-C-Sarma) suggests that drastic differences in target cell specificity, cytopathic activity, and pathogenicity of FeLVs in vivo are principally the consequence of subtle alterations in the extracellular glycoprotein gene (Riedel NO, manuscripts in preparation).[72] Thus, retrovirus glycoprotein gene variants that arise in certain cells, tissues, or stages of infection and possess altered cell tropism and pathogenicity may be responsible for induction of immunodeficiency or other disease syndromes.[33,34,73,74,77,78]

Both Southern blotting and immunofluorescence results indicate that the principal targets for FeLV-FAIDS variant replication and cytopathic effect (ie, bone marrow, intestine, and lymphoid tissues) are concordant. Apparently, noncytopathic viral replication was detected in several epithelial tissues important to viral excretion and contagious transfer (eg, mucosal epithelium of the pharynx, esophagus, nostrils, salivary gland), as has been demonstrated previously for the Rickard isolate of feline leukemia virus.[27] The causal relationship, if any, between unintegrated retroviral DNA replication and host cell death, originally identified by Keshet and Temin[69] in cell cultures infected with avian reticuloendotheliosis virus, remains unclear. The presence of UVD per se may not be directly responsible for cytotoxicity, since UVD in the absence of cell degeneration has been observed in HIV-infected T cell lines[78] and in the proliferative bone lesions of avian osteopetrosis.[71] The unintegrated replication of an immunodeficiency disease-associated FeLV genome in target tissues of infected cats does, however, provide an additional stimulus for study of the relationship between retroviral nonintegrative replication and genesis of cytopathic disease.

The correlation among FeLV-FAIDS replication in intestinal germinal epithelium, persistent diarrhea, and necrosis of mucosal epithelium detected in infected cats suggests that intestinal tropism may be a primary rather than exclusively a secondary manifestation of immunodeficiency disease-inducing retroviruses. The association of AIDS with enteropathy, chronic diarrhea, and intractable weight loss, now recognized as the chief presenting symptom characteristic of African AIDS,[11] has been considered secondary to opportunistic infections associated with immunosuppression (eg, cryptosporidiosis). In SPF cats with FeLV-FAIDS–associated enteritis, unlike the situation in naturally infected people or cats with immunodeficiency syndrome, neither pathogenic bacteria, viruses, nor parasites are associated with or required for development of the intestinal lesions. Although the necrosis and regeneration of the intestinal crypt epithelium in FeLV-FAIDS–infected cats resembles that caused by feline parvovirus (an indigenous feline virus which also infects mitotically active cells and could potentially be responsible for enteritis in cats naturally infected with FeLV), our studies indicate that the feline parvovirus is not involved in FeLV-FAIDS–associated enteropathy. In that intestinal crypt cell degeneration also has been associated with the enteropathy affecting many AIDS patients,[64] further consideration should be given to intestinal epithelium as a target tissue for cytopathic retroviruses.

FeLV-associated immunodeficiency syndrome, therefore, can be rapidly and consistently transmitted experimentally with a naturally occurring isolate of feline leukemia virus. The course of feline AIDS varies with and can be manipulated by the age of the animal at time of infection. Our results further suggest that the onset of clinical disease is associated with the replication, first in bone marrow and then in lymphoid tissues and intestine, of a disease-specific viral variant, the accelerated cytopathic replication of which is responsible for precipitation of immunodeficiency disease. It seems probable that such immunosuppressive FeLV variants are generated continually in nature and that previous experimental studies in which AIDS-like syndromes have been induced in cats may have involved inocula containing similar lymphocytopathic virus genomes. It also seems plausible that similar mechanisms involving more and less pathogenic, and possibly defective, variants of the human AIDS retroviruses are involved in onset and progression of human AIDS.

Since this article was submitted, Pedersen et al[79] have reported the isolation of a feline lenti-like virus (designated FTLV) from a group of cats with multiple chronic infections suggestive of underlying immunosuppression syndrome. This newly recognized non-FeLV feline retrovirus, which contains a Mg^{2+}-dependent reverse transcriptase, is of type D morphology, has been propagated only in freshly isolated, mitogen-pulsed feline lymphocytes, and is distinct from the pathogenic FeLV isolate we describe. FeLV-FAIDS transcriptase strongly prefers Mn++ catalysis, is of C type morphology, replicates efficiently in fibroblasts as well as lymphocytes, contains characteristic FeLV gag and env proteins, and hybridizes with a DNA probe specific for exogenous FeLV LTR U3-sequences.[47] Cats inoculated with the original FeLV-FAIDS inoculum, subpassaged virus, and normal SPF cats are negative for FTLV antibody by immunofluorescence and Western blotting assays (performed in the laboratory of Dr Niels C. Pedersen). Neither the original FeLV-FAIDS inoculum nor inoculated lymphocyte or fibroblast cultures generate Mg^{2+}-dependent reverse transcriptase activity. Moreover, the full-length genomes of the FeLV-FAIDS common form and variant A viruses described here have recently been molecularly cloned (Overbaugh JM et al, manuscript in preparation) and the variant virus shown to be capable of producing both lymphocyte killing in vitro and fatal immunodeficiency syndrome in vivo. Characterization of the pathogenic determinants of this immunodeficiency-inducing feline leukemia virus should contribute significantly to the understanding of retrovirus-mediated immunodeficiency diseases.

ACKNOWLEDGMENT

We thank Ronna E. Dornsife, Department of Pathology, Colorado State University, for performing clonogenic marrow progenitor cell assays. We also thank Oswald Jarrett and David E. Onions, Department of Veterinary Pathology, University of Glasgow for performing the FeLV interference subgroup assay and Niels C. Pedersen and Janet K. Yamamoto of the School of Veterinary Medicine, University of California, Davis for performing FTLV antibody assays.

Interleukin 2-Activated Killer Cells in Patients Following Transplants of Soybean Lectin-Separated and E Rosette-Depleted Bone Marrow

By Carolyn A. Keever, Karl Welte, Trudy Small, Janet Levick, Mary Sullivan, Michael Hauch,
Robert L. Evans, and Richard J. O'Reilly

During the early period following bone marrow transplantation before the immune system has reached full functional maturity, unprimed, nonspecific lytic systems may play a critical role as antiviral or antitumor effectors. The reconstitution of cells with this potential is of particular importance in recipients of bone marrow that has been depleted of mature T lymphocytes to prevent graft v host disease (GVHD). We examined the recovery of natural killer (NK) cells and interleukin 2 (IL 2)-augmented lymphokine-activated killer cells (LAK) in 48 patients at various intervals following transplantation of bone marrow depleted of mature cellular elements by treatment with soybean agglutinin and sheep RBCs (SBA$^-$E$^-$ BMT). We found normal levels of both NK and LAK activity as early as 3 weeks following SBA$^-$E$^-$ BMT. When compared with cells from controls, NK and LAK precursors from transplant recipients appeared to be activated in vivo in that freshly isolated peripheral blood mononuclear cells (PBMCs) from patients had an elevated cytolytic activity toward NK-insensitive targets and a more rapid response to activation by IL 2. In patients as well as controls, both LAK precursors and LAK effectors lacked antigens present on mature T lymphocytes (CD3, CD4, or CD8) but expressed antigens present on NK cells (CD2, CD16, and NKH1$_A$). The LAK cells did not lyse either donor or host peripheral blood T cell targets. The activity of NK effectors but not LAK precursors survived the in vivo total body irradiation used for pretransplant conditioning in three patients studied. LAK precursors could be demonstrated as early as 18 days following transplant at a time when the bone marrow contained primarily donor-derived cells. Little or no LAK activity could be generated from cells of the SBA$^-$E$^-$ BM graft itself, suggesting that LAK precursors differentiate rapidly from more primitive progenitors in the marrow graft. Thus, our data indicate that the NK and LAK lytic systems are among the earliest activities to recover during immune reconstitution following T cell-depleted BMTs.

© 1987 by Grune & Stratton, Inc.

IN EXAMINING the basis of the immune deficiency present during the early period following bone marrow transplantation (BMT),[1-4] we and other researchers found that peripheral blood T cells in BMT patients differ from normal T cells in regard to a number of interleukin 2 (IL 2)-dependent functions.[5-11] The type and duration of the functional T cell deficits depends on whether the patient received conventional, unfractionated bone marrow containing mature T cells or marrow depleted of T cells by treatment with soybean agglutinin and E rosetting (SBA$^-$E$^-$ BMT). Initially, we observed in recipients of conventional grafts that circulating T cells produced little or no IL 2 when stimulated with phytohemagglutinin (PHA) or OKT3 during the first 18 months after BMT. In most of these patients peripheral blood mononuclear cell (PBMC) proliferative responses to OKT3 could be restored to nearly normal levels by the addition of IL 2 to the cultures.[7] In recipients of SBA$^-$E$^-$ BMT, the capacity of OKT3 to trigger T cell proliferation and IL 2 production was also deficient in the early posttransplant period.[8] Unlike responses in conventional BMT recipients, however, T cell proliferative responses to OKT3 in recipients of SBA$^-$E$^-$ BMT were only partially restored by exogenous IL 2. Moreover, during the first 8 weeks after BMT, most SBA$^-$E$^-$ BMT recipients had circulating T cells that spontaneously secreted IL 2, an activity not detected in patients receiving conventional grafts. These differences may reflect the absence of mature donor-derived IL 2-responsive cells in patients receiving SBA$^-$E$^-$ BMT.

In this study, we examined PBMCs from patients following SBA$^-$E$^-$ BMT for the regeneration of NK cells, and IL 2-inducible nonspecific cytotoxic cells (LAK). Our results demonstrate that unlike T cell functions, unprimed and IL 2-activated nonspecific cytolytic activities of PBMCs from patients receiving T cell-depleted grafts recover fully by week 3 posttransplant. Mature, IL 2-responsive cells appear not to have been transfused in the marrow inoculum, since these cells are removed during T cell depletion. These early IL 2-responsive cells share many of the phenotypic characteristics of NK cells.

MATERIALS AND METHODS

Patients and controls. Forty-eight patients were studied following transplantation with marrow from HLA-identical siblings that had been depleted of T cells by treatment with SBA and E rosetting based on the method of Reisner et al.[12] Included in the study group were 22 patients with chronic myelogenous leukemia (CML); 11 patients with acute myelogenous leukemia (AML) in first or second remission; 8 patients with acute lymphoblastic leukemia (ALL) in first, second, or third remission; 3 patients with non-Hodgkins lymphoma (NHL), and 2 patients with myelodysplastic syndrome (MYD).

Pretransplant conditioning was performed with cyclophosphamide (60 mg/kg/day × 2) and hyperfractionated total body irradiation (1,320 or 1,440 rad). Patients received no posttransplant

prophylaxis against rejection or graft v host disease (GVHD). All patients studied achieved durable engraftment, as shown by cytogenetic analysis of bone marrow and peripheral blood leukocytes.

Most studies were performed at weekly intervals from week 3 to week 8 posttransplant. Twenty patients were studied at intervals up to 18 months posttransplant. Normal controls consisted of 34 laboratory personnel and two bone marrow donors.

Reagents. Human recombinant interleukin 2 (rIL 2) was kindly provided by the Cetus Corporation (Emeryville, CA). Monoclonal antibody (MoAb) to the IL 2 receptor Tac,[13] was a gift from Dr Thomas Waldmann (National Institutes of Health, Bethesda, MD). $NKH1_A$ was kindly provided by Dr J. Ritz (Harvard University, Boston). $NKH1_A$ is an IgM mouse MoAb raised against cloned NK cells[14] and reacts with the same 200-kd molecule recognized by Leu 19.[15] The OKT series of MoAbs were purchased from Ortho Diagnostics (Raritan, NJ) (OKT3, T11, T4, and T8), and the Leu 7 hybrid line was obtained from the ATLL (Bethesda, MD). Directly fluoresceinated MoAbs, HLE, mouse IgG, and Leu 11c as well as phycoerythrin-conjugated mouse IgG and unconjugated Leu 11b were purchased from Becton Dickinson (Mountain View, CA). Fluoresceinated Leu 11, T11, T3, and B1 and phycoerythrin-conjugated T3, DR, and NKH1 were purchased from Coulter Immunology (Hialeah, FL).

Cell preparations. PBMCs were separated from heparinized blood by centrifugation on Lymphoprep (Nyegaard, Oslo). The low-density cells were collected and washed twice with Ca^{2+}, Mg^{2+} free Hank's balanced salt solution (HBSS) and resuspended in RPMI 1640 supplemented with 25 mmol/L HEPES, 100 U/mL penicillin, 100 μg/mL streptomycin, and 2 mmol/L L-glutamine (RPMI). In some experiments, monocytes were depleted by adherence on plastic tissue culture dishes for 1 hour at 37°C. Monocyte-depleted PBMCs are referred to as peripheral blood lymphocytes (PBLs).

LAK and cytotoxic T lymphocytes cultures. For generation of LAK cells, PBMCs or PBLs were adjusted to a concentration of 1×10^6 cells/mL in RPMI containing 10% heat-inactivated human serum (HS) (M.A. Bioproducts, Walkersville, MD) and 100 U/mL rIL 2. No more than 20×10^6 cells were placed in 25-cm^2 tissue culture flasks and incubated from 2 to 9 days at 37°C in a humidified atmosphere of 5% CO_2. In one experiment, cytotoxic T lymphocytes (CTLs) were generated by coculture of 1×10^6 cells/mL PBLs from a normal control with an equal number of irradiated (3,000 rad), previously frozen PBLs from a bone marrow donor. The cells were cultured for 7 days in RPMI-10%HS supplemented with 100 U/mL rIL 2 as described above.

Cytotoxicity assays. The cytolytic activities of freshly isolated cells, CTLs, and LAK cells were measured in a standard ^{51}Cr release assay. The targets used were the NK-sensitive cell line K562 established from a patient with CML, the lymphoma cell line Daudi, and a cultured melanoma cell line SK-Mel-30 (kindly provided by Dr Alan Houghton, Memorial Sloan-Kettering Cancer Center, New York)[16] or PBMCs cultured for 72 hours with a 1:100 dilution of PHA-M (GIBCO, Grand Island, NY) (PHA blasts). The targets were labeled with 250 μCi Sodium ^{51}chromate (New England Nuclear, Boston) in 0.5 mL RPMI-10% FBS for 1 hour at 37°C. Following three washes, the targets were resuspended in RPMI-10% FBS at 5×10^4 cells/mL. Cultured effector cells were recovered from the flasks, washed twice in RPMI-10% FBS, and adjusted to yield effector to target cell (E:T) ratios from 100:1 to 0.5:1. Replicate cultures in a total volume of 0.2 mL were plated in 96-well round bottomed microtiter plates (Costar, Cambridge, MA), centrifuged at 1,000 rpm for 5 minutes, and incubated at 37°C for 4 hours. Spontaneous release was determined by incubating targets with 0.1 mL medium, and maximum ^{51}Cr release was determined by addition of 0.1 mL 5% Triton X-100 (New England Nuclear). At the end of the culture period, supernatants were harvested with a filter harvesting system (Skatron, Sterling, VA), and the filters were counted in a Beckman 5000 γ counter (Beckman Instruments, Irvine, CA). Data were expressed as either the percentage of specific lysis at a given E:T ratio as calculated from the equation: % specific lysis = [cpm experimental − CPM spontaneous)/(CPM maximum − CPM spontaneous)] × 100 or as lytic units, defined as the number of cells/10^6 resulting in specific lysis of 33.3% of 5,000 target cells.[17]

Cold-target competitions. Unlabeled targets were mixed with ^{51}Cr-labeled targets at ratios of unlabeled (cold) to labeled (hot) from 20:1 to 1:1 before addition to the microtiter plates. Effector cells were added at a constant E:T ratio (usually 10:1) to the various cold:hot (C:H) combinations, and the percentage of specific lysis was determined in the cytotoxicity assay described above. Results are expressed as the percentage of specific lysis at the indicated C:H ratios.

Immunofluorescence. Indirect and two-color direct immunofluorescence were performed using standard techniques.[18,19] Samples were analyzed on an EPICS C cell sorter (Coulter).

Treatment with Tac MoAb. Tac MoAb was added at the beginning of 3-day LAK cultures of PBLs from one normal control and two patients, at final culture concentrations ranging from 1:5,000 to 1:250 of purified ascites. Saturation of Tac binding sites was obtained with a dilution of 1:5,000 Tac as determined by indirect immunofluorescence (data not shown).

LAK precursor and effector depletion. PBLs from patients and normal controls were treated with MoAb plus complement or with complement alone prior to or following culture in rIL 2. Sodium azide containing MoAbs were dialyzed against PBS prior to use. PBLs were incubated for 60 minutes at 4°C with 0.1 mL/10^6 cells of 1:20 dilutions of OKT3, OKT11, OKT4, or OKT8, with a 1:125 dilution of $NKH1_A$, and with a 1:50 dilution of Leu 11b. The cells were centrifuged, and the MoAb was removed prior to addition of 0.5 mL of a 1:5 dilution of low-toxicity rabbit complement (Pel-Freez, Rogers, AR) and incubated at 25°C for 60 minutes. Cells treated prior to culture in rIL 2 were washed once with RPMI-10% FBS and then incubated for a second time with rabbit complement for 30 minutes at 25°C. The cells were washed twice in RPMI and adjusted for LAK culture or for cytotoxicity assay. LAK effector cells were counted and then adjusted to the same volume as those treated with complement alone prior to testing in the cytotoxicity assay. Freshly isolated PBLs treated with $NKH1_A$ or Leu 11b plus complement as described above had no lytic activity to K562 in 4-hour ^{51}Cr release assays (data not shown). PBLs that had been incubated overnight at 37°C to shed bound antibody were restained with directly FITC-conjugated OKT3, OKT11, OKT4, or OKT8 following antibody plus complement treatment and showed >97% depletion of the appropriate population.

RESULTS

NK cell activity following SBA^-E^- BMT. PBMCs were isolated from 30 patients 3 to 8 weeks following transplantation with HLA-matched bone marrow and tested for cytolytic activity to the NK-sensitive cell line K562. The results were compared with those from 34 normal control subjects tested simultaneously. The data shown in Table 1 demonstrate the early return of NK activity following SBA^-E^- BMT with a mean specific lysis of K562 of 46.3% in the patient group as compared with 48.1% for the controls. Both Daudi lymphoma cells and the melanoma cell line SK-Mel-30 were resistant to lysis by PBMCs from normal controls (1.9% ± 2.4% and 8.0% ± 8.1% specific lysis, respectively). There was low but greater lysis of both targets

Table 1. K Cell Activity Following SBA$^-$E$^-$ BMT

Target	Specific Lysis (%)* Normal Controls	No. Tested	Specific Lysis (%)* Patients Weeks 3-8	No. Tested	P Value†
K562	48.1 ± 18.8	34	46.3 ± 21.2	30	.60
Daudi	1.9 ± 2.4	7	16.9 ± 5.4	10	<.001
SK-Mel-30	8.0 ± 8.1	19	15.2 ± 15.4	13	.20

PBMCs from patients 3 to 8 weeks posttransplant and controls were tested in 4-hour ^{51}Cr release assays as described in the Materials and Methods section. Only the highest value was used for patients tested more than once during this interval.

*Results are expressed as the percentage of specific lysis ± SD at an effector/target ratio of 100:1.

†Mann-Whitney U test.

by PBMCs from the patients; the increased activity was significant only for Daudi (Mann-Whitney U test, $P < .001$). In one experiment, depletion of Leu 11$^+$ cells by antibody and complement removed the cytolytic activity of patient PBLs to both K562 and Daudi (38.2% and 25.8% specific lysis before treatment to 0.1% and 0.9%, respectively). Depletion with OKT3 plus complement had no effect on the killing of either target, thus indicating that both activities were mediated by T3$^-$ NK cells.

LAK activity following SBA$^-$E$^-$ BMT transplantation. In preliminary experiments with control PBLs, the addition of >100 U/mL of rIL 2 to LAK cultures did not increase lytic activity significantly. The results of three experiments, including two patients 8 weeks posttransplant are shown in Table 2. Although patient PBLs had somewhat more cytolytic activity with 250 U/mL of rIL 2, the difference was not great; culture with 500 U/mL appeared to decrease the activity slightly. Subsequent cultures of cells from both patient and controls were performed using 100 U/mL rIL 2. The results shown in Fig 1 are expressed as lytic units/10^6 PBMCs following 6 to 7 days of culture in IL 2. As early as week 3 following SBA$^-$E$^-$ BMT, the median LAK activity to all three targets, K562 (panel A), Daudi (panel B), and SK-Mel-30 (panel C) was not significantly different from the control group ($0.1 < P < .375$, Mann-Whitney U test). No significant change in the lytic activity was noted during the first 8 weeks post SBA$^-$E$^-$ BMT or in patients tested up to 76 weeks posttransplant. In none of 29 experiments was there lytic activity to any target following 3 to 7 days of culture under the same conditions in the absence of rIL 2 (data not shown).

Kinetics of LAK generation during culture in IL 2. The kinetics of the generation of LAK activity differed between patients and controls in that when assays were performed after 3 to 4 days of culture in rIL 2 (Table 3) there was significantly more lytic activity to both K562 and SK-Mel-30 by LAK cells from patients than by those from controls ($P < .05$). We performed LAK assays at 2-day intervals on PBMCs from 9 patients between 4 weeks and 5 months posttransplant, from 6 patients 6 to 18 months following transplantation, and from 12 normal controls. The data shown in Fig 2 are expressed as the percentage of the maximum lysis of K562 (panel A) or SK-Mel-30 (panel B) when tested at an E:T ratio of 10:1. Normal control PBMCs showed a plateau of maximal activity at days 5 to 6 to both targets. The mean percentage of specific lysis at day 6 of K562 was 71.5%±12.4% and of SK-Mel-30 was 64.0% ±19.3% on day 5. PBMCs from patients <5 months post SBA$^-$E$^-$ BMT had an earlier peak of activity; by day 4 the maximal percentage of specific lysis toward K562 (58.4% ± 27.4%) and SK-Mel-30 (58.2% ± 20.0%) was reached. By 5 months post-BMT, PBMCs from the patients required 6 days of culture with IL 2 to be maximally activated, similar to the normal control group.

Specificity of LAK cells. We examined the possibility that in addition to LAK cells, culture with rIL 2 may expand donor-derived or residual host CTL that may have autoreactivity[20] or that recognize minor histocompatibility antigens of either the host or the marrow donor.[21] LAK cells from five patients were tested for the ability to lyse 3-day phytohemagglutinin (PHA) blasts prepared from host or donor PBMCs frozen prior to transplantation. There was no lysis of the PHA blasts in any experiment (Table 4), although K562 and Daudi targets were readily lysed. In one experiment, donor-specific CTL generated from PBLs of a normal control could effectively lyse both donor and pretransplant host PHA blasts.

Cold-target competition experiments were performed on LAK cells from three patients <4 weeks posttransplant and two normal controls to determine if both NK-sensitive and NK-resistant targets were recognized by the same IL 2-

activated effector cells. As shown in Table 5, cold K562 and cold SK-Mel-30 (C:H ratios of 20:1) were nearly equally able to compete for hot SK-Mel-30 and hot K562, respectively, in all experiments performed. PHA blasts from a normal control, however, were unable to compete for the killing of labeled K562 or SK-Mel-30 in either of two patients tested. Therefore, cells responding to IL 2 during the early posttransplant period apparently have not been primed to either donor or host cells, and the activated killer population apparently binds equally well to the NK-sensitive and the NK-insensitive cultured tumor targets.

Effect of TBI on NK and LAK. During the course of total body irradiation (TBI) given in eight fractions over a period of 3 days, we obtained blood specimens from three patients before, at the midpoint (720 rad) and immediately after the completion of 1,440 rad TBI to determine the in vivo effect of irradiation on NK activity and on LAK precursors (Table 6). We tested the NK activity of the freshly isolated PBLs and placed cells in culture with rIL 2 for 72 hours before performing LAK assays. The NK activity of PBL derived from two patients progressively increased during TBI and was maintained at a high level in the third patient (722). LAK activity, however, could not be generated from PBLs from patient 607 following 720 rad TBI or in patients 627 and 722 following 1,440 rad. Prior to transplantation, the patients were further cytoreduced with cyclophosphamide but due to the extremely low peripheral counts following this treatment further pretransplant NK and LAK studies could not be performed. At day 18 post BMT, LAK activity could be generated following culture in rIL 2 in PBLs from patient 627 and, when tested at day 30, NK activity was completely normal. Cytogenetic analysis of bone marrow from this patient at day 14 posttransplant revealed 1 host and 3 donor metaphases; by day 30 only 27 donor and only 2 host metaphases were observed.

In addition to NK and LAK studies, PBL from patient 722 were tested by one-color and two-color immunofluorescence to determine the phenotype of the surviving cells. The results

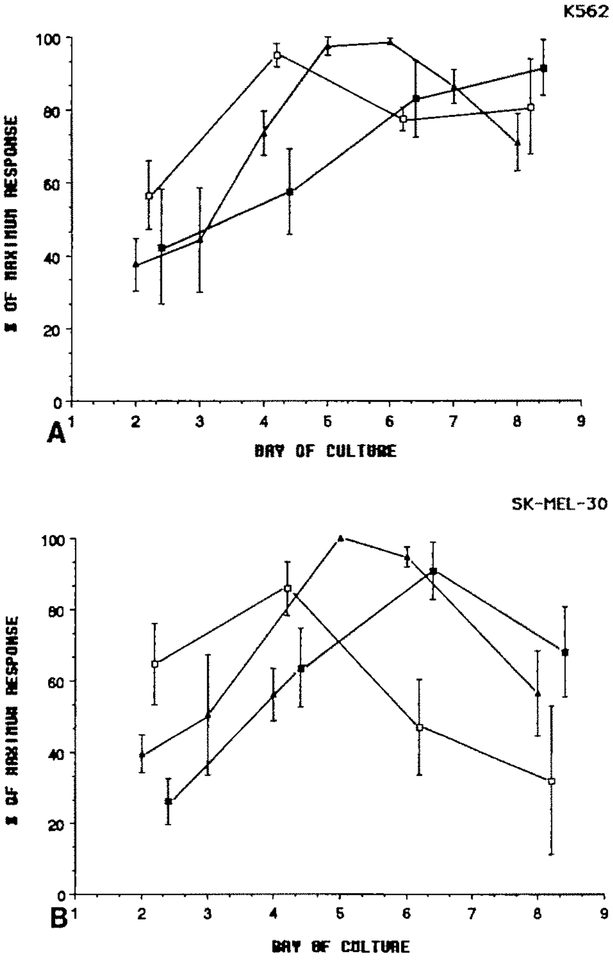

Fig 2. Kinetic response to rIL 2 induction of LAK activity of PBMCs from normal controls (—▲—) (n = 12); from patients <5 months after SBA^-E^- BMT (—□—) (n = 9); and patients >6 months posttransplantation (—■—) (n = 6). Results are expressed as the percentage ± SEM of the maximum cytotolytic response to K562 (A) and SK-Mel-30 (B) when assayed on the day indicated.

*Results are expressed as the percentage of specific lysis ± SD of triplicate ^{51}Cr release assays. NK assays were incubated for 12 hours; LAK assays were incubated for 4 hours.

†Effector/target cell ratio.

‡Number of days before or following BMT.

shown in Table 7 indicate that the majority of PBLs were T3$^+$, T11$^+$ T cells, with 20% and 6% NKH1$_A$$^+$ cells surviving 720 and 1,440 rad, respectively. The proportion of Leu11$^+$ cells increased somewhat following 720 rad, with more of the cells coexpressing NKH1$_A$ (69% following 720 rad *v* 40% before irradiation) but were undetectable following 1,440 rad. None of the NKH1$_A$$^+$ cells jointly expressed T3 at either irradiation dose.

Presence of LAK precursors in bone marrow fractions. To determine if the rapid reappearance of LAK cells following SBA$^-$E$^-$ BMT was due to mature precursors transfused with the graft itself, we tested fractions of bone marrow from four donors in LAK assays (Table 8). There was little LAK activity following 4 days of culture in IL 2 of unseparated marrow from one donor, but a selective enrichment of LAK precursors was observed in the low-density, E rosette-positive fraction obtained following SBA treatment (SBA$^-$E$^+$) of this donor as well as in SBA$^-$E$^+$ fractions from two additional donors tested. The SBA$^-$E$^-$ fractions (the bone marrow graft), in contrast, were severely depleted of cells that could be activated to lyse the LAK target SK-Mel-30. The IL 2-activated SBA$^-$E$^-$ fractions were more variable in their ability to kill the NK-sensitive target K562 with specific lysis at an E:T ratio of 25:1 ranging from 8.6% following 6 days of culture to 29.6% on day 5 of culture. This variability may reflect quantitative differences in the depletion of mature LAK precursors or may be due to the generation of NK cells from immature precursors in the SBA$^-$E$^-$ fractions.[22,23] Maximum K562 lysis by SBA$^-$E$^-$ fractions was much less, however, than that by LAK cells from patients at week 3 post BMT following 3 days (E:T 10:1 = 46.7 ± 4.5) or 6 days (51.1% ± 6.3%) of culture in rIL 2.

Effect of Tac MoAb on LAK generation. IL 2-mediated proliferative responses can be blocked by the addition of MoAb directed to the α chain of the IL 2 receptor, Tac.[24] Conflicting results have been reported, however, concerning the ability of Tac MoAbs to inhibit the IL 2-mediated activation of NK cells[25-27] or LAK cells.[28,29] Table 9 shows the results following 3-day cultures of PBLs from two patients <8 weeks post SBA$^-$E$^-$ BMT and from one control in the presence of the indicated concentrations of Tac plus rIL 2. The lytic activity of control PBLs as well as patient PBLs could be inhibited to varying degrees by Tac but could not be completely blocked. PBLs from the patient with the lowest lytic activity were most effectively blocked by Tac (93.6% inhibition).

BMCs were isolated from patient 722 before, during, and immediately following TBI.

*Values for single-color fluorescence represent percentage of the total lymphoid population positively reacting with the test antibody minus the percentage of cells exhibiting staining with an irrelevant control antibody.

†Values for two-color fluorescence represent percentage of indicated subpopulation of cells expressing the second cell surface antigen.

Phenotype of the LAK precursors and effectors. PBLs from both patients and controls were treated with MoAbs plus rabbit complement prior to culture in rIL 2 to identify the phenotype of the LAK precursor or following culture to identify the LAK effector. Table 10 shows the results from 11 experiments. In no experiment were we able to decrease the generation of LAK cells significantly with depletion of OKT3-, OKT4-, or OKT8-positive cells from PBLs of patients or controls. In agreement with the results of Grimm et al,[30] treatment with OKT3 generally resulted in increased LAK activity. In our studies, however, removal of OKT11$^+$ cells did not enhance activation. We were able to deplete LAK precursors to varying degrees by treatment with MoAbs directed to antigens present on NK cells, eg, OKT11,

†Bone marrow cells were removed prior to treatment with soybean agglutinin (SBA) and sheep RBCs. Low-density bone marrow cells were obtained by separation over Ficoll-Hypaque and were cultured in medium containing 100 U/mL rIL 2 and 10% pooled human serum for the indicated number of days as described in the Materials and Methods section.

‡Cells were obtained from NH$_4$CL-lysed pellets following treatment of the bone marrow with SBA and SRBC. Low-density cells were cultured as described above.

§Low-density, SBA-negative, and E rosette-depleted bone marrow cells cultured as described.

Table 9. Effect of Anti-TAC on The Generation of LAK Activity

UPN	Week Posttransplant	Target	Lytic Units* IL-2	Lytic Units* + Anti-Tac†	Ascites Dilution	Inhibition (%)
Control	—	K562	341.4	98.3	1:5,000	71.0
		SK-Mel-30	118.1	35.0	—	70.6
566	4	K562	20.4	3.0	1:250	86.0
		SK-Mel-30	11.2	0.7	—	93.6
546	5	K562	475.2	159.1	1:500	67.0
		SK-Mel-30	305.3	208.0	—	31.8

LAK cultures were initiated in the presence of the indicated dilution of anti-Tac ascites. A final dilution of 1:5,000/10^6 cells gives maximal fluorescence intensity in indirect assays.

*Results are expressed as the number of lytic units/10^8 cells.

†IL 2 plus anti-Tac.

Leu 11b, and NKH1_A, although no single treatment completely eliminated the generation of LAK cells. We were unable to reduce the activity of LAK effector cells by treatment with MoAbs to CD3 or CD8 plus complement. As in the precursor depletion experiments, the only MoAbs effective in reducing lytic activities were OKT11, Leu 11b, and NKH1_A, the most effective MoAb being NKH1_A.

Correlation of LAK activity with clinical parameters. LAK cells were generated by culture in IL 2 of PBMCs from all patients tested. There were differences in the lytic activity of individual patients and, as shown in Fig 1 and Table 3, some patients had very high activity. Because patients were tested following 6 to 7 days of culture as well as after 3 to 4 days, they were analyzed separately to determine if the level of LAK activity differed among the groups. Although some groups were small, there appeared to be no correlation of LAK activity with disease, age, speed of engraftment (day to ANC of 1,000) or the incidence of infections during the posttransplant period. Too few patients have been accrued and followed for a sufficient period to assess whether there is any correlation between quantitative aspects of LAK cell regeneration and leukemic relapse. This study is currently in progress (data not shown).

DISCUSSION

The course and kinetics of immunologic reconstitution following SBA$^-$E$^-$ BMT would be expected to differ from that following a conventional transplant, since the contribu-

*Effector/target cell ratio in all assays was 10:1. Results are expressed as percentage of complement control.

†PBLs were treated with MoAb and complement prior to culture in rIL 2 for 72 to 96 hours.

‡PBLs were incubated with MoAb and complement following culture in medium containing IL 2 as described.

tion of mature cellular elements from the graft[31] and the effects of GVHD prophylaxis[32] as well as GVHD itself,[4,5,33] are largely eliminated. Indeed, in our studies of patients post SBA$^-$E$^-$ BMT, we have demonstrated a delay in the regeneration of IL 2-sensitive T cells capable of proliferating in response to mitogen.[8] Unlike recipients of conventional marrow, however, recipients of SBA$^-$E$^-$ BM grafts transiently develop a population of T cells that spontaneously secrete IL 2 early in the posttransplant period. We were therefore interested in determining whether other cell populations, such as NK cells or LAK cells that might be sensitive to exogenous or endogenously produced IL 2, emerge during the early stages of immunologic reconstitution.

Ault et al[33] have demonstrated that the predominant population of lymphoid cells appearing between days 10 and 20 following CD5$^+$ T cell-depleted BMT, have the phenotype and function of NK cells. Similar early recovery of NK function has been reported following transplantation of both conventional marrow[35,36] and bone marrow depleted of T cells by MoAb plus complement.[37,38] Likewise, we found that as early as 3 weeks post SBA$^-$E$^-$ BMT, lysis of K562 by PBMCs from patients was equal to that by normal control NK cells. In the early posttransplant period, we also observed increased lysis of two NK-insensitive targets, the Burkitts' lymphoma cell line Daudi and an adherent melanoma cell line SK-Mel-30 by patient PBMCs as compared with concurrently tested normal controls. Similar enhanced lytic activity toward an NK-resistant B lymphoblastoid cell line was reported by Rooney et al[37] in patients 12 to 14 weeks following transplantation of bone marrow depleted of T cells by two T cell-specific MoAbs and complement.

The development of IL 2-inducible nonspecific cytotoxic cells (LAK) during the posttransplant period was examined in a murine system by Merluzzi et al,[38] who showed that LAK cells could be generated at 2 weeks postsyngeneic BMT, preceding by 2 weeks the capability to mount a specific CTL response. We found a similar early appearance of LAK precursors 3 weeks following SBA$^-$E$^-$ BMT. Cultures of patient PBMCs in rIL 2 for 6 to 7 days resulted in LAK effectors with activities equal to or only slightly lower than those from a normal control group. Following 3 to 4 days of culture in rIL 2, however, the lytic activity of patient LAK cells was significantly greater than LAK cells from the controls. We found that unlike those of controls or patients late after transplant, the LAK precursors developing during the first 5 months posttransplant had a maximal response after 3 to 4 days of culture in rIL 2. PBMCs from normal controls and patients tested between week 20 and week 76 posttransplant generated peak LAK activity after 5 to 6 days of culture, as has been reported for cancer patients and normal controls using noncultured tumor targets.[30,39,40] This accelerated response of LAK precursors to IL 2 coupled with the capacity of lymphocytes isolated from patients early post BMT to kill NK-insensitive targets spontaneously suggest the presence of a population of cells that has been activated in vivo. This activation may be a response to the IL 2 that we have reported to be produced spontaneously by T cells following SBA$^-$E$^-$ BMT.

We questioned whether rIL 2 might activate cells within the PBLs that have autoreactivity[20] or cells with reactivity to minor alloantigens expressed on host cells.[21] To address this possibility, we tested PHA blasts prepared from donor and/or host PBMCs as targets in LAK assays. Although both autologous PBL targets as well as PHA blasts can be lysed at low levels by LAK cells from some individuals,[39,41,42] IL 2-activated effectors from our patients showed no cytolysis of either donor or host targets. Furthermore, we demonstrated in cold-target competition experiments a population of LAK cells that recognized equally well both NK-sensitive and NK-insensitive unrelated targets but not third-party PHA blasts.

The origin of the LAK precursors developing early posttransplant has not been definitively determined. Our studies of the radiosensitivity of LAK precursors in vivo suggest that this activity is more sensitive than the lytic ability of freshly isolated NK cells to the irradiation dosage (1,440 rad) used for pretransplant cytoreduction. Although we have not as yet characterized the emerging LAK cells in clonal assays as donor or host, we have observed LAK precursors as early as 18 days posttransplant from a patient who by cytogenetic analysis of bone marrow had dividing cells predominantly (94%) of donor origin. The rapid regeneration of LAK activity posttransplantation does not appear to be due to enrichment of LAK precursors in the SBA$^-$E$^-$ BM graft. Our data indicate rather that LAK precursors are concentrated in the E$^+$ fraction collected following treatment with SBA. Following culture of SBA$^-$ E$^-$ marrow in medium containing IL 2, there was no substantial lysis of NK-resistant targets, although there was some lytic activity towards K562. This activity may reflect the IL 2-induced generation of NK cells from early marrow precursors as reported in murine systems.[22,23] Thus, mature LAK precursors in the host appear to be depleted by pretransplant conditioning and the early appearance of the LAK response postgrafting apparently is due to the rapid growth and differentiation of donor-derived LAK precursors from more primitive cells in the SBA$^-$E$^-$ BM inoculum. Formal cytogenetic studies of LAK cells are needed, however, to rule out the possibility that primitive progenitors of LAK cells persist through cytoreduction and contribute to the LAK activities detected early post-BMT.

Recent evidence suggests that both LAK precursors and effectors derive from cell populations with the morphology and phenotype of NK cells,[40-45] although CD3$^+$ cells bearing the NKH1$_A$ antigen may have minor activity.[45] Studies by Itoh et al[43] using both positive and negative selection of Leu 11$^+$ PBLs suggested that this population of LGLs are the LAK precursors. More recently, cells within the Leu 11$^+$, NKH1$_A{}^+$ cell population have been shown to be most strongly activated by IL 2 to lyse fresh or cultured NK-resistant tumor targets and to maintain this phenotype following culture in IL 2.[44,45] Our results in both controls and patients post-BMT confirm that the LAK precursors do not bear the classic markers of mature T cells, eg, CD3, CD4, or CD8. We were able to deplete LAK precursors partially with OKT11, Leu 11b, and NKH1$_A$ plus complement, all of which are antigens present on LGLs with NK activity. Likewise in our experiments, removal of OKT3$^+$ or OKT8$^+$ effector cells did not reduce killing of either NK-sensitive or NK-resistant targets. As in our precursor experiments, however, the removal of cells with NK phenotypes did decrease effector function. The most complete depletion of activity followed treatment with the MoAb $NKH1_A$ plus complement.

We further characterized the LAK phenomenon post-BMT by examining whether IL 2 stimulated the generation of LAK cells directly by binding to its receptor (Tac)[13] on LAK precursors. During incubation with rIL 2, we previously showed a marked increase in the number of Tac$^+$ cells in cultures of PBMCs from patients and controls,[8] suggesting either induction by IL 2 of its receptor[46] or, alternatively, expansion of preexisting Tac-positive cells. Blocking of IL 2 receptors by the addition of Tac at the initiation of LAK cultures resulted in up to a 93.6% reduction in the subsequently tested lytic activity. Other investigators have reported that the enhanced lytic activity of NK cells exposed to IL 2 in short-term cultures is not blocked by Tac[25,27] and that this activation likely occurs through the newly described β chain receptor.[47] The subsequent generation of LAK activity is inhibited by Tac, however.[28,29] Therefore, the activity detected in our patients early post-SBA^-E^- BMT is more characteristic of LAK cells than of preactivated NK cells.

From our studies, both NK cells and IL 2-inducible precursors of cells which lyse both NK-sensitive and NK-resistant tumor targets but not peripheral blood targets of donor or host origin appear to emerge early after SBA^-E^- BMT. In patients, as well as in the controls we have examined, the LAK effectors and their precursors share phenotypic characteristics with NK cells and do not bear antigens present on mature cytotoxic or helper T cells. Our studies also suggest, however, that these LAK cells differ from NK cells in that they are radiosensitive and are generated by the direct action of IL 2 through the TAC surface receptor. The redeveloping populations of NK and LAK cells may contribute to the process of immunologic recovery after transplantation by providing helper factors for B lymphocytes[48,49] or by serving as antiviral effectors.[50] Their potential role in engraftment or against the reemergence of host leukemic cells[51] remains to be determined.

ACKNOWLEDGMENT

We would like to thank Karen Pekle and Lorna Barrett for excellent technical assistance and Elizabeth Harrison for secretarial assistance.

Regulation of Erythropoieten Production in a Human Hepatoblastoma Cell Line

By Ove J. Nielsen, Stephen J. Schuster, Randal Kaufman, Allan J. Erslev, and Jaime Caro

Production of immuno and biologically active erythropoietin was documented to occur in the human hepatoblastoma cell line HepG-2. The expression of the erythropoietin gene was further verified by Northern blot analysis using a single stranded RNA probe. In vitro studies showed that erythropoietin production by these cells was not stimulated by hypoxia or cobalt chloride, but was related to the proliferative activity of the cells in culture. In addition it was found that the secretion of erythropoietin was almost completely abrogated by tunicamycin, an inhibitor of N-linked glycosylation. This effect of tunicamycin was also observed in a permanently transfected cell line that secretes erythropoietin in large quantities.

© 1987 by Grune & Stratton, Inc.

ERYTHROPOIETIN is a hematopoietic growth factor that plays an essential role in the differentiation of committed erythroid progenitor cells into mature erythroid precursor cells.[1,2] It is a heavily glycosylated protein with a mol wt of ~34,000 Daltons, approximately one half of which is made up by carbohydrates.[3] The peptide backbone consists of 166 amino acids and contains three potential N-glycosylation sites.[4,5] In adults erythropoietin is synthetized primarily by the kidney,[6] and to a small extent by the liver.[7] In both organs the rate of erythropoietin synthesis is augmented by anemic, hypoxic and histiotoxic hypoxia.[8,9]

Although the liver is the main source of extrarenal erythropoietin in the adult organism, erythropoietin production has not been observed in physiologic short term cultures of adult hepatic parenchymal cells. Such synthesis has been claimed for cultures of adult rat Kupffer cells[10] and fetal mouse hepatocytes.[11] The amount of erythropoietin produced, however, is exceedingly small and usually not measurable unless the culture medium is concentrated up to 60-fold. Nevertheless in one study the rate of production of erythropoietin by fetal mouse hepatocytes was found to respond to hypoxia but not to cobalt chloride.[12]

After screening a number of established human hepatoma cell lines for erythropoietin production we found that the HepG-2 cell line,[13] which has served as a valuable tool for the investigation of the synthesis of a number of plasma proteins, also secretes erythropoietin. A similar secretion of erythropoietin by human hepatoma cells has been described by Okabe et al,[14] but in the present studies we were able to characterize the production of erythropoietin by HepG-2 cells by studying the effects of hypoxia, cobalt chloride, and cellular growth rate. Furthermore, using this cell line and a cell line permanently transfected with the human erythropoietin gene, we have examined the role of the carbohydrate component of the erythropoietin molecule on erythropoietin synthesis and secretion.

MATERIALS AND METHODS

Cell cultures. The human hepatoblastoma cell line HepG-2 (passages 100-160), generously provided to us by B. Knowles (Wistar Institute, Philadelphia), was routinely maintained in culture flasks (T-75 Corning) containing MEM 10% fetal calf serum (GIBCO, Grand Island, NY). For the experimental protocols the cells were transferred to 35-mm plates and grown to confluence. Each plate contained 2 mL of culture media and culture periods were routinely 48 hours in a 5% CO_2, 37°C incubator (Forma Scientific). The cell density at the time of confluency was between 1.6 and 1.8 × 10^6 cells per plate. After the termination of the incubation period, supernatants were harvested, centrifuged, and stored at −20°C until assayed. Lysates of cells were prepared by washing monolayers with 0.9% NaCl followed by the addition of proteolysis inhibitor buffer (0.05 mol/L Na citrate, 2,000 U Trasylol, 1 mol/L EDTA, 0.1 mol/L phenylmethylsulphonylfluoride [PMSF], 10 mmol/L benzamidine). The plates were frozen at −20°, thawed and homogenized with 1 mL homogenization buffer (0.1M PO_4 pH 7.6, 4.5% bovine serum albumin, 50 μg/mL leupeptin, and 1 mmol/L PMSF). The lysate was spun at 3,000 rpm for 30 minutes and the supernatant saved for assays. The studies relating to the effect of hypoxia on the HepG-2 cells were performed in a sealed modular incubator chamber (Billup-Rothenberg, CA) that was equilibrated with mixtures of CO_2, nitrogen and oxygen to give the desired oxygen tension. Cobalt chloride (Fisher) was dissolved in sterile saline and added in the desired concentration. Tunicamycin (Sigma, St Louis) was dissolved in 0.01 mol/L NaOH to a stock solution of 0.5 mg/mL. The cells were exposed for 18 hours to tunicamycin before the initiation of the experiment and tunicamycin was present in the media during the whole incubation period.

Measurement of erythropoietin. Erythropoietin levels in supernatants and cell lysates were measured by a sensitive double antibody radioimmunoassay as previously described.[8,15] Pure radiolabeled recombinant erythropoietin (Genetics Institute, Boston) was used as a tracer in the competitive assay and the antibody was developed in rabbits against human urinary erythropoietin. The lower level of sensitivity of this assay is ~2 to 4 mU/mL of sample.

Biologic erythropoietic activity of HepG-2 supernatants was determined in the hypertransfused polycythemic mice assay as previously described.[16] The level of sensitivity of this assay is ~50 mU/mL and some supernatants were concentrated five to ten times (Amicon PM-10 membranes) before being assayed.

Measurements of transferrin and albumin. Double-antibody enzyme-linked immunoassays of both human albumin and transferrin were developed in our laboratory by modification of standard methods.[17] Alkaline phosphatase conjugated goat anti-rabbit IgG (Cappel) was used as the second antibody in both assays. The

primary antibody against transferrin was developed in our laboratory and the anti-human albumin antibody was obtained from Cappel. The lower limit of sensitivity in both assays was ~2.0 to 4.0 μg/mL.

Northern blots. Total mRNA was extracted from confluent monolayers of HepG-2 cells by a modification of the Chirgwin method.[18] Cells were directly homogenized in 4 mol/L guanidium-isothiocyanate buffer, centrifuged at 12,000 rpm for 30 minutes, and the supernatant was subsequently pelleted through a 5.7 mol/L CsCl cushion after overnight centrifugation at 35,000 rpm at 20°C in a Beckman ultracentrifuge. Poly A^+ RNA was selected by affinity chromatography onto an oligo dt-cellulose column (Pharmacia, Piscataway, NJ).[19] Northern blot analyses were carried out essentially as described by Lehrach et al.[20] RNA was denatured by formaldehyde-formamide and subjected to electrophoresis in 1.2% agarose gels. The gels were blotted into Nytran filters and hybridized against a ^{32}P labeled single stranded RNA probe.[21] This probe consists of a 660 base pair (bp) Sma I—*Eco*RI, mouse Epo genomic fragment representing 160 bp of intron IV and 500 bp of exon V inserted in a pSP65 plasmid and was provided to us by C. Shoemaker (Genetics Institute, Boston). This region was ~90% homology with the human gene. Hybridization was carried out at 65°C with probe (10^7 cpm/mL) in 50% formamide, 10% dextran sulfate (wt/vol), 20 mmol/L of $NaPo_4$, pH 6.5, 5 × SSC, 0.2% sodium dodecyl sulfate (SDS), 0.05% bovine serum albumin (BSA), 0.05% Ficoll, 0.05% polyvinylpyrrolidine (PVP), 200 μg/mL of denatured salmon sperm DNA, 1 mg/mL yeast tRNA and 100 μg/mL of each of poly A, poly I, and poly C. After 12 hours of hybridization the filters were washed at 65°C with decreasing concentration of salts starting at 5 × SSC, 0.1% SDS and final wash in 0.1 × SSC, 0.1% SDS. (SSC is 0.15 mol/L NaCl, 0.015 mol/L sodium citrate.) Washed filters were further digested with RNAse A as described by DeLeon et al.[22] Filters were exposed for 48 hours to Kodak XAR-5 film at −70°C using intensifying screens.

Radiolabeling experiments. Confluent monolayers of HepG-2 cells were incubated for 48 hours in the presence of ^{35}S methionine or ^{3}H mannose (Amersham, Amersham, IL) in order to measure total protein synthesis and glycolyslation, respectively. Tunicamycin was added at variable concentrations from a stock solution of 0.5 mg/mL in 0.01 mol/L NaOH. After overnight preincubation with tunicamycin the media was replaced with fresh media containing radiolabeled tracers (50 μCi per plate of either ^{35}S methionine or ^{3}H mannose). Supernatants were collected after 48 hours incubation and the incorporated label was separated from the free isotopes using gel filtration on a G-25 sephadex column, (Pharmacia PD-10, disposable columns), as modified from Gilman et al.[23] The columns were eluted with 0.15 mol/L NaCl, 0.05 mol/L PO_4 pH 7.4 buffer and aliquots were counted by liquid scintillation.

Immunoprecipitation studies were conducted in HepG-2 cells and Chinese Hamster Ovary (CHO) cells transfected with the human erythropoietin gene (Genetics Institute). Cells were incubated with 500 μCi/plate of ^{35}S cysteine in cysteine-free media (GIBCO) in the presence or absence of tunicamycin, as described above. Supernatants and cell lysates were immunoprecipitated with a mixture of two monospecific antibodies raised in our laboratory against synthetic oligo peptides corresponding to the 1-26 amino-terminal and 150-166 carboxy-terminal sequences of the human erythropoietin molecule. These antibodies were generated essentially as described by Sue and Sytkowski[24] except that the peptides were linked to keyhole limpet hemocyanine instead of albumin. Samples for immunoprecipitation were incubated for 24 hours with a final 1:100 dilution of antibodies followed by precipitation using Protein A Sepharose 4B (Pharmacia). Immunoprecipitates were analyzed by 12% SDS-PAGE (Laemelli) followed by autoradiography.[25]

RESULTS

Erythropoietin production by HepG-2 cells. Culture supernatants from confluent monolayers were assayed for erythropoietin activity using radioimmunoassay. Serial dilutions of culture media displaced radiolabelled pure erythropoietin in a parallel way to human urinary Epo. In confluent cultures erythropoietin production ranged from 40 to 150 mU/mL per 10^6 cells cultured for 48 hours. This production has been stable over more than 50 cell passages. The erythropoietic material was found also to be active in vivo as measured by the hypertransfused mice assay. Slightly lower values were observed with the bioassay suggesting the presence of some desialated material.

Cell growth and erythropoietin production. The influence of growth rate on erythropoietin production was studied in cultures maintained for four consecutive three-day periods. Cultures were initiated at a low cell density and high proliferative rate and maintained until overconfluent. Supernatants were harvested at the end of each period and replaced with new media. Parallel cultures were used to determine cell numbers (duplicate determinations of three replicas). As shown in Fig 1 maximal erythropoietin production occurs at densities between 5 and 10 × 10^4 cells/cm², at which time the cells are at their maximal proliferative activity. When cultures reach confluence (densities >20 × 10^4/cm²) there is a significant decrease in erythropoietin production.

Effect of hypoxia and cobalt on erythropoietin production by HepG-2 cells. Confluent cultures of HepG-2 cells were subjected to increasing degrees of hypoxia by incubating them for 48 hours with predetermined mixtures of different concentrations of oxygen and nitrogen in the presence of a constant 5% CO_2 atmosphere. As shown in Fig 2, a lowering of the oxygen tension from 20% to 2% induced a more than tenfold decrease in Epo production. Control cultures produced 80 ± 5 mU of Epo per 10^6/cells per mL of media and no differences in cell counts were observed.

Similarly, cobalt chloride, another known stimulus of erythropoietin synthesis in vivo, did not stimulate Epo production. As shown in Fig 3, there was a dose-dependent

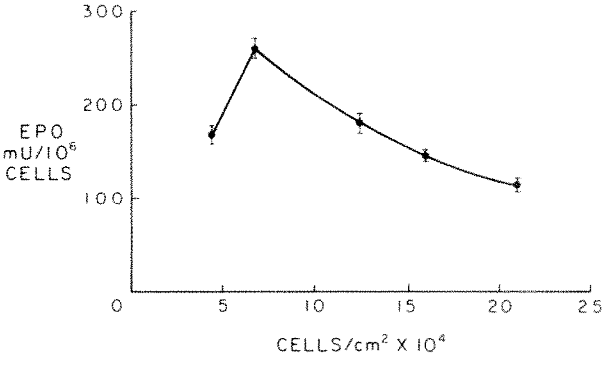

Fig 1. Dependence of Epo production on cell density. HepG-2 cells were maintained in culture for four consecutive three-day periods. The media was totally exchanged at each period interval. Epo was measured by RIA and expressed as mU/10^6 cells. Cell counts were performed in duplicate cultures.

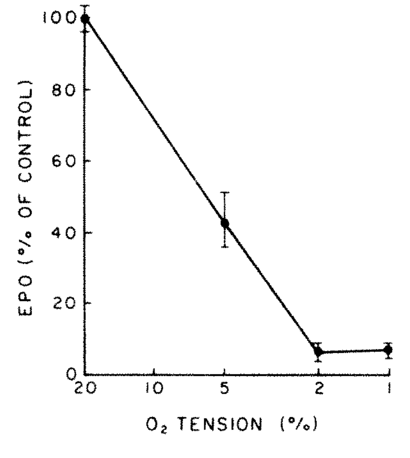

Fig 2. Effect of hypoxia on erythropoietin production. Confluent HepG-2 cells were cultured for 48 hours under conditions of variable hypoxia. Epo was measured by RIA and expressed as percent of the cultures maintained at 20% O_2.

suppression of Epo production when cells were incubated for 48 hours at increasing doses of cobalt. The levels decreased from 68 ± 5 mU/mL in the nontreated plates to nondetectable levels at the highest concentration of cobalt. The suppressive effect of hypoxia and cobalt was probably secondary to a general inhibitory effect, since similar changes were observed in the synthesis of albumin and transferrin.

Effect of tunicamycin or erythropoietin secretion. Tunicamycin, a potent inhibitor of glycosylation,[26,27] was used to study the role of the carbohydrate component of the erythropoietin molecule on its synthesis and secretion. In order to evaluate the extent of glycosylation of proteins secreted by tunicamycin-treated cultures, radiolabeling experiments were performed using ^3H mannose as a tracer. The possible inhibitory effect of tunicamycin on total protein synthesis was evaluated by measuring the incorporation of ^{35}S methionine. Separation of free and incorporated label was obtained by gel filtration. Figure 4 shows that in doses of 2.5 to 5 μg/mL tunicamycin will produce a 95% inhibition in ^3H mannose-labeled protein and a 35% inhibition of ^{35}S methionine-labeled protein.

In comparison, the specific effect of tunicamycin on the secretion of albumin, transferrin, and erythropoietin is depicted in Fig 5. While even the lowest concentration of tunicamycin (0.625 μg/mL) was associated with an almost complete abrogation of erythropoietin secretion from 51 ± 2 mU/mL to 8 ± 2 mU/mL, both albumin (a nonglycosylated protein) and transferrin (6% carbohydrates) were only moderately affected, at a rate reflecting the nonspecific inhibitory effect of tunicamycin on total protein synthesis. Intracellular levels of erythropoietin showed no significant changes in the presence or absence of tunicamycin (12 ± 2 mU/plate *v* 14 ± 2 mU/plate).

The effect of tunicamycin on the level of specific Epo mRNA was studied by Northern blot analysis of poly A+ RNA obtained from confluent HepG-2 cells cultured in the presence or absence of tunicamycin (5 μg/mL) for 48 hours. Figure 6 shows the positive hybridization signal at around 18 S obtained with a ^{32}P-labeled single-stranded RNA probe and shows that the intensity of the signal in treated and untreated cultures is equivalent. The mobility of the mRNA closely corresponds to the signal observed by Jacobs et al[5] using human fetal liver cells. However, there is also a smaller minor hybridization band that may be the result of breakdown products or represent a different species present in the tumor cell line.

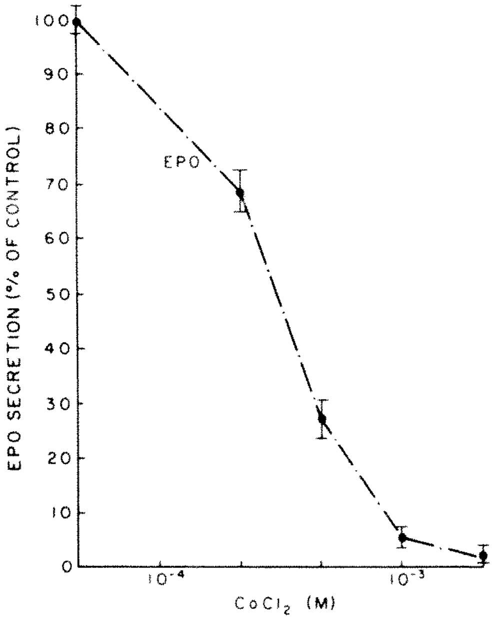

Fig 3. Effect of cobalt on erythropoietin production. Confluent HepG-2 cells were cultured for 48 hours in the presence of cobalt chloride at variable concentrations. Results are expressed as percent of cultures in the absence of added cobalt.

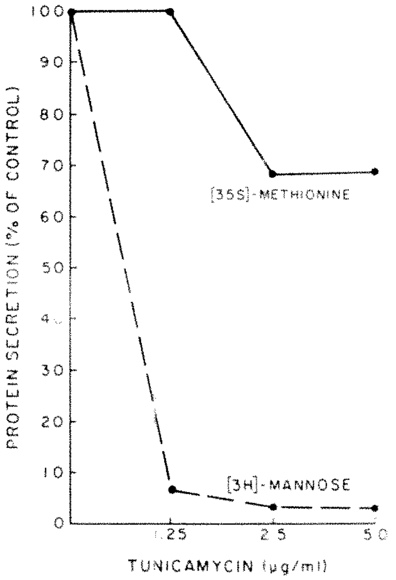

Fig 4. Dose-response curve of the effect of 48 hours exposure to tunicamycin on total protein synthesis (^{35}methionine ●——●) and glycosylation (^3H mannose ●-----●). Free and incorporated tracers were separated by gel filtration. Values are expressed as percent of secreted proteins in the absence of tunicamycin.

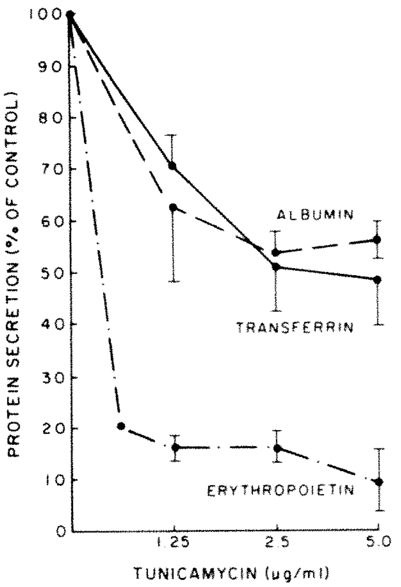

Fig 5. Effect of tunicamycin on the secretion of erythropoietin, albumin, and transferrin. HepG-2 cells were exposed to different concentrations of tunicamycin for 48 hours and supernatants were assayed for each specific protein by RIA or ELISA. Values are mean ± SD and are expressed as percent of protein secreted in the absence of tunicamycin.

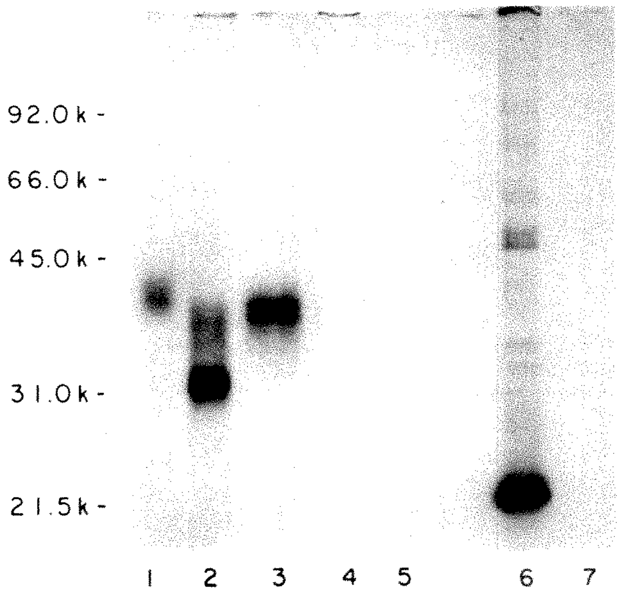

Fig 7. Immunoprecipitation of CHO cells transfected with the human Epo gene. CHO cells were incubated with ^{35}S cysteine in the presence (5 μg/mL) or absence of tunicamycin. Supernatants and cell lysates were immunoprecipitated with specific anti-Epo antibodies followed by SDS-PAGE and autoradiography. Lanes: (1) Radioiodinated pure Epo; (2) cell lysate of transfected cells; (3) supernatant of transfected cells; (4) cell lysate of nontransfected cells; (5) supernatant of nontransfected cells; (6) cell lysate of transfected cells with tunicamycin; (7) supernatant of transfected cells with tunicamycin.

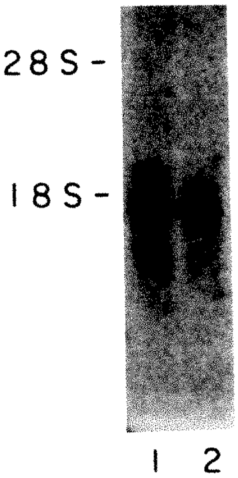
To provide further evidence of the specific suppressive effect of tunicamycin on erythropoietin secretion by mammalian cells, immunoprecipitation studies were conducted in CHO cells transfected with the human erythropoietin gene, since the relatively low level of expression of erythropoietin in the HepG-2 cells precluded the experiment in this cell line. CHO cells were incubated with ^{35}S cysteine (500 μCi/plate) in the presence and absence of tunicamycin (5 μg/mL). Supernatant and cell lysates were immunoprecipitated with specific antierythropoietin antibodies obtained against erythropoietin oligopeptide sequences. Figure 7 shows no immunoprecipitable material in the tunicamycin-treated culture supernatants (lane 7) as compared with the nontreated control (lane 3). Furthermore, intracellular erythropoietin appears to accumulate in the treated cells as a major strong single band with an apparent mol wt of ~21.5 kd (lane 6) compared with an apparent mol wt of ~36.0 kd of the mature molecule (lane 2). At ~45 kd there is also a minor band that may represent aggregates of aglyco-Epo or, more likely, nonspecific coprecipitation of other intracellular labeled proteins. Interestingly, intracellular erythropoietin in the nontreated cells showed the presence of two forms, one with the apparent mol wt of the mature erythropoietin and another form with a slightly lower mol wt. This latter band probably represents erythropoietin molecules with immature glycosylation patterns. Further studies using Endo H will be necessary to clarify this point.

Fig 6. Northern blot analysis of Poly A$^+$ RNA from HepG-2 cells. RNA was extracted from HepG-2 cells cultured in the presence or absence of tunicamycin for 48 hours. After electrophoresis and transfer to nylon filters they were hybridized with a single-stranded ^{32}P mRNA probe. Lane 1 (control) and lane 2 (tunicamycin 5 μg/mL) show radioautography of 10 μg per lane of Poly$^+$ RNA.



DISCUSSION

The liver is the main site of extrarenal erythropoietin production in adult animals[28,29] and may play a predominant role in the production of erythropoietin during fetal life.[30] Increased erythropoietin production has been observed in patients with hepatomas and in accord with a previous report by Okabe et al[14] the present study showed that certain human hepatoblastoma cells can produce erythropoietin. Our cell line, HepG-2, established originally by Knowles et al[13] from a child with an hepatoblastoma, has been found to secrete a number of plasma proteins, especially high levels of alpha feto-protein. Production of erythropoietin was documented with both radioimmune assay and in vivo bioassay and by the presence of specific mRNA in northern blot analysis.

In vivo hypoxia constitutes a potent stimulus for erythropoietin production both by the kidney and the liver. Such hypoxic stimulus has also been found to induce Epo synthesis in cultures of fetal liver cells.[12] In the present study, however, cultures of HepG-2 cells failed to respond to hypoxia with increased Epo production. On the contrary there was an actual decrease in Epo synthesis as the oxygen tension was lowered. Furthermore, cobalt chloride, a pharmacologic stimulator of Epo production, also failed to elicit a stimulating response. The reason for this lack of response remains obscure but is compatible with the contention that hormone production in malignant cells is not subjected to the regulatory mechanisms operating under physiologic conditions.

Several in vivo studies have shown that hepatic erythropoietin synthesis is enhanced in conditions of accelerated cellular proliferation. This phenomenon has been observed after partial hepatectomy, hepatocyte injury, or in the recovery phase of acute hepatitis.[31-33] In our cell line it was found that peak erythropoietin production coincided with peak proliferative activity. It is tempting to suggest that the activation of the gene in the regenerating liver and in the cell line may be mediated by a similar mechanism.

The availability of this cell line has offered the opportunity to explore the biological significance of the carbohydrate component of the erythropoietin molecule on its intracellular processing and secretion. The role of *N*-linked glycosylation was examined with the use of tunicamycin, which blocks the addition of *N*-acetyl glucosamine to dolichol phosphate and thereby inhibits the formation of the core oligosaccharide.[34] In the presence of tunicamycin the secretion of erythropoietin was almost completely abrogated. In contrast, secretion of another glycoprotein, transferrin, and a nonglycosylated protein, albumin, were only moderately affected.

Measurements of specific erythropoietin mRNA in treated and nontreated cells showed no difference in hybridization signal between the two groups, suggesting that tunicamycin had no specific effect on transcription, but was acting at a posttranscriptional or secretory level.

To confirm the impression that the effect of tunicamycin was due to a lack of secretion of the nonglycosylated protein, supplementary studies were conducted in CHO cells transfected with the human erythropoietin gene. These cells secrete about a thousand-fold more Epo than HepG-2 cells and were therefore suitable for immunoprecipitation studies. The studies in CHO cells confirmed the lack of secretion of erythropoietin and demonstrated that tunicamycin-treated cells did synthesize the hormone that was accumulated intracellularly.

In conclusion we describe a human hepatoblastoma cell line that constitutively secretes erythropoietin into the culture media. Erythropoietin synthesis in this cell line appears not to be regulated by the physiologic modulators of erythropoietin production such as hypoxia or cobalt; however, it is related to the proliferative activity of the cells. Using this cell line and permanently transfected CHO cells, we have shown that secretion of the erythropoietin molecule depends on intact *N*-linked glycosylation.

ACKNOWLEDGMENT

We are greatly indebted to B. Knowles (Wistar Institute, Philadelphia), who provided us with the HepG-2 cell line, and C. Shoemaker (Genetics Institute, Boston), who provided us with the Epo probes. We also greatly appreciate the technical help of J. Wilson, the graph work of D. Likens, and the secretarial work of D. Riso.

Recovery of Contact Hypersensitivity Responses Following Murine Bone Marrow Transplantation: Comparison of Gamma-Irradiation and Busulfan as Preparative Marrow-Ablative Agents

By Wolfram E. Samlowski and Carol L. Crump

Bone marrow transplantation (BMT) is often followed by significant morbidity and mortality due to protracted immunodeficiency. We have hypothesized that the bone marrow-ablative regimen may delay the recovery of normal immune function following transplantation by impairing the interaction of host endothelial cells with circulating graft-derived lymphocytes. This report compares the relative effects of busulfan (an alkylating drug) and gamma-irradiation on the tissue-specific localization potential of lymphocytes and the eventual recovery of immune function within syngeneic murine transplant recipients. Localization of normal lymphocytes into peripheral lymph nodes of irradiated BMT recipients was markedly less (<50%) than in busulfan-treated or normal mice over the first 2 months post-BMT. This finding correlated with irradiation-induced endothelial cell edema and microvascular occlusions within lymphocyte-receptive areas of the nodal microvasculature. The effect of both preparative regimens on the recovery of contact hypersensitivity (CHS) was also analyzed. This response recovered more quickly (between 1 and 2 months) in busulfan-pretreated animals. Further experiments demonstrated that the decrease in CHS responsiveness appeared, in part, related to a depression in the capacity of lymphocytes to localize into skin sites of antigen deposition within irradiated mice. The impairment of tissue-specific lymphocyte localization may represent a novel mechanism by which whole body irradiation can contribute to delayed immunologic reconstitution following bone marrow transplantation.

BONE MARROW transplantation (BMT) has gained widespread acceptance in the treatment of a wide range of clinical conditions, including congenital immunodeficiency, aplastic anemia, and leukemia.[1,2] While representing a major advance in the treatment of these diseases, the procedure is also associated with significant morbidity associated with severe protracted alterations in immunologic function.[3,4,5] Depressions of both humoral and cellular immune functions occur during the first 100 days after transplantation. This pan-immunodeficiency is thought to represent a consequence of the aggressive chemotherapy or radiotherapy protocols used to ablate the recipient's immunohematologic system, before donor marrow infusion.[4]

The eventual hematologic and immunologic recovery post-BMT is closely linked to the engraftment, proliferation, maturation and differentiation of donor-derived stem cells.[4] Some recovery of peripheral blood lymphocyte subsets can usually be demonstrated within 3 to 6 months of BMT.[6-9] Despite the relatively early reappearance of phenotypic T and B cells, functional immunologic recovery may take over 2 years.[3,4,7,9,10] During this period, serum antibody production, cytotoxic T cell function, mitogen responsiveness, as well as other lymphocyte functions appear to recover. Some complex immunologic responses, such as antigen-specific helper T cell function, IgA secretion, and contact hypersensitivity responses, appear to be even more delayed in their recovery.[10-13] In one study, helper T cell function was found to be depressed as late as 4 to 6 years post-BMT.[11]

The degree of histocompatibility between the bone marrow donor and recipient does not appear to significantly influence the rate at which immunologic recovery occurs following BMT. Immunologic reconstitution occurs at a similar pace following human twin, allogeneic and autologous transplants.[14,15] The development of graft-v-host disease, however, significantly worsens the severity and duration of the various cellular and humoral immune deficits observed posttransplantation.[16,17]

It is possible that current BMT protocols have detrimental effects on the recovery of the immune system posttransplantation by producing unintended effects on host tissues. We have hypothesized that some of the post-BMT immunologic deficits are produced by toxicity of the bone marrow-ablative regimen on the endothelial cells of the recipient. Alterations in the capacity of endothelial cells to bind graft-derived lymphocytes may account for decreased tissue localization potential of immune effector cells and thereby result in depressed immunologic function.

Under normal circumstances, mature lymphocytes continually migrate throughout the body, passing from the bloodstream through the various lymphoid organs and eventually returning to the bloodstream. The ability of lymphocytes to migrate through tissues is termed recirculation.[18,19] Virtually the entire lymphocyte content of peripheral lymph nodes enters the nodal parenchyma from the bloodstream via this process.[20] Tissue-specific extravasation appears to require the selective interaction of lymphocyte surface receptors with lymph node microvascular endothelial cells.[21] The adhesion process appears to take place in histologically distinct cuboidal endothelium-lined post-capillary venules, known as high endothelial venules (HEV).[22,23] Analogous tissue-specific extravasation-mediating structures are also associated with the endothelium of other lymphoid organs, such as the

Peyer's patches,[24] mesenteric lymph nodes,[23] peribronchial lymphatic tissue,[25] and synovium.[26]

Continual lymphocyte recirculation through peripheral lymph nodes is believed to enhance the probability that a T cell, which is committed during differentiation to a single antigen epitope, can encounter its specific antigen.[23,27] The antigen recognition process is aided by the simultaneous concentration of antigen-presenting cells (APCs) within peripheral lymph nodes via the afferent lymphatic drainage.[28] The peripheral lymph nodes also contain all of the humoral and cellular regulatory elements needed to amplify or depress immune responsiveness. The peripheral lymph nodes, therefore, serve as structures that facilitate the antigen recognition process and enhance immune surveillance of host tissues.

Our previous studies established that marrow-ablative doses of gamma-irradiation (>7.5 Gy) caused distinctive ultrastructural changes in murine and human lymph node HEV.[29] These alterations in murine HEV were associated with a depressed capacity of lymphocytes to localize into irradiated lymph nodes from the bloodstream.[29] Due to the importance of peripheral lymph nodes in the initiation and regulation of immune responses, we hypothesized that this depressed localization capacity should be associated with demonstrable changes in immune function.

In this report we compare the effects of two commonly used bone marrow-ablative agents,[2] busulfan (an alkylating drug) and gamma-irradiation, on HEV histology and lymphocyte tissue localization potential. Since the two preparative regimens differed significantly in their endothelial toxicity, it proved possible to assess their respective effects on the timecourse of immunologic reconstitution following BMT.

MATERIALS AND METHODS

Animals. Six- to ten-week-old C3H/HeN mice were obtained from the animal production facility of the National Cancer Institute (Bethesda, MD). All mice were housed at a maximum density of six animals per 18 × 28 cm cage and maintained on Wayne sterilizable Lab Blox (Wayne Pet Food, Chicago) and acidified water ad libitum. Mice were age and sex matched for each experiment. Before exposure to either preparative regimen, the experimental animals were pretreated for two days with 0.5 mg of gentamycin sulfate administered intraperitoneally (IP). Throughout the course of the experiment, recipient mice also received oral nonabsorbable antibiotics (35 mg of neomycin and 2,500 units of polymyxin B per 200 mL of drinking water). This treatment was used to reduce mortality due to infection during the experiment.

Preparation of lymphocytes. Peripheral lymph nodes (PLN) (inguinal, axillary, brachial, and cervical) were excised from donor mice and gently dissociated in RPMI 1640 medium (GIBCO, Grand Island, NY) with 5% fetal bovine serum (Sterile Systems, Logan, UT) (complete medium). The cell suspension was layered onto a glass-wool column to remove adherent as well as nonviable cells. Cell suspensions were always ≥99% viable by trypan blue exclusion.

Gamma-irradiation of mice. Recipient mice were lethally irradiated with 7.5 Gy (1 Gy = 100 rad) per whole body at 4.8 Gy/min using a Gammator (Isomedix, Parsippany, NJ) containing a cesium source. Animals were reconstituted with $\sim 10^7$ syngeneic nucleated bone marrow cells immediately following irradiation. The irradiated mice were then placed into sterile cages, in a laminar airflow environment and given sterile food and antibiotic-containing water ad lib.[29]

Busulfan treatment of mice. Busulfan (Burroughs Wellcome, Research Triangle, NC), 6.25 mg, was dissolved in 200 μL dimethylsulfoxide and 800 μL warm (37°C) phosphate-buffered saline (PBS, pH 7.4). Antibiotic pretreated mice were given daily doses of 25 mg busulfan/kg body weight IP for six sequential days. This dose has been established as the hematologic LD_{100} for mice (reference 30 and unpublished observations). Animals were reconstituted with 10^7 nucleated marrow cells 24 hours following the last dose of busulfan, a point at which all active drug has been cleared from the circulation.[31] Animals were then maintained in the same fashion as irradiated BMT-recipients.

Radiolabeling of lymphocytes with [^{51}Cr] for localization studies. Lymphocytes were radiolabeled with [^{51}Cr] (as sodium chromate, specific activity 250-500 mCi/mg Cr; Amersham, Arlington Heights, IL). Lymphocyte suspensions (10^8 viable cells/mL) were incubated with 100 μCi [^{51}Cr] for half an hour at 37°C. Radiolabeled cells were washed three times in complete medium, adjusted to 10^7 lymphocytes per milliliter in RPMI and 0.2 mL was injected intravenously (IV) into normal, busulfan-treated, or gamma-irradiated recipient mice. The administration of gamma-irradiation or busulfan was timed in such a manner that the comparative localization studies involving the infusion of [^{51}Cr]-labeled lymphocytes into the various experimental groups could all be performed from a single preparation of radiolabeled cells.

Radiolabeling of lymphocytes with [^{125}I] for localization studies. Cells synthesizing DNA following antigen sensitization were labeled with [^{125}I] (as iododeoxyuridine [^{125}IUDR], Amersham, sp act 5 Ci/mg). Lymphocytes were isolated from antigen-sensitized donor mice, and a single cell suspension prepared (5×10^7 cells/mL). A total of 2 μCi of [^{125}IUDR] was incubated per milliliter of the cell suspension for two hours (37°C) with periodic gentle agitation. This was followed by extensive washing and resuspension of the cells to 10^8/mL. Each recipient was infused IV with 4×10^7 [^{125}IUDR] labeled cells.

Isotope quantitation and data presentation. Animals were killed four hours after infusion of labeled cells. The mice were autopsied, and individual organs were removed and placed into separate vials for counting in a Beckman Gamma 8000 gamma counter (Beckman Instruments, Irvine, CA), as was the remaining carcass. Data are presented as the percentage of radioactivity recovered per individual organ, as compared with the total radioactivity recovered from the experimental animal. Background values were subtracted from each one-minute count. This method of data calculation precludes errors introduced by inoculation variation between animals, as organ distribution is independent of the number of radiolabeled cells injected over a wide dose response range.[32] Localization experiments were run using two to three animal groups because of high concordance between animals. Each experiment was repeated at least twice.

Assessment of relative marrow ablative potential of irradiation and busulfan regimens. Relative bone marrow stem cell ablation produced by gamma-irradiation (a single dose of 7.5 Gy) or busulfan (25 mg/kg/d for six days, IP) was quantified by an in vitro granulocyte-macrophage colony assay (CFU-GM). One femur from each mouse within three animal groups (which had previously been exposed to one of the preparative regimens) was isolated, and the marrow irrigated out with a syringe. Each femur contains ~4.5% of the total mouse bone marrow compartment.[33] Following gentle dissociation of each animal's marrow into a single cell suspension, erythrocytes were lysed with Tris-buffered 0.16 mol/L ammonium chloride. The remaining nucleated cells were counted by phase microscopy. The CFU-GM were assessed by plating the entire nucleated bone marrow cell population from each femur into 2 mL of 0.8% methylcellulose (Dow Chemical Co, Midland, MI), in the presence of murine post-endotoxin serum (a source of GM-colony stimulating factor [GM-CSF]) at a predetermined optimal concentration.[34] After 12 days colonies of >40 cells were counted. Normal murine bone marrow cells (10^6 cells per 60 mm plate), cultured in the presence of GM-CSF served to establish the maximum colony formation potential. Bone marrow cells plated in the absence of GM-CSF served as a negative control.

Immunoperoxidase staining of frozen sections. Frozen sections were incubated for 30 minutes with MECA-325 (generously supplied by E. Butcher, Stanford, CA). MECA-325 is a monoclonal rat-anti-mouse endothelial cell antibody (IgGl), which was produced by fusing spleen cells from rats that had been immunized with mouse (Balb/c) lymph node stroma with SP 2/0 mouse myeloma cells.[35] This monoclonal antibody binds specifically to murine HEV, and not other lymph node structures.[35] No cross reaction occurs with capillaries, arteries, and arterioles that do not have the cuboidal endothelial features associated with specific lymphocyte binding.[35] To identify MECA-325 binding, a biotinylated rabbit-anti-rat antiserum (Cappel) was used as a second stage reagent. This reagent did not bind to mouse lymph node sections in parallel control slides. Immunoperoxidase staining was then performed using a modified avidin-biotin-peroxidase complex technique.[36]

Sensitization and elicitation of contact hypersensitivity (CHS). Experimental and control mice were sensitized on the shaved abdomen with 25 μL of 0.25% 2,4-dinitro-1-fluorobenzene (DNFB; Sigma, St Louis) in a vehicle of acetone/olive oil (4:1) on two consecutive days. Four days after the first sensitization, a challenge dose of 10 μL 0.25% DNFB was applied to the right hind footpad.[37] Footpad swelling was measured (using a micrometer) 24 and 48 hours after challenge. The increment in footpad swelling of a constant area of the challenged *v* the contralateral unchallenged footpad was expressed in units of 10^{-3} inches. The increment in swelling (2 to 3 measurements/animal) for each mouse was then averaged with the remainder of the 4-5 animal group, and the results reported as the mean ± SEM.

Adoptive transfer of CHS. Normal mice were sensitized with 25 μL of 0.25% DNFB on the shaved abdomen and 10 μL DNFB on each footpad and ear on two consecutive days (donors). Four days after the initial sensitization, popliteal, inguinal, axillary, brachial, and cervical nodes were excised and gently dissociated in complete medium. The resulting single cell suspensions were injected IV into previously transplanted mice (either irradiated or busulfan-pretreated) at 4×10^7 cells/recipient. The recipients of the cell infusion were challenged with 10 μL 0.25% DNFB on the right hind footpad immediately following cell transfer. The increment in footpad swelling was determined 24 and 48 hours later. Age-matched normal syngeneic mice that received an adoptive transfer of sensitized lymphocytes served as a positive control.

In some experiments, the antigen-sensitized lymphocytes were radiolabeled with [^{125}IUDR] before their adoptive transfer. In these experiments, the animals were challenged on one ear (instead of the footpad), and the increment in ear swelling ($\times 10^{-4}$ inches) was measured only at 24 hours. Each animal was then killed and its organs (including each ear separately) assayed to determine the distribution of the infused radiolabeled cells (as described above).

Direct injection of hapten-modified lymphoid cells and effector lymphocytes into the skin. Syngeneic spleen cells were treated with buffered ammonium chloride to lyse erythrocytes (as described above). Splenocytes were trinitrophenylated by incubation of suspensions of 10^7 cells/mL in PBS containing 2.5 mmol/L 2,4,6-trinitrobenzene sulfonic acid ($TNBSO_3$) for ten minutes at 25°C. After hapten modification, the cells were extensively washed in medium and resuspended at 10^8 cells/mL to use as targets for antigen-primed effector cells. The effector cells were generated by sensitizing mice on the belly, footpad, and ears (as described above) with a single application of 7% 2-chloro-,1,3,5-trinitrobenzene (TNCB). These mice subsequently served as donors for sensitized lymphocytes four days later. The antigen-sensitized lymphocytes were also suspended at 10^8 cells/mL, and mixed 1:1 with hapten-modified target cells. Groups of irradiated BMT recipients or normal control mice were injected with 10 μL of the combined cell suspension in the right ear. The increment in ear swelling (compared with the contralateral ear) was determined 48 hours later to minimize any residual swelling due to injection trauma ($\times 10^{-4}$ inches). Mice that received an equivalent volume of sensitized effector lymphocytes without hapten-modified splenocytes served as a negative control.

RESULTS

The initial experiment was designed to compare the relative effects of irradiation or busulfan exposure on tissue localization of normal lymphocytes within BMT recipients. These experiments were performed by infusing 2×10^6 normal [^{51}Cr]-labeled peripheral lymph node lymphocytes IV into previously transplanted mice (0.2 mL/recipient). Four hours following the infusion of radiolabeled lymphocytes, the animals were killed and autopsied. Each organ (peripheral lymph nodes, spleen, mesenteric nodes, gut, liver, kidneys, lungs and the residual carcass) was counted separately in a gamma counter to determine the primary localization of the cells. The results (Fig 1) are expressed as a percentage of the injected cells that localized within the peripheral lymph nodes (±SEM), compared with the total recovery from each animal. As early as 1 week post-BMT, a time when the function of both the hematopoietic and immunologic systems of the BMT recipient remain ablated by the preparative regimen, lymphocyte localization into the lymph nodes of previously irradiated mice was <50% of controls. No evidence of lymphocyte sequestration in any other organ could be demonstrated as a cause for the depression in cells reaching the peripheral lymph nodes (data

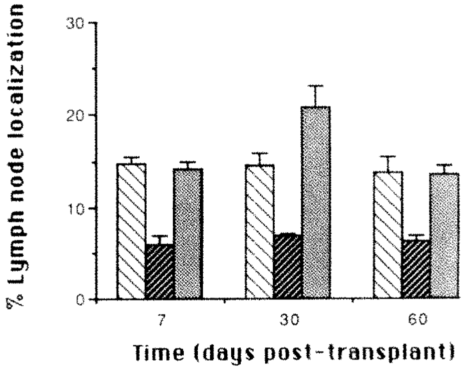

Fig 1. Localization of normal lymphocytes into the peripheral lymph nodes of BMT recipients. Mice were transplanted, using busulfan (25 mg/kg/d × 6 days) or irradiation (7.5 Gy) as the marrow-ablative regimen. Animals received 2×10^6 [^{51}Cr]-labeled normal peripheral lymph node lymphocytes as an IV infusion either 7, 30, or 60 days after BMT. Four hours after infusion of cells, the recipients were killed and autopsied. Radioactivity recovered from the pooled peripheral lymph nodes (inguinal, brachial, axillary, and cervical) is expressed as a percentage of the total radioactivity retained within each animal. The results are expressed as the average of three animal groups (±SEM). ▧, Control; ▨, irradiated; ▒, busulfan.

not shown). The decrease in lymphocyte localization into peripheral lymph nodes in irradiated mice persisted through the 1- and 2-month timepoints. These times were chosen for experimental evaluation because significant graft-derived hematologic recovery occurs by 1 month post-BMT. By 2 months following syngeneic murine transplantation, phenotypic recovery of graft-derived lymphocytes in the blood and lymphoid tissues may be observed.[38] Busulfan-treated mice did not exhibit significant depression in the capacity of lymphocytes to localize into nodes at any time tested. This suggests that busulfan, unlike gamma-irradiation, does not adversely affect the lymphocyte-receptive endothelium within peripheral lymph nodes.

These results could also be explained if the marrow-ablative dose of busulfan was less potent than that of gamma-irradiation. If this were true, less lymph node microvascular damage might also be expected. We performed an experiment to directly assess the degree of bone marrow stem cell ablation produced by both of the experimental regimens. Groups of three mice were pretreated with either busulfan or irradiation. Hematologic reconstitution by BMT was not performed. Twenty four hours after the last exposure to either preparative agent, the marrow content of one femur per animal (~4.5% of its total bone marrow)[33] was assessed for its ability to form CFU-GM. Care was taken to assess CFU-GM in busulfan-pretreated mice at a time when all drug and its active metabolites were believed to have been cleared from the circulation.[31] To establish the normal CFU-GM content per femur, a group of normal age- and sex-matched control mice served as a control. The results of this experiment (Table 1) established that busulfan-pretreatment decreased the number of CFU-GM by a factor of $>10^4$/femur, compared with 10^3 for 7.5 Gy-irradiated animals. The apparent differences in lymphocyte recirculation potential produced by the two regimens cannot, therefore, be accounted for by less intensive marrow ablation within the busulfan-treated group. These two regimens likely differ in their effects on the lymph node HEV structures.

Table 1. Cytoreductive Potential of the Irradiation and Busulfan Treatment Protocols

Group	Nucleated Cells Recovered per Femur	CFU-GM Recovered per Femur	Stem Cells Reduction by Preparative Regimen (%)
None	5.6×10^7	11,200	0
Irradiation	5.0×10^6	7.8	99.03
Busulfan	3.4×10^5	0.8	99.003

The decrement in bone marrow stem cells within animals exposed to either busulfan (25 mg/kg/d × 6 days IP) or irradiation (7.5 Gy) was quantified with the CFU-GM assay. Three animal groups were treated with each of the preparative regimens. Twenty-four hours following completion of the marrow-ablative regimen, a single cell suspension was prepared from the bone marrow contained within one femur from each animal. Erythrocytes were lysed with buffered ammonium chloride and the number of nucleated cells counted. The entire nucleated cell content of each femur (~4.5% of the total marrow mass of a mouse)[33] was then plated into 0.8% methyl cellulose in RPMI 1640 medium, 20% fetal bovine serum, and a predetermined optimal concentration of murine post-endotoxin serum (a source of GM-CSF). After 12 days, the resulting CFU-GM colonies (>40 cells) were counted. The CFU-GM content of normal femurs was established by plating 10^6 nucleated bone marrow cells, derived from age-matched controls, into culture as described above. The CFU-GM content of a normal femur was then calculated based on: (the total number of nucleated cells per femur [$\times 10^6$ cells] × (CFU-GM/10^6 cells plated into culture).

The microanatomy of the peripheral lymph node HEV was directly examined by immunochemical techniques. Frozen sections of mouse peripheral lymph nodes were prepared from animals 2 months postexposure to either busulfan or irradiation. These sections were stained with the monoclonal antibody, MECA-325, using an immunoperoxidase technique.[36] This monoclonal antibody specifically identifies lymphocyte-receptive areas of endothelium within peripheral lymph nodes (high endothelial venules).[35] The immunoperoxidase-stained sections of gamma-irradiated lymph nodes (Fig 2A) demonstrated a marked disorganization of the HEV histology, with apparent edema and proliferation of the endothelial cells, producing microvascular occlusions. Lymph nodes from busulfan-pretreated animals (Fig 2B) were found to have a normal appearing HEV architecture, with cuboidal endothelium and patent vascular lumens. A MECA-325–stained section of a lymph node from a normal animal is presented for comparison (Fig 2C). Electron microscopy (EM) was also performed at the 2-month timepoint. The EM studies confirmed our previous findings of severe intracellular edema within endothelial cells of previously irradiated HEV.[29] Lymph node endothelial cells from busulfan-pretreated mice, on the other hand, were ultrastructurally normal (data not shown).

Since the capacity of lymphocytes to enter peripheral lymph nodes appears to be impaired by prior irradiation, it follows that immunologic hyporesponsiveness might occur as a consequence. Contact hypersensitivity (CHS) was the initial response evaluated, because CHS is known to be depressed for years following BMT in humans.[3,4] CHS may be particularly susceptible to preparative-regimen–induced endothelial damage, because lymphocyte recirculation is thought to play an important role in this response. The sensitization and amplification phases of this response take place, in part, following localization of circulating lymphocytes into the region lymph nodes that drain the antigen-exposed skin.[39,40] Antigen-sensitized CHS-effector T cells that are subsequently generated in the peripheral lymph nodes are thought to exit the node via efferent lymphatics and migrate via the thoracic duct into the bloodstream. These sensitized lymphocytes exhibit the capacity to extravasate from the bloodstream specifically into sites of subsequent antigen exposure in the skin.[39,40]

The effects of the BMT-preparative regimen on the induction of CHS-responsiveness were assessed by testing groups of mice transplanted using either busulfan or irradiation 1 and 2 months previously. Mice were sensitized with DNFB on their shaved abdominal skin. Four days after the initial sensitization, the challenge dose of DNFB was applied to the right hind-footpad. The degree of swelling was measured with a micrometer 24 hours later, and compared with the contralateral normal footpad. A group of sensitized and challenged age-matched normal mice served to establish the normal range of CHS-responsiveness for each experimental timepoint. A nonsensitized group that was exposed only to

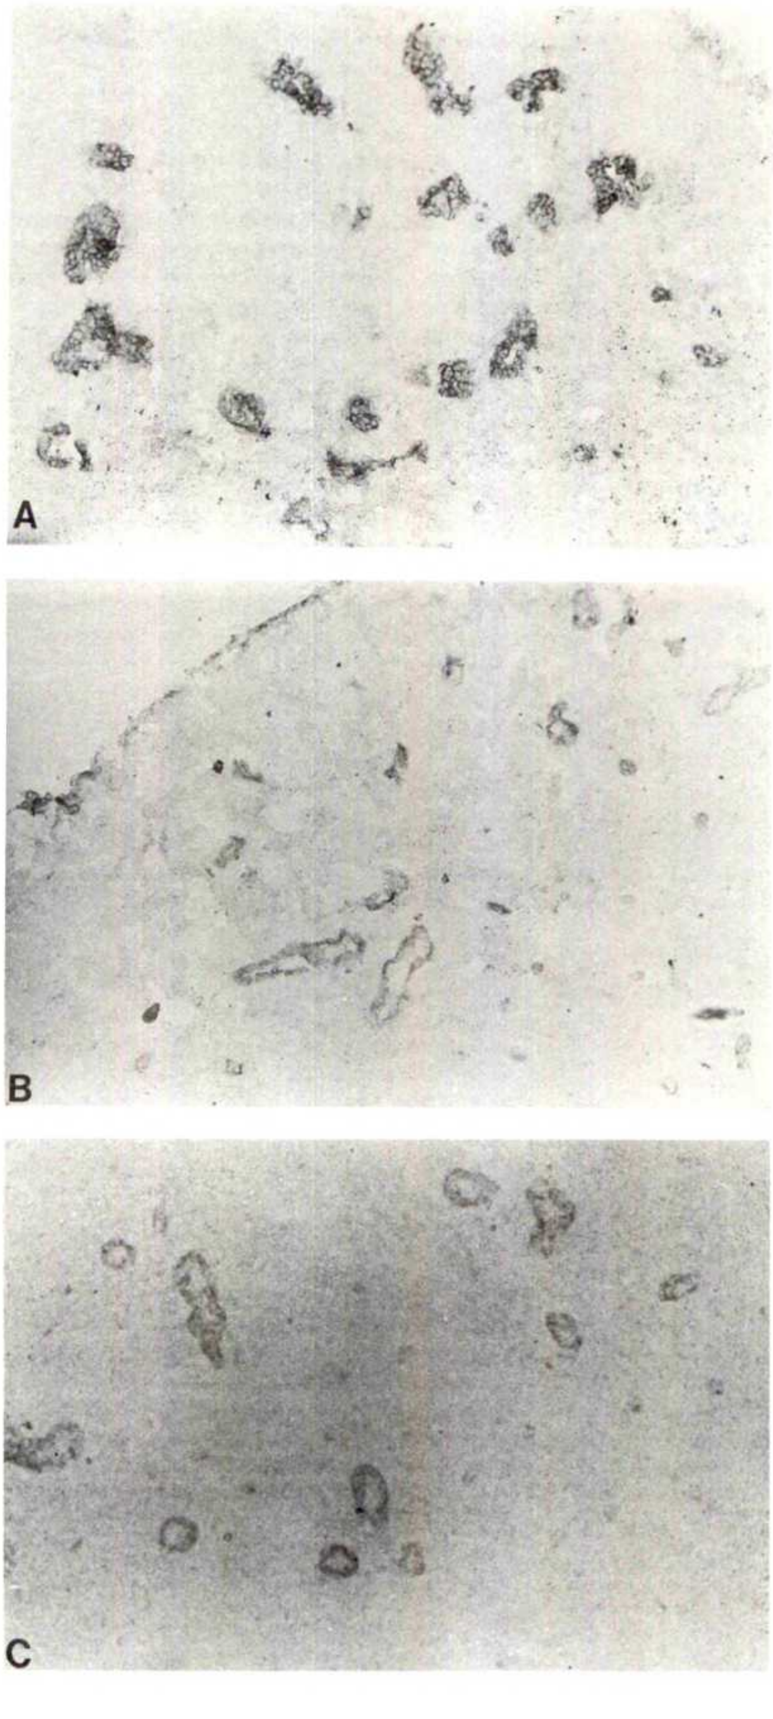

Fig 2. Immunoperoxidase staining of peripheral lymph node HEV with the monoclonal antibody MECA-325. Mice were exposed to either irradiation (A) or busulfan (B) marrow ablation, followed by syngeneic hematopoietic reconstitution. Frozen sections (6 μm) were prepared from their lymph nodes, obtained 2 months after BMT, and stained with MECA-325 by immunoperoxidase technique as described in the Materials and Methods section. The irradiated lymph nodes exhibit apparent endothelial cell proliferation, edema, and occlusion of vascular lumens, unlike busulfan exposed nodes. For comparison, a normal peripheral lymph node is also shown (C).

the challenge dose of DNFB served as a negative control. This experiment (Fig 3) demonstrated that the de novo induction of CHS-responsiveness was markedly diminished in both the irradiated and busulfan-treated groups at 1 month posttransplantation. By 2 months, however, the busulfan group had recovered a normal degree of CHS-responsiveness. The 2-month irradiated group, on the other hand, still exhibited a markedly depressed response.

These results indicate that this antigen-specific immunologic response is depressed longer in previously irradiated mice than in busulfan-pretreated BMT recipients. The elicitation of CHS responses, however, requires a complex system that involves multistep antigen sensitization, amplification, and effector phases. Any experimental result must therefore be intrepreted with caution, since irradiation could be acting at one or multiple steps in the response. Additional experiments were performed, analyzing two specific components of the CHS response, to better define some of the potential mechanisms resulting in the observed depression of CHS responsiveness.

The effector phase of the CHS response (ie, the ability of sensitized effector lymphocytes to localize into the skin from the bloodstream and produce edema) can be tested by means of an adoptive transfer experiment. Such an experiment was performed by allowing antigen sensitization to proceed in normal animals. A single-cell suspension of lymphocytes was prepared from the lymph nodes of these donor mice, and 4 × 10^7 cells/mouse were infused IV into groups of experimental animals. This experiment was performed in groups of mice transplanted 1 and 2 months previously, using either the busulfan or irradiation protocol. Mice were challenged with antigen on one footpad immediately following the adoptive transfer of cells. The increment in foodpad swelling was determined 24 hours later (Fig 4). Parallel groups of normal age-matched control mice were used at each time point to establish the maximum expected degree of swelling elicited by such an adoptive transfer of effector cells. The results of this experiment (Fig 4) demonstrate a marked reduction in the capacity of normal DNFB-sensitized effector lymphocytes to elicit swelling in footpad challenge sites in previously irradiated mice (28% and 34% of control at 1 and 2 months post-BMT, respectively). This experiment suggests that prior radiotherapy interferes with either the ability of effector T cells to localize into the skin of irradiated BMT recipients or the subsequent ability of these cells to elicit swelling within cutaneous tissues. The response was somewhat depressed at 1 month following busulfan exposure. By 2 months, however, the ability to adoptively transfer CHS responsiveness into busulfan-treated recipients was not different from normal. Measurement of footpad swelling at 48 hours (to exclude the possibility that irradiated animals exhibited a delayed, but otherwise normal, CHS response) demonstrated a similar pattern to the 24-hour measurements, but were uniformly reduced in magnitude within each group of mice.

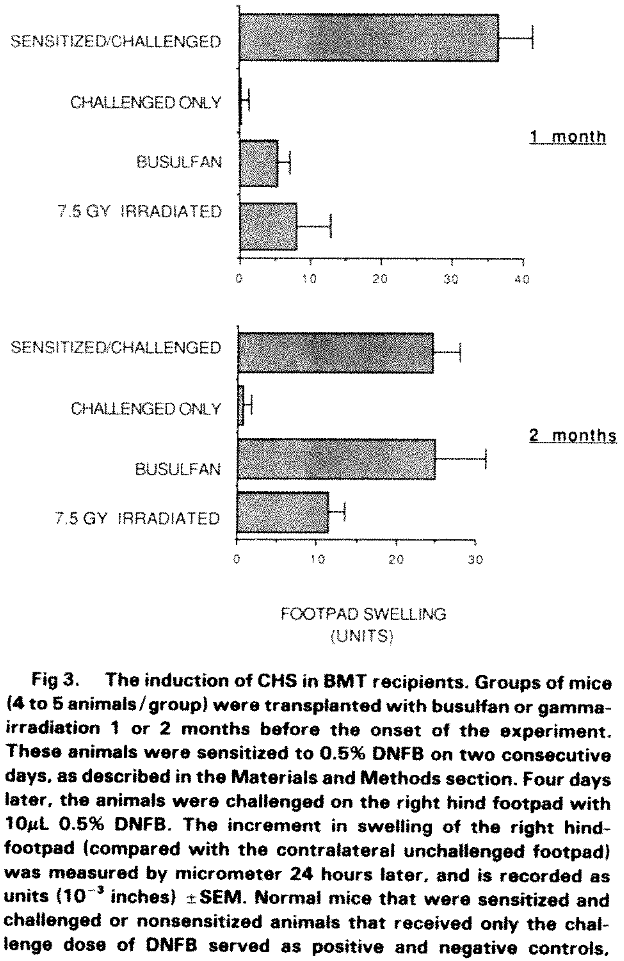

Fig 3. The induction of CHS in BMT recipients. Groups of mice (4 to 5 animals/group) were transplanted with busulfan or gamma-irradiation 1 or 2 months before the onset of the experiment. These animals were sensitized to 0.5% DNFB on two consecutive days, as described in the Materials and Methods section. Four days later, the animals were challenged on the right hind footpad with 10μL 0.5% DNFB. The increment in swelling of the right hind-footpad (compared with the contralateral unchallenged footpad) was measured by micrometer 24 hours later, and is recorded as units (10^{-3} inches) ±SEM. Normal mice that were sensitized and challenged or nonsensitized animals that received only the challenge dose of DNFB served as positive and negative controls, respectively.

The possibility that previous irradiation of the skin is responsible for the failure to produce edema was then addressed. Four days after sensitization of normal donor

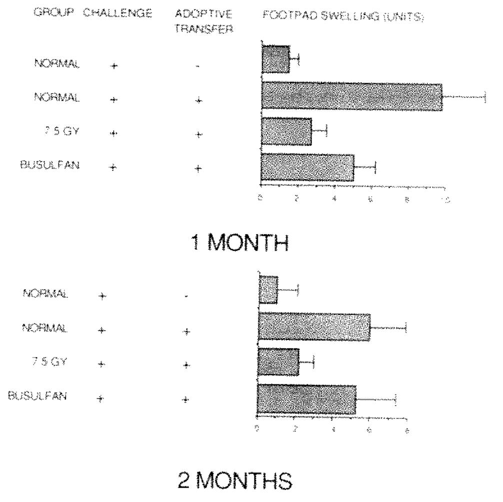

Fig 4. The adoptive transfer of CHS to previously transplanted mice. Normal mice were sensitized to DNFB and served as donors for the adoptive transfer of antigen-sensitized peripheral lymph node lymphocytes. A single cell suspension of peripheral lymph node lymphocytes from these mice (4 × 10^7 cells per recipient) was injected IV into groups of previously transplanted mice (1 or 2 months post-BMT). These recipients were immediately challenged on the right hind-footpad with 10 μL 0.5% DNFB. Twenty-four hours following challenge, the increment in footpad swelling was measured (10^{-3} inches ±SEM).

mice with trinitrochlorobenzene (TNCB), donor animals were killed and their lymph nodes excised. A single cell suspension was prepared from the sensitized lymphocytes contained within these nodes. An equal number of these cells and antigen-haptenized spleen cell targets were mixed in a small volume of media, and 10 μL injected into the right ear pinnae of mice that had been irradiated 2 or 8 months previously. The increment in ear swelling was measured with a micrometer 48 hours after injection, to minimize any degree of edema attributable to injection trauma. A parallel group of normal mice injected with sensitized effector lymphocytes and antigen served as a positive control. Animals that received only the same number of antigen-primed lymphocytes without antigen (in equivalent volume of medium) served as a negative control. The results of this experiment (Fig 5) demonstrated that the degree of ear swelling that could be elicited in both the irradiated and unirradiated groups was similar. The response was also shown to be antigen dependent, since animals that received only sensitized lymphocytes, but no antigen, did not develop ear swelling. The conclusion of these experiments is that irradiated skin is capable of responding to a local CHS stimulus with the same degree of edema as normal skin.

These experiments suggested that irradiation-induced depressions in CHS responsiveness were, in part, due to a decrease in the ability of effector lymphocytes to localize into the skin from the bloodstream. This possibility was experimentally tested by preparing a single cell suspension of DNFB-sensitized lymphocytes derived from normal mice. Proliferating cells within this suspension (presumably undergoing clonal expansion in response to antigen exposure) were labeled with ^{125}IUDR for two hours. Cells from this suspension (4 x 10^7 cells/recipient) were then infused IV into previously transplanted mice. These animals were immediately challenged with DNFB on the right ear. As in preceding adoptive transfer experiments, the increment in swelling was measured at 24 hours. The mice were subsequently killed and autopsied. Each ear (as well as other organs and carcass) were counted separately in a gamma counter to determine the percentage of the recovered radiolabel within the antigen-challenged ear site compared with the non-challenged ear. The results of this experiment (Table 2) confirmed the previously noted depression in the capacity to adoptively transfer CHS to previously irradiated recipients. The depression in edema generation was paralleled by a depression in the influx of radiolabeled lymphocytes into this site. Busulfan treated mice exhibited a depression in lymphocyte localization into the ear challenge site (and depressed CHS responsiveness) 1 month post-BMT. By 2 months, however, the ability of adoptively transferred effector lymphocytes to elicit edema and enter sites of antigen challenge was significantly better than their irradiated counterparts, and approached the response within normal age-matched (control) recipients.

DISCUSSION

The optimal preparative regimen for use in human BMT is a controversial issue, centered mainly around the marrow-

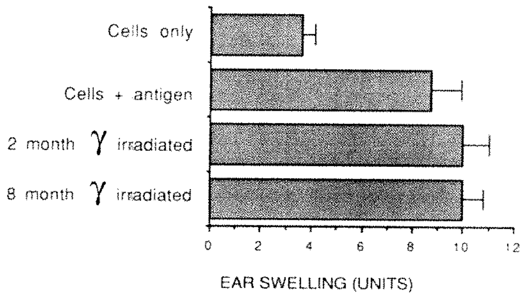

Fig 5. The assessment of CHS responses produced by coinjecting antigen and effector cells directly into the skin. TNBSO$_3$-haptenized normal spleen cells were produced by techniques described in the Materials and Methods section to serve as target cells. Normal mice were sensitized to 7% TNCB to provide an effector cell population. The peripheral lymph nodes of these mice were isolated and used to prepare a single cell suspension of effector lymphocytes. Both effector and target cells were suspended at 10^8 cells/mL, and mixed in a 1:1 ratio. A small volume (10 μL) of this combined cell suspension was injected into the right ear pinnae of irradiated recipients. The increment in right ear swelling (×10^{-4} inches) was measured at 48 hours to minimize any edema due to injection trauma. Similar injections into the ears of normal mice served to establish potential maximal edema generation by CHS effector cells in the presence of antigen. A group of mice that received an equivalent volume of media containing effector lymphocytes, but no antigen, served as a negative control.

Table 2. Localization of Adoptively Transferred CHS Effector Lymphocytes Into Cutaneous Sites of Antigen Deposition

Time Post-BMT	Ear Challenge	Ear Localization of Lymphocytes (%)	Ear Swelling (U)
Normal			
1 mo	+	3.2 ± 0.2	18.5 + 5.1
	−	0.1 ± 0.03

2 mo	+	2.2 ± 0.5	11.5 + 0.8
	−	0.5 ± 0.3	

Normal donor mice were sensitized on two sequential days with DNFB as described in the Materials and Methods section. A single cell suspension was prepared from the peripheral lymph node lymphocytes of these animals. The sensitized effector lymphocytes were labeled for two hours with 2 μCi [^{125}IUDR] per 5 × 10^7 cells, followed by extensive washes. Groups of experimental mice that had been transplanted 1 or 2 months previously using either the busulfan or irradiation protocols were infused with 4 × 10^7 of these cells per recipient. Each recipient was then immediately challenged with 10 μl DNFB applied to the right ear. After 24 hours, the increment in ear swelling, comparing the challenged *v* the unchallenged ear, was established with a micrometer. This measurement is expressed in units ± SEM (10^{-4} in). The mice were subsequently killed and autopsied, and their organs (including each ear, individually) and carcass counted in a gamma counter to determine the relative distribution of cells. The percentage of sensitized lymphocytes localizing to the challenged and nonchallenged ear is shown.

ablative capacity[41] and acute toxicity of busulfan or irradiation-based regimens.[1,2] The long-term sequellae of either preparative regimen are not yet fully known.[42] We raised the possibility that irradiation-based protocols might cause long-term effects of the microvasculature of irradiated/transplanted mice when we noted protracted atrophy of the peripheral lymph nodes in these animals.[29] Since 95% of the lymphocyte content of peripheral nodes enters this tissue from the bloodstream, our observation implied that the anatomy or function of the lymphocyte-receptive endothelium of the lymph nodes (HEV) was, in some way, affected by the preparative regimen.

Acute exposure of microvascular endothelial cells to low doses of radiation (4.5 to 7.5 Gy) has been shown to produce increased vascular permeability, vasodilation, and intimal swelling, particularly within the skin.[43,44] These changes are believed to be reversible. Radiation-induced vascular fibrosis and decreases in capillary density have not generally been observed with doses <20 to 40 Gy.[45] Our previous studies in mice established that exposure of the lymph node microvasculature to relatively low doses of gamma-irradiation (>7.5 Gy) caused significant anatomic changes. Endothelial cell edema and microvascular occlusions were observed within areas of lymphocyte-receptive endothelium (HEV), which persisted for more than 6 to 8 months post-BMT. These histologic findings correlated with a depressed capacity for normal lymphocytes to enter irradiated lymph nodes from the bloodstream.[29] Similar changes were found on examination of lymph nodes derived from irradiated human BMT recipients up to 1 year post-BMT.[29] The lesions in both murine and human BMT-recipients were histologically distinct from previously described radiation-induced microvascular lesions.[43-45]

The current investigation established that busulfan had little effect on lymphocyte recirculation and HEV anatomy in mice. While irradiation caused apparent endothelial cell proliferation, intracellular edema, and microvascular occlusions, busulfan did not affect the appearance of HEV structures. These anatomic changes correlated with a depression in the ability of lymphocytes to localize into the lymph nodes of irradiated, but not busulfan-treated mice.

Since lymph nodes are believed to be important sites for antigen recognition and amplification of immune responses,[23,27] we hypothesized that changes in lymphocyte localization into these organs following BMT would be accompanied by demonstrable depressions in immune function. We compared the effects of busulfan and irradiation on the reconstitution of CHS responsiveness in transplant recipients. CHS is believed to be an anatomically restricted (compartmentalized) immune response that involves a circuit that Streilein has termed the skin-associated lymphoid tissue (SALT).[39] Lymphocyte tissue localization is believed to be necessary for this response. During the afferent limb (ie, antigen sensitization), the continual migration of T cells into peripheral nodes contributes to foreign antigen recognition and the development and clonal expansion of CHS-effector cell populations.[40] The antigen-sensitized effector lymphocytes are also believed to gain the capacity to localize selectively from the blood into sites of antigen challenge in the skin.[39,40]

Our studies demonstrated that CHS responsiveness recovered more quickly in busulfan-treated mice than in irradiated animals. The cause of the depression of CHS responsiveness in irradiated animals is difficult to interpret, since one step or multiple steps in the antigen sensitization and effector phases of the response could be affected by irradiation. Subsequent experiments established that one of the mechanisms that may contribute to a diminished CHS response in irradiated animals was the depressed capacity of lymphocytes derived from normal donors to localize into irradiated skin sites. Since proliferating cells were labeled in these studies, our results may reflect an irradiation-induced depression in the skin localization of the CHS effector cells. It should be remembered, however, that recruited, nonantigen-sensitized lymphocytes contained in the adoptively transferred population may also contribute to the cellular influx into the skin. The role of each cell population in the generation of the CHS response is as yet not fully characterized. Our preliminary studies appear to indicate that the ability of the recruited (nonantigen-sensitized) lymphocyte population to enter the skin is also significantly depressed following irradiation (unpublished data). Locally injected effector cells, on the other hand, appear to have a normal capacity to elicit skin edema, and are unaffected by the prior irradiation. This appears to exclude the possibility that irradiation alters the ability of the skin itself to respond to cellular and soluble stimuli required to elicit the CHS response.

The capacity of normal CHS effector cells to migrate into the skin of busulfan-treated recipients was also depressed at early times post-BMT, perhaps due to a transient effect of the drug on lymphocyte receptive endothelium. Two months after BMT, the capacity of CHS effector cells to enter the skin of busulfan-treated mice had recovered, unlike their irradiated counterparts. The two preparative regimens, therefore, appear to exhibit differing effects on the interaction of circulating normal lymphocytes with the skin microvasculature. Whether this difference is due to alterations in lymphocyte binding to endothelial cells or anatomic occlusions of vessels (as in irradiated peripheral lymph nodes) remains to be established. These experiments have, for the first time, correlated the lymphocyte tissue localization process and the restoration of normal immune function post-BMT.

There have been a number of human BMT studies[13,46-48] that have attempted to define the recovery of contact hypersensitivity following tranplantation. This immune response appears to be depressed for years following human BMT.[3,4] The majority of these studies were based on limited numbers of patients.[46-48] These reports also do not distinguish between de novo induction of contact hypersensitivity and cellular "memory" responses to recall antigens.[46-48]

Witherspoon et al recently reported the results of skin testing in 332 allogeneic and twin transplants.[13] These investigators found that skin test responses to recall antigens remained depressed for up to 4 years following transplantation. The de novo induction of CHS to DNFB was also assessed. This response appeared to recover 2 years or more after transplantation. No differences could be detected in the percentage of responding patients or in the timecourse of

CHS recovery between twin and allogeneic transplant recipients. The presence of acute or chronic graft-v-host disease, however, was found to significantly depress the frequency of positive skin test responses. Patients prepared with total body irradiation alone were hyporesponsive to DNFB sensitization for a more protracted period following transplantation than were patients treated with cyclophosphamide alone (an alkylating agent).[13] Patients pretreated with a combination of the two agents (presumably with attenuated doses of both) responded more like the cyclophosphamide pretreated group.[13] The findings of Witherspoon et al appear to support our conclusion that alkylating agents may be less detrimental to the recovery of CHS responses than total body irradiation, but caution must be used in extrapolating between the two studies. Human BMT patients represent a more complex system than our syngeneic murine transplantation model, and Witherspoon's patients were treated with a different set of preparative regimens than we used (with potentially differing toxicities). Despite these differences, similar mechanisms may contribute to the irradiation-induced depression in CHS responsiveness observed within both studies.

Other mechanisms are also likely to contribute to the depressed CHS responses seen in transplant recipients. Delayed T cell precursor proliferation and maturation in the posttransplant period may depress cellular immune function.[3,4,7,9] Depressions in the function of irradiated thymic epithelium may contribute to the delayed reconstitution of functional T cell subsets in secondary lymphoid organs.[49] Reconstitution of the T cell repertoire may not necessarily be complete following BMT. Relative imbalances in the number and functional capacities of helper and suppressor T cells may also develop and result in dominant suppression of immune responses.[9,10]

It is attractive to speculate that irradiation-induced depression of lymphocyte migration into the peripheral lymph nodes also contributes to the depressed recognition of antigens applied to the skin (ie, the afferent phase of the immune response). It is difficult, however, to establish this point experimentally. A number of distinct intracellular, intercellular, and cytokine-mediated processes are required for effective antigen sensitization and clonal expansion of effector lymphocyte populations. Dissecting the various elements of the afferent phase from each other in vivo is not a simple task. Experiments designed to estimate the relative efficiency of CHS effector cell generation within the peripheral nodes of irradiated v busulfan-treated mice are now in progress. If the number of CHS-effector cells within the nodes of irradiated animals is depressed, further studies will be necessary to establish the responsible mechanism(s).

We have intentionally used a simplified syngeneic transplantation protocol to avoid any potential interference with immunologic reconstitution by graft-v-host disease. The analysis of the marrow-ablative and immunologic consequences of single agents has allowed the comparison of their relative effects on microvascular anatomy, lymphocyte localization potential, and eventual immune reconstitution. This experimental model could easily be adapted for the evaluation of more complex preparative regimens. Such studies appear to be necessary to more accurately duplicate human BMT protocols. Most preparative regimens used in human BMT involve multiple, potentially interacting agents, to achieve host bone marrow ablation. Furthermore, immunomodulatory drugs such as methotrexate, azathioprine, cyclosporine A, and corticosteroids are often administered to allogeneic BMT recipients to decrease the frequency of graft-v-host disease. Each of these agents has the potential to interfere with lymphocyte localization into tissue. We have already demonstrated that corticosteroids act on endothelial cells and reversibly impair the ability of normal lymphocytes to enter peripheral lymph nodes and the skin following their parenteral administration to mice. Corticosteroids additionally appear to block CHS-effector cell functions following in vitro treatment of lymphocytes.[50] Further investigation of the effects of BMT-preparative regimens on the immunologic reconstitution of the host may lead to effective marrow-ablative regimens that minimize alterations in the lymphocyte recirculation process and allow rapid recovery of the immune system following transplantation.

ACKNOWLEDGMENT

Helpful suggestions from Drs James P. Kushner and Raymond A. Daynes are sincerely appreciated.

Platelet-Activating Factor Both Stimulates and "Primes" Human Polymorphonuclear Leukocyte Actin Filament Assembly

By Meir Shalit, Guissou A. Dabiri, and Frederick S. Southwick

The phospholipid inflammatory mediator, platelet-activating factor (PAF), can stimulate polymorphonuclear leukocyte (PMN) chemotaxis. Conversion of cytoplasmic actin from monomers to filaments is associated with PMN motile functions. Using the fluorescent actin filament stain nitrobenzodiaxole phallicidin, we have investigated PAF's effects on human PMN actin polymerization. Concentrations of PAF between 1×10^{-11} to 1×10^{-6} mol/L induced actin filament (F-actin) assembly. An optimal concentration of PAF ($1\text{-}5 \times 10^{-8}$ mol/L) induced a significantly lower rise in relative F-actin content (1.72 ± 0.07 SEM) than an optimal concentration (5×10^{-7} mol/L) of the chemotactic peptide FMLP (2.21 ± 0.06). Unlike FMLP (F-actin content: 1.25 ± 0.04 at five seconds), PAF stimulation was associated with a delay of more than five seconds (1.04 ± 0.01 at five seconds) before an increase in F-actin could be detected. F-actin concentration reached maximum levels by 30 to 60 seconds. Prolonged stimulation (20 minutes) with PAF was associated with two phases of polymerization and depolymerization. Like FMLP, the initiation of actin filament assembly by PAF required receptor occupancy, this reaction being totally blocked by the PAF receptor inhibitor, SKI 63-441. As evidenced by the lack of inhibition by nordihydroguaiaretic acid (5 to 20 μmol/L), the production of leukotriene B_4 was not required for the PAF-induced changes in F-actin. Like FMLP, PAF's ability to stimulate PMN actin polymerization was inhibited by pertussis toxin (.05 to 2.5 μg/mL) but not impaired by the addition of EGTA and/or the calcium ionophore A23187. Preincubation with 1×10^{-11} to 1×10^{-8} mol/L PAF for 2 to 60 minutes enhanced the rise in F-actin content induced by low concentrations of FMLP (5×10^{-12} to 1×10^{-10} mol/L) indicating that this phospholipid was capable of "priming" the PMN actin polymerization response.

WHEN EXPOSED to a chemotactic gradient, polymorphonuclear leukocytes (PMNs) polarize and migrate. These motile functions require marked changes in the shape and consistency of the peripheral cytoplasm. Actin, the most abundant contractile protein found in the cytoplasm of PMNs, plays a critical role in controlling phagocyte motility.[1] This protein exists as 42,000 dalton monomers, G-actin, or can polymerize to form filaments, F-actin.[2] Actin filament formation could serve to increase the rigidity of the peripheral cytoplasm and mediate the shape changes associated with chemotaxis.[1,3] Unstimulated PMNs contain a high percentage of G-actin.[4,5] Stimulation with the synthetic chemotactic peptide f-met-leu-phe (FMLP) causes the rapid conversion of actin monomers to filaments.[4-10]

In addition to peptide chemotactic agents, such as FMLP, lipid inflammatory mediators such as platelet activating factor (PAF) may play an important role in activating PMN motility. This agent is synthesized and released by stimulated macrophages, platelets, and neutrophils.[11,12] In addition to being released, a high percentage of PAF synthesized by PMNs remains membrane bound.[13] PAF has been shown to induce PMN chemotaxis as well as degranulation and aggregation.[14,15] This agent has also been shown to induce PMN actin polymerization.[16-18]

We have used nitrobenzoxadiazole (NBD)-phallicidin, a fluorescent stain that binds specifically to F-actin[7,19] and flow cytometry to systematically examine the effects of this lipid chemotactic agent on neutrophil actin polymerization. We have found that stimulation with PAF, unlike FMLP, is associated with a five-second lag period before filament assembly begins. Prolonged exposure to this agent is associated with two phases of PMN actin polymerization and depolymerization. In addition to directly stimulating actin polymerization, PAF also can "prime" human PMNs, making the PMN actin polymerization response more sensitive to suboptimal concentrations of FMLP.

MATERIALS AND METHODS

Aprotonin, benzamidine, dimethyl sulfoxide (DMSO), EDTA, EGTA, FMLP, gelatin, HEPES, leupeptin, lysophosphatidyl choline, phenylmethyl-sulfonyl fluoride (PMSF), and triton X-100 were purchased from Sigma Chemical Company, St Louis. L-α-phosphatidylcholine, β-acetyl-γ-O-alkyl (PAF), DL-α-lysophosphatidyl choline, γ-O-hexadecyl (lyso-PAF), A23187 were obtained from Cal-Biochem, San Diego. Bovine serum albumin was purchased from Reheis Chemical Company, Phoenix; pertussis toxin from List Biological Laboratory, Campbell, CA. Nitrobenzoxadiazole-phallacidin was obtained from Molecular Probes, Junction City, OR. The PAF antagonist SRI 63-441 was kindly supplied by C.W. Winslow of Sandoz, Hanover, NJ.

A modified Hank's buffer (138 mmol/L NaCl, 6 mmol/L KCl, 1.2 mmol/L $MgSO_4$, 5 mmol/L $NaHCO_3$, 0.64 mmol/L Na_2HPO_4 (pH 7.4), 0.66 mmol/L KH_2PO_4, 5.6 mmol/L glucose, 20 mmol/L HEPES) was used in all assays. $CaCl_2$, final concentration of 1 mmol/L, was added to cell suspensions ten minutes before cell stimulation unless otherwise noted in the text.

FMLP and A23187 (final concentrations 10 mmol/L) were dissolved in DMSO and kept frozen at −70°C until used. PAF and lyso-PAF were dissolved in modified Hank's solution containing

Blood, Vol 70, No 6 (December), 1987: pp 1921-1927

0.25% BSA (final concentration 10 mmol/L) and stored at −70°C. Just before addition to cells, the stock solutions were diluted in modified Hank's solution. BSA could not be used in our experiments since this protein quenched NBD-phallacidin fluorescence. The PAF antagonist SRI 63-441 was dissolved in modified Hank's solution just before use.

Preparation of neutrophils. Six milliliters of venous blood were drawn from normal human volunteers into syringes containing 0.4 mL of 10% EDTA. RBCs were removed by hypotonic lysis, followed by centrifugation at 400 g for five minutes. Cells were resuspended in modified Hank's buffer and centrifuged at 400 g for five minutes. This procedure was repeated once and cells resuspended in modified Hank's to achieve a final concentration of 1.5×10^6 cells/mL. These preparations contained a mixture on average of 83 ± 1.4% (SEM) PMNs, 11 ± 1.7% lymphs and 5.1 ± 0.8% monocytes as determined by Wright stain (nine determinations). Platelets were not seen in any of our preparations. This method was developed to minimize handling of cells and reduce the likelihood of inadvertent PMN activation prior to chemotactic stimulation. On several occasions PMNs were purified by Ficoll/Hypaque which yielded >95% PMNs. Unstimulated F-actin content of PMNs tended to be higher in these preparations; however, the relative increase in PMN F-actin induced by PAF was comparable to cells purified by our other method. Cells were maintained at room temperature unless otherwise noted. All experiments were performed within three hours of venipuncture.

Neutrophil stimulation and fixation. Cell suspensions, 0.5 mL aliquots, (0.75×10^6 cells per sample) were preincubated for seven minutes at 25°C. Various concentrations of stimulants or antagonist, 0.5 mL, were added to each sample. The reaction was stopped by addition of 0.1 mL of 37% formaldehyde. Cells were incubated in fixative for 15 minutes at 25°C before staining.

NBD-Phallacidin staining. Staining was performed according to the method of Howard and Oresajo.[9] Briefly, 50 μL of modified Hank's buffer containing 3.46×10^{-6} mol/L NBD-phallacidin and 2.1 mg/mL lysophosphatidyl-choline were added to the fixed cell preparations, mixed and incubated for ten minutes at 37°C. Cells were then centrifuged at 12,000 g for one minute, supernatants removed, and pellets resuspended in 1.5 mL of modified Hank's solution.

Quantification of F-actin content by flow cytometry. Stained cells were filtered through nylon mesh and analyzed within two hours of staining in most cases. We have found that stained samples could be stored at 4°C in Hank's buffer for 16 hours without detectable differences in F-actin content as compared with the samples analyzed immediately after staining. The intracellular fluorescence was determined by an Ortho Spectrum III (Ortho Diagnostic Systems, Westwood, MA) flow cytometer equipped with an argon laser (488 emission, 500 mW output). Using the combination of low angle forward light scatter and 90° angle light scatter, lymphocytes, monocytes, remaining erythrocytes, and debris were excluded from analysis by appropriate gating. All intensities of cellular fluorescence were recorded on the linear scale ranging from 0 to 255 channels. Fluorescent histograms plotting cell number (vertical axis) *v* fluorescence channel (horizontal axis) were recorded for each sample. In all instances histograms yielded a normal distribution (the peak fluorescence channel corresponded to the mean fluorescence). An average of 5,000 to 10,000 PMNs were analyzed per sample. Relative PMN F-actin content was expressed as the ratio of mean fluorescence intensity of stimulated cells to mean fluorescence intensity of neutrophils in buffer. Unstimulated values were comparable when cells were incubated in modified Hank's buffer or 0.01% DMSO (the highest concentrations used in our experiments) in modified Hank's buffer.

Triton-insoluble cytoskeleton associated actin. A modification of the method described by White et al[6] was used. Human PMNs were purified by Ficoll/Hypaque and then suspended in modified Hank's buffer, centrifuged at 400 g and resuspended in the same buffer to achieve a final concentration of 1.5×10^7 cells per mL. Highly purified preparations of PMNs were required for this assay, since unlike FACS analysis that allows exclusive measurement of PMNs, the Triton-insoluble assay measures shifts in F-actin content of all cells in the solution. Five hundred microliters of the cell suspension was added to 55 μL of FMLP or PAF solution. The reaction was stopped by the addition of 65 μL of triton-stop solution containing 10% triton X-100, 7.5 mg% benzamidine, 4 mg% aprotinin, 1 mg% leupeptin, 1 mmol/L PMSF, 54 mmol/L Pipes, 22.5 mmol/L HEPES, 9 mmol/L EGTA, 1.8 mmol/L $MgCl_2$.

After mixing by two gentle inversions, the solution was allowed to sit for two minutes at 25°C, and then centrifuged for two minutes at 12,000 g in an Eppendorf table top centrifuge. The resulting pellet (the triton-insoluble fraction) was then solubilized in 100 μL of gel sample buffer containing 8 mol/L urea, 1 g% sodium dodecyl sulfate, 2 g% β-mercaptoethanol, 10 g% sucrose, 0.06 mol/L Tris-HCl, pH 6.8. The sample was next sonicated for 20 to 30 seconds using a Branson sonifier, model 200 with a tapered micro tip (Danbury, CT), output 3. Samples were then immediately boiled for five minutes and electrophoresed into 5% to 15% polyacrylamide slab gels. Triton-insoluble cytoskeleton-associated actin was quantified as previously described.

Statistics. The statistical significance of differences between means was determined using Student's *t* test.

RESULTS

The effects of varying concentrations of PAF on PMN F-actin content. Figure 1 demonstrates the effect of varying PAF concentration on neutrophil actin polymerization. A wide range of PAF concentrations 10^{-11} to 10^{-6} mol/L caused an increase in neutrophil F-actin content. A maximal relative F-actin concentration was observed at concentrations of 1-5 × 10^{-8} mol/L PAF. Above this concentration range a moderate decrease in F-actin content was observed.

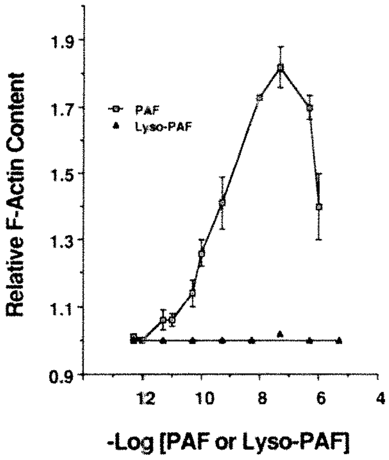

Fig 1. F-actin content as a function of PAF and Lyso-PAF concentration. 7.5×10^5 PMNs (similar numbers of cells were used for all experiments) were exposed to increasing concentrations of PAF or lyso-PAF for 60 seconds at 25°C. Cells were then fixed with 3.7% formalin, lysed, stained, and analyzed by FACS for relative F-actin content. The points represent the mean ± SEM of four to eight trials on separate days. Higher lyso-PAF concentrations (5×10^{-8}-5×10^{-6} mol/L) represent the mean of three determinations, lower concentrations represent values from one experiment.

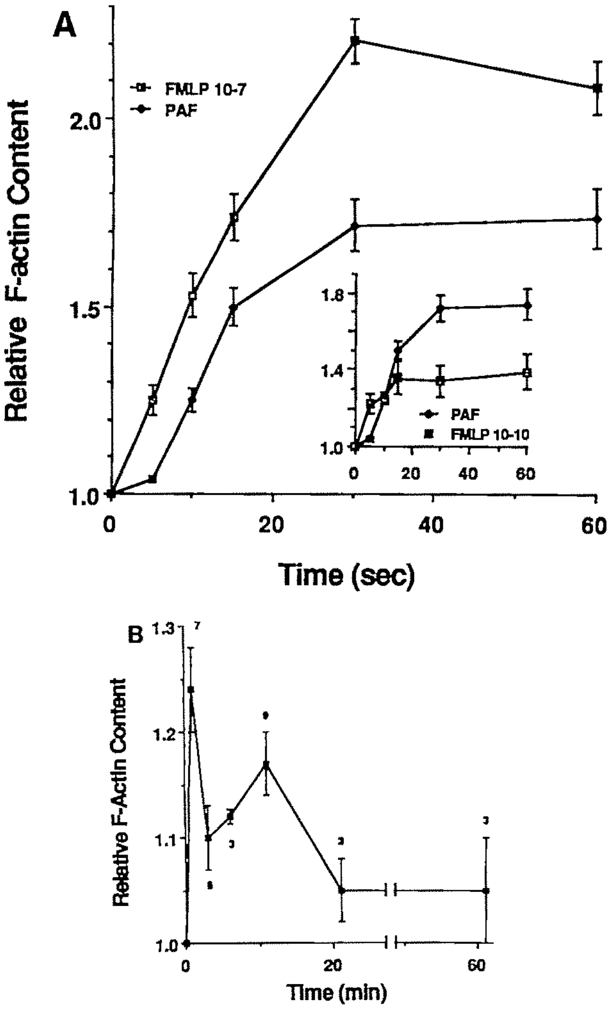

Fig 2. (A) Early time course of the changes in relative F-actin content in human PMNs exposed to optimal concentrations of PAF and FMLP. PMNs were exposed to 1 × 10^{-8} mol/L PAF (closed diamonds) or 5 × 10^{-7} mol/L FMLP (open squares) at time = 0 sec, at 25°C. At the indicated times cells were analyzed as described in Fig. 1. The points plotted represent the mean ± SEM of 13 (FMLP) and 8 (PAF) trials determined on separate days. Note the difference in F-actin content after five seconds stimulation with the two stimuli (FMLP 1.25 ± 0.04 *v* PAF 1.04 ± .01). This difference was statistically significant, ($P < .001$). Actin filament concentrations were also measured after five minutes stimulation with PAF and FMLP (respective values: 1.34 ± 0.05 and 1.74 ± 0.08 SEM, five determinations). Inset: F-actin content of PMNs stimulated with 1 × 10^{-10} mol/L FMLP (open squares) compared with PMNs stimulated with 1 × 10^{-8} mol/L PAF (closed diamonds). Note that after five seconds stimulation with this lower concentration of FMLP, F-actin content (1.22 ± 0.02 SEM, three determinations) was also significantly higher than after five seconds' stimulation with an optimal concentration of PAF ($P < .001$). (B) The effects of prolonged exposure of PAF on PMN actin filament content. PMNs were incubated at 25°C with 1 × 10^{-10} mol/L PAF and F-actin content measured at the times indicated. Bars represent the SEM, the numbers above the bars, the number of separate determinations.

Stimulation with the PAF analog lyso-PAF at concentrations of 5 × 10^{-13} to 5 × 10^{-6} mol/L failed to stimulate neutrophil actin assembly.

The kinetics of actin filament assembly following PAF stimulation. As shown in Fig 2A, exposure of human PMNs to an optimal concentration of PAF (1 × 10^{-8} mol/L) for various time periods resulted in a rise in F-actin content that reached a maximum value by 30 seconds. PAF's effects on PMN actin polymerization were delayed as compared with FMLP. After a five-second exposure to PAF there was no significant rise in F-actin content (F-actin content 1.04 ± .01 SEM, eight experiments) while FMLP (5 × 10^{-7} mol/L) induced a substantial increase in F-actin during the same period (relative F-actin concentration 1.25 ± 0.04 SEM, 13 experiments). Use of higher concentrations of PAF, up to 5 × 10^{-7} mol/L failed to shorten this delay period (five seconds; F-actin content, 1.03). Concentrations of PAF of 10^{-6} mol/L or higher could not be used, since as observed by other investigators,[20] these concentrations were associated with cell lysis. Addition of a low concentration of FMLP, 1 × 10^{-10} mol/L, was not associated with a delay in actin filament assembly. The initial rise in F-actin content after five seconds, 1.22 ± .05 SEM (three determinations), was nearly identical to that induced by 5 × 10^{-7} mol/L FMLP (Fig 2A inset).

Although the onset of actin filament formation was delayed, once this reaction began, the actin filament assembly rate associated with PAF was comparable to FMLP (4.4% increase in F-actin content/s *v* 4.8%/s for FMLP), and maximum F-actin concentrations were observed after a 30-second exposure to either stimulus. The peak concentration of F-actin induced by PAF was considerably lower than that induced by an optimal concentration of FMLP (1.72 ± 0.07, 10 experiments *v* 2.21 ± 0.06, 13 experiments). At each time point, F-actin content was significantly lower following PAF stimulation as compared with FMLP ($P < .05$). F-actin content following 30 seconds stimulation with optimal concentrations of the two agents was also measured using the triton-insoluble-cytoskeleton assay.[6] By this method PAF was also shown to induce a smaller rise in F-actin content as compared with FMLP (relative F-actin content: 1.6 *v* 2.0).

F-actin content rapidly decreased when PMNs were exposed to PAF for greater than one minute, reaching a nadir between 2 and 6 minutes, then actin filament concentration again increased reaching a second peak after approximately ten minutes. This reaction was followed by a second decline in F-actin content. Figure 2B shows the effects of prolonged exposure to 1 × 10^{-10} mol/L PAF; similar kinetics were observed when PMNs were exposed to 1 × 10^{-8} mol/L PAF for extended periods.

Effects of a PAF receptor antagonist (SRI 63-441), pertussis toxin, and NDGA on PAF-induced PMN actin filament assembly. The PAF receptor inhibitor (SRI 63-441) blocked neutrophil actin filament assembly induced by PAF, complete inhibition being observed at 1 × 10^{-6} mol/L, 50% inhibition at 1 × 10^{-7} mol/L, and no inhibition at 1 × 10^{-8} mol/L (Fig 3).

The role of G proteins in mediating PAF-induced actin

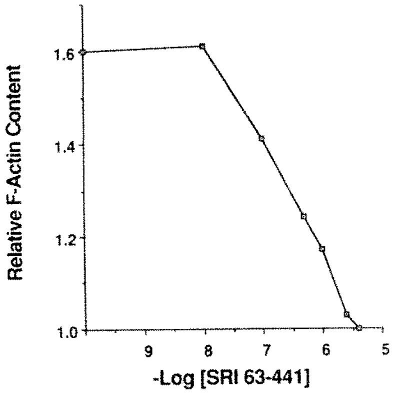

Fig 3. The effects of the PAF receptor antagonist SRI 63-441 on PAF stimulation of PMN actin polymerization. PAF 1 × 10^{-8} mol/L, was added simultaneously with varying concentrations of SRI 63-441. Samples were fixed, lysed, and stained after incubation at 25°C for 60 seconds. Values represent the mean of two determinations performed on separate days. The far left hand value (1.6) represents the F-actin content of PMNs stimulated in buffer.

filament assembly was examined using pertussis toxin. As observed with FMLP, incubation of cells for 90 minutes with 400 ng/mL of this agent caused a 50% to 60% inhibition of PAF-induced neutrophil actin assembly. Incubation with the same concentration of pertussis toxin for two hours resulted in 80% inhibition of both the PAF-and FMLP-induced rise in F-actin concentration. Higher concentrations of pertussis toxin (2.5 μg/mL) also resulted in marked inhibition of FMLP- and PAF-induced actin polymerization (Fig 4).

It has been suggested by some investigators that PAF activates PMNs by inducing endogenous production of leukotriene B_4.[21,22] To investigate whether production of this agent might be responsible for PMN actin polymerization, cells were preincubated with the lipoxogenase inhibitor, nordihydroguaiaretic acid (NDGA) before stimulation. Preincubation with 5, 10, and 20 μmol/L NDGA for five minutes at 37°C (concentrations previously shown to cause near total inhibition of leukotriene production by PAF[21-23]) failed to significantly inhibit the rise in F-actin content induced by PAF. A higher concentration (50 μmol/L) of this reagent inhibited both FMLP and PAF stimulation of actin polymerization and was associated with blebbing of the PMN peripheral cytoplasm, suggesting a more generalized toxic effect.

The effects of EGTA and the ionophore A23187 on PAF- and FMLP-induced neutrophil actin filament assembly. To assess the calcium requirement of PAF-induced neutrophil actin assembly, EGTA and the calcium ionophore A23187 were added to the incubation media. As shown in Fig 5, EGTA in the presence or absence of A23187 failed to inhibit PAF's effects on actin filament assembly. Addition of 1 mmol/L EGTA to the media also failed to inhibit the second rise in F-actin content observed after 20 minutes' exposure to PAF (Fig 2B). Similarly FMLP-stimulated PMN actin filament formation was not inhibited by addition of EGTA and/or A23187 to the buffer. In an additional experiment not depicted in Fig 5, PMNs were preincubated with EGTA for 20 minutes followed by exposure to A23187 for four rather than two minutes to further deplete intracellular calcium stores. This condition also failed to inhibit PAF- and FMLP-induced rises in F-actin content. Values were comparable to those depicted in column d of Fig 5. As observed by other investigators,[24] A23187 in the presence or absence of EGTA caused moderate increases in F-actin concentration (1.33 ± 0.14 and 1.59 ± 0.06, respectively, after two minutes exposure, three determinations). A23187 alone, however, had no significant effect on

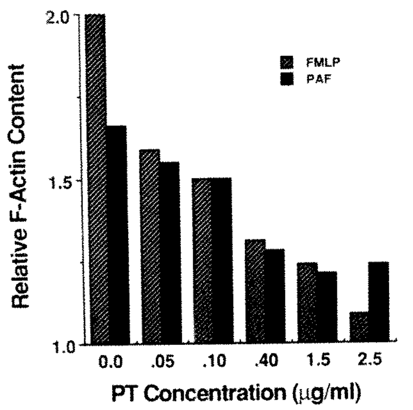

Fig 4. The effects of pertussis toxin (PT), on PAF and FMLP stimulation of PMN actin polymerization. PMNs were incubated with increasing concentrations of PT for 90 minutes at 37°C. Cells after being washed once in buffer were stimulated with PAF 1 × 10^{-8} mol/L or FMLP 5 × 10^{-7} mol/L for 60 seconds.

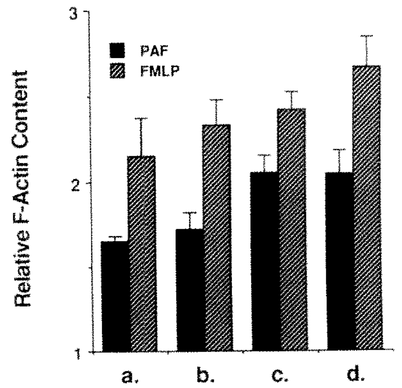

Fig 5. The effects of EGTA and the calcium ionophore A23187 on PAF and FMLP stimulation of PMN actin polymerization. PMNs were incubated at 25°C (a) in buffer containing 1 mmol/L CaC_2, (b) in buffer containing 1 mmol/L $CaCl_2$ and 5 × 10^{-7} mol/L A23187 for two minutes, (c) in buffer without added calcium plus 1 mmol/L EGTA for 20 minutes, or (d) in EGTA buffer for 20 minutes followed by the addition of A23187 for two minutes. PMNs were then stimulated with 2.5 × 10^{-8} mol/L PAF or 5 × 10^{-7} mol/L FMLP for 60 seconds at 25°C. Samples were analyzed as described in Fig 1. Values represent the mean ± SEM of experiments performed on three different days. The differences in F-actin content induced by PAF or FMLP under these four conditions were not statistically significant, with the exception of condition (d). The FMLP induced rise in F-actin content was significantly higher under these conditions when compared with PMNs stimulated with FMLP in buffer (a)(P = .014).

Table 1. Percent Increase in Relative F-Actin Content After 60 Second Stimulation With Various Concentrations of PAF or FMLP Alone and in Combination

[FMLP] (mol/L)	10^{-8}	10^{-9}	10^{-10}	10^{-11}	None
[PAF] (mol/L)					
10^{-8}	117 ± 23 (2)	—	98	—	70 ± 10 (2)
5×10^{-10}	—	108	—	—	62
$5\text{-}10 \times 10^{-11}$	—	81 ± 14 (2)	52 ± 11 (4)	—	28 ± 3 (6)
$1\text{-}10 \times 10^{-12}$	—	31	37 ± 21 (4)	21 ± 9 (3)	3 ± 1 (8)
None	119 ± 11 (2)	36 ± 5 (4)	11 ± 3 (9)	9 ± 3 (3)	0 (17)

PAF and FMLP were added simultaneously to 7.5×10^6 PMNs and cells fixed after 60 seconds. F-actin content was measured as described in Fig 1 and Materials and Methods. Numbers in parentheses represent the number of separate determinations. Values are percentages ± SEM.

PAF- or FMLP-induced neutrophil actin polymerization (Fig 5, column b).

Combined stimulation with PAF and FMLP As shown in Table 1, when PMNs were exposed to low concentrations of PAF and FMLP simultaneously, the F-actin content increased to levels higher than that induced by either stimulus alone. The resulting rise in F-actin content was generally equivalent to or above the sum of the rise in F-actin content induced by the individual chemotactic stimuli. This additive effect was seen when concentrations of FMLP of 7.5×10^{-10} to 1×10^{-11} mol/L were combined with 1×10^{-8} to 1×10^{-12} mol/L concentrations of PAF. Use of optimal concentrations of FMLP as well as PAF failed to stimulate increases in F-actin content above that induced by FMLP alone.

Preincubation of PMNs with PAF (1×10^{-10} mol/L) for 2, 5, 10, 20, and 60 minutes also enhanced F-actin production in response to a low concentration of FMLP (5×10^{-10} mol/L). At each time point the rise in F-actin was greater than the sum of the two individual stimuli (data not shown). As shown in Table 2, preincubation of PMNs with varying concentrations of PAF (1×10^{-11} to 1×10^{-8} mol/L) for 60 minutes resulted in an enhanced F-actin response to low concentrations of FMLP (5×10^{-12} to 1×10^{-10} mol/L). F-actin content was 20% to 200% greater than the sum of rises in F-actin content induced by the individual stimuli. Monocyte contamination did not appear to play a role in PAF "priming," since PAF preincubation of PMNs purified by Ficoll/Hypaque resulted in comparably greater than additive responses to low concentrations of FMLP (data not shown). Preincubation of PMNs with FMLP (5×10^{-11} to 5×10^{-10} mol/L), rather than PAF, for 60 minutes followed by addition of a higher concentration of FMLP for 60 seconds (1×10^{-10} to 1×10^{-9} mol/L) was associated with a less than additive rise in F-actin content in all instances (Table 3). The combined stimulus resulted in an F-actin content that was 10% to 62% below the sum of the individual stimuli.

DISCUSSION

Human and rabbit PMNs rapidly increase their F-actin content after being stimulated with FMLP. Under optimal conditions this chemotactic stimulus increases F-actin content by approximately twofold within 30 seconds. Other agents have also been shown to stimulate PMN actin polymerization including leukotriene B_4, phorbol myristate acetate, and arachidonic acid.[16] PAF has also been shown by the triton-insoluble cytoskeleton assay to induce a rise in the F-actin content of rabbit PMNs.[16,17] The fluorescent F-actin stain, NBD-phallicidin, has recently been used to measure F-actin content in PMNs.[7] Using this assay we have systematically compared the individual effects of PAF and FMLP on human PMN actin filament assembly and have also investigated how these two agents in combination may affect in vivo PMN actin polymerization. The NBD-phallicidin assay makes possible careful kinetic analysis of PMN actin filament formation and also allows reproducible quantitation of relative F-actin concentration.[9] These investigations have demonstrated several differences between FMLP and PAF.

First, on examining the kinetics of the PAF-induced rise in F-actin content, we found a brief but reproducible lag period of five seconds between the time of stimulation and the initial increase in F-actin content. This delay in actin polymerization was not observed after stimulation with FMLP even

Table 2. Percent Increase in Relative F-Actin Content After 60 Minutes Stimulation With Varying Concentrations of PAF Alone, After 60 Seconds Stimulation With Varying Concentrations of FMLP Alone and After 60 Minutes Stimulation With PAF Followed by 60 Seconds Stimulation With FMLP

[FMLP] (mol/L)	10^{-10}	5×10^{-11}	5×10^{-12}	None
[PAF] (mol/L)				
10^{-8}	54 ± 8 (+50)	42 ± 1 (+27)	24 ± 2 (+20)	18 ± 1
10^{-9}	44 ± 5 (+38)	37 ± 3 (+28)	38 ± 4 (+138)	14 ± 2
10^{-10}	35 ± 5 (+35)	31 ± 3 (+35)	30 ± 8 (+200)	8 ± 3
10^{-11}	39 ± 9 (+95)	30 ± 2 (+76)	11 ± 1 (+175)	2 ± 2
None	18 ± 4	15 ± 3	2 ± 1	

Numbers in parentheses represent the percent rise above the sum of the two individual stimuli: % F-actin content above additive = 100 × [F-actin content of PMN receiving combined stimuli − (F-actin content of PMN stimulated with FMLP × 60 + F-actin content after PAF × 60 min)]/(F-actin content after FMLP + F-actin content after PAF). Values are percentages ± SEM of three to seven separate determinations.

Table 3. Percent Increase in Relative F-Actin Content After 60 Minutes Stimulation With Varying Concentrations of FMLP Alone, After 60 Seconds Stimulation With Varying Concentrations of FMLP Alone and After 60 Minutes Stimulation with FMLP Followed by 60 Seconds Stimulation With a Second Higher Concentration of FMLP

[FMLP] (mol/L; 60 sec)	10^{-9}	5×10^{-10}	1×10^{-10}	None
[FMLP] (mol/L; 60 min)				
5×10^{-10}	66 (−31)	—	—	38
1×10^{-10}	61 (−12)	47 ± 9* (−10)	—	11 ± 2
5×10^{-11}	57 (−20)	31 ± 7 (−42)	13 ± 6 (−62)	13
None	58	41 ± 2	21 ± 7	

Numbers in parentheses represents the % below the sum of the two individual stimuli: % F-actin content below additive = 100 × [F-actin content of PMN receiving combined stimuli − (F-actin content of PMN stimulated with FMLP × 60 s + F-actin content after PAF × 60 min)]/(F-actin content after FMLP + F-actin content after PAF).

*Values are percentages ± SEM of three separate determinations; other experiments represent the mean of two separate determinations.

when low concentrations of FMLP were used to stimulate actin filament assembly. Stimulation with higher concentrations of PAF did not shorten the time of initial actin filament assembly, therefore a delay in binding of PAF to PMN membrane receptors seemed an unlikely explanation for our findings. Such a lag period might be present if PAF's effects on actin filament assembly were mediated by the production of a second compound, such as leukotriene B_4. However, preincubation of PMNs with the lipoxegenase inhibitor, nordihydroguaiaretic acid (NDGA), a condition that should block leukotriene production,[21-23] did not affect PAF-induced actin polymerization. When human PMNs bind PAF they rapidly metabolize this agent.[25] We cannot exclude the possibility that the observed lag period represents the time required to metabolize PAF to a more active byproduct.

Not only the early kinetics of polymerization, but also the time course of depolymerization may differ from FMLP. Prolonged incubation with PAF was associated with two phases of polymerization and depolymerization. The initial rapid rise in F-actin content was followed by a decrease in F-actin over the ensuing two to six minutes. Depolymerization was then followed by a moderate second rise in F-actin content that in turn was followed by a second depolymerization phase. With the exception of Sklar et al,[10] who observed two phases of polymerization and depolymerization during the first two minutes of oligopeptide stimulation, other investigators have described a single abrupt rise in F-actin content followed by a single phase of depolymerization following FMLP stimulation.[6,9] The cause of this second rise in F-actin content is not clear, but could be the result of PMN aggregation or the production of second mediator that in turn induces a second actin polymerization reaction.

There are also a number of similarities between these two chemotactic agents. Receptor inhibitor studies indicate that PAF, like FMLP, requires receptor occupancy to induce PMN actin polymerization.[10] The marked inhibitory effects of pertussis toxin on human PMNs suggest that as observed in rabbit PMNs,[24] both chemotactic agents require functioning G-proteins[26] to stimulate actin polymerization.

Neither PAF nor FMLP required extracellular calcium to induce increases in F-actin concentration. This finding suggests that the large influx of ionized calcium generally associated with PAF[24,27] and FMLP[28] stimulation is not required for actin filament assembly. The effects of combined treatment of PMNs with EGTA and A23187 are complex and variable; therefore, no firm conclusions can be drawn from our experiments concerning the importance of intracellular calcium in mediating PAF- and FMLP-induced actin filament assembly. These experiments do suggest that these two classes of chemotactic agent may function similarly, since this treatment failed to inhibit actin filament assembly induced by either reagent.

In addition to acting directly to induce neutrophil aggregation, degranulation, superoxide production, chemotaxis, and actin polymerization, PAF can regulate neutrophil responses to other stimuli. PAF can desensitize the PMN aggregation response to leukotriene B_4.[21] When combined with opsonized zymosan, PAF induces an additive rise in superoxide production.[29] When combined with FMLP, PAF synergistically enhances the oxidative response. Maximum enhancement is observed when optimal oxidative concentrations of both chemotactic agents are used (10^{-7} mol/L FMLP and 10^{-8} mol/L PAF).[30]

Our studies demonstrated that PAF also is able to modulate PMN actin responsiveness to FMLP. However, unlike the oxidative response, PAF only enhanced the effect of suboptimal FMLP concentrations. Simultaneous addition of or preincubation for up to 60 minutes with PAF caused an enhanced response to FMLP. Particularly after prolonged preincubation with PAF, the combined effect of these two chemotactic agents on F-actin content was consistently greater than the sum of the effects of two individual stimuli. Preincubation with FMLP followed by exposure to a second higher concentration of FMLP, on the other hand, resulted in a less than additive response. These findings suggest as observed for oxidative metabolism, that PAF may act as a "priming" stimulus[31] for FMLP. Although these two chemotactic agents bind to separate receptors, they may have common intermediate biochemical pathways serving to induce PMN actin filament assembly. PAF could serve to activate one or more proteins responsible for this reaction, a condition that might augment PMN actin assembly in response to a second stimulus. It is also possible that PAF stimulation may increase the number and/or affinity of FMLP receptors.

Understanding how these two chemotactic agents affect actin filament assembly alone and in combination are of importance in understanding the in vivo inflammatory response, since both of these chemotactic agents may be present in inflammatory exhudates and PAF may be synthesized and retained on the membrane surface of stimulated PMNs.[13] The present findings suggest that the lipid chemotactic agent, PAF, not only can induce PMN actin filament assembly, but may also serve to make the PMN actin response more sensitive to low concentrations of peptide chemotactic agents like FMLP.

ACKNOWLEDGMENT

We would like to thank Sally Zigmond for her many helpful suggestions and Burton Zweiman for generously allowing us to use his FACS.

Cytogenetic Studies and In Vitro Colony Growth in Patients With Mastocytosis

By Birgitta Swolin, Stig Rödjer, and Gösta Roupe

Cytogenetic analysis of bone marrow cells and in vitro growth for bone marrow granulocytic-macrophage stem cells have been performed in 13 patients with mastocytosis, six with systemic mastocytosis, and seven with urticaria pigmentosa. Clones with chromosome abnormalities were found in five patients. The number of clusters and/or colonies after seven days in culture was increased in seven patients, compared with the growth in a control group. Three patients with chromosome abnormalities showed an abnormal growth pattern, yet exhibited normal peripheral blood values. Two patients with systemic mastocytosis had clones with chromosome abnormalities and some abnormal hematological values. The proportion of patients with chromosome abnormalities and an abnormal growth pattern was higher among these patients with mastocytosis than in healthy control subjects. These results may be of interest when discussing the origin of mast cell disorders and indicate an association with the myeloproliferative disorders.

MASTOCYTOSIS is a rare disorder with manifestations either in the skin, as urticaria pigmentosa, or as a generalized form, systemic mastocytosis, or even as mast cell leukemia. Anemia, leukocytosis, thrombocytopenia, or eosinophilia may be present.[1] An increased number of mast cells in the bone marrow and lesions with varying numbers of lymphocytes, eosinophils together with mast cells, may be found.[2]

Certain patients with mastocytosis can initially be diagnosed as having or may later develop a myeloproliferative disorder.[3,4] Many patients with myeloproliferative diseases have chromosome abnormalities in bone marrow cells[5]; however, cytogenetic analysis has been reported in only a few cases with mastocytosis and normal karyotypes were then observed.[4,6,7] The in vitro colony-forming capacity of bone marrow granulocytic-macrophage stem cells can also show an abnormal growth pattern in myeloproliferative disorders. Animal cell culture studies indicate that the mast cell may be of bone marrow origin.[8] Due to these findings it would be of interest to investigate patients with mastocytosis with techniques that have revealed abnormalities in the myeloproliferative disorders. This paper reports on cytogenetic studies and bone marrow colony growth in 13 patients with mast cell disease. To our knowledge, no systematic studies have previously been carried out.

MATERIAL AND METHODS

Patients. Thirteen adult patients (median age 40 years) with mastocytosis participated, after informed consent, in the present study. Clinical data are presented in Table 1. The six patients (four males, two females) with systemic mastocytosis were 30 to 69 years of age (median 58 years) with a disease duration varying from 2 to 27 years (median 5.5 years). The age ranged between 19 and 60 years (median 28 years) for the seven patients (two males, five females) with urticaria pigmentosa and was lower than for patients with systemic mastocytosis. The disease duration was also shorter varying from 1 to 5 years (median 3 years).

The diagnosis of the skin disease was based on clinical criteria for urticaria pigmentosa, ie, multiple reddish-brown maculae that urticate after rubbing. The extension of the skin disease was calculated from the number of macular skin lesions, which was estimated as small, moderate, or large. The severity of the pruritus was estimated by each patient. None of the patients had a history of flush attacks, headache, or decreasing BP.

The clinical diagnosis was confirmed in all the patients by histological examination of punch biopsies from hyperpigmented macular spots from the abdominal skin. The diagnosis of systemic mastocytosis was based on direct demonstration of an increased number of mast cells in the bone marrow section and an increase in the urinary excretion of methylimidazole acetic acid.[2] Patient no. 6 with systemic mastocytosis had an increased number of mast cells in the bone marrow but normal excretion of methylimidazole acetic acid in urine. Splenomegaly was found in three patients (Table 1).

Control group. For comparison, the in vitro bone marrow colony growth capacity for granulocytic-macrophage stemcells was studied in nine subjects (seven males and two females) aged 23 to 70 years with a median age of 39 years, after informed consent. These healthy subjects had normal peripheral blood values and bone marrow morphology.

Sampling procedure. Bone marrow (1 to 2 mL) from the sternum or iliac crest was aspirated. The cells were suspended in 3 mL McCoy's medium (Flow Laboratories) containing 125 IU heparin (Kabi Vitrum) for colony growth and the marrow was suspended in 6 mL McCoy's medium for cytogenetic analysis.

The assay of colony formation was measured by using a two-layered semisolid, agar culture system described by Pike and Robinson.[13] Placenta extract was used as source of the colony-stimulating factor, according to Burgess et al,[14] instead of using mononuclear cells in the feeder layer. The top layer was seeded with 1×10^5 mononuclear cells per milliliter per dish. The cells were isolated on Isopaque-Ficoll. The cultures were incubated at 37°C, in a humified atmosphere of 5% CO_2 in air. Four dishes for each culture were used as for unstimulated controls, the mean value was given. After seven and ten days the dishes were examined with an inverted microscope. Aggregates of more than 40 cells were defined as colonies, 21 to 40 cells as macroclusters, and three to 20 cells as microclusters.[15] Under these conditions the highest value for colonies was attained on day 10 and the colony growth reached a plateau in the amount of placenta extract used. Growth was linear for up to ten times the cell concentration used. The reproducibility was good and tested from two sequential cultures in six subjects.

In the last six patients examined, the dishes were fixed and stained with May-Grünwald-Giemsa to evaluate the morphology of the

*Scintigraphic examination of the spleen was performed according to Larsson and Nelp in 1966.[9] Reference value <81 cm^2.[10]

†See Ridell et al.[2] The upper limit of mast cells for reference subjects is 71/mm^2.

‡U-MeImAA (urine methylimidazole acetic acid) was measured by high performance liquid chromatography as described by Granerus,[11] Granerus and Wass.[12] Reference values – 1.2 to 3.8 mg/24 h.

cells. The enumerated colonies and clusters included neutrophils, macrophages, eosinophils, and mast cells, as determined by the morphological appearance with this staining.

Chromosomes from bone marrow cells were prepared with conventional techniques. When no evaluable metaphases could be obtained in direct preparations, marrow cells were also studied after 48 hours in culture. G- and Q-banding was used.[16,17] Chromosome identification and karyotypes were classified in accordance with the International System for Human Cytogenetic Nomenclature,[18] ie, a clone was defined as at least two cells with the same numerical and/or structural abnormality.

Routine laboratory techniques were used for the determination of peripheral blood parameters. Plasma cobalamines (B_{12}) and folates concentrations were assayed with microbiological techniques.

RESULTS

The laboratory results are presented in Table 2. The hemoglobin concentration was normal in all patients except two (cases no. 1 and 2) with systemic mastocytosis (Table 2). The leukocyte counts were normal in all patients. Differential leukocyte count showed no significant abnormality; however, slight eosinophilia was found in patients no. 2 and 3. Patient no. 1 exhibited an increased platelet number, while all other patients had normal levels. All patients had serum iron and total iron binding capacity within reference values. Patients no. 1 and 2 exhibited an increased plasma B_{12} concentration and none of the patients had been given drugs containing B_{12}. Plasma and blood folates levels were normal in all patients.

The cytogenetic analysis of the bone marrow cells revealed clones with chromosome abnormalities in five patients (Table 3, Fig 1). Clones were present only to a minor extent, except in patient no. 8, and were revealed in three patients after a 48-hour culture. The type of abnormality was 5q−, 9p+, 11q−, +13 and −16, +mar in each patient. In patient no. 1 a loss of one no. 16 was seen and it cannot be excluded that the marker derives from no. 16. We regard the deletions in patients no. 2 and 6 as interstitial deletions. Patient no. 8 had some extra unidentified material on the short arm of

chromosome No. 9, which did not seem to be a pericentric inversion, however C banding was not performed. The extra G chromosome in patient no. 9 bore the closest resemblance to a no. 22. The other eight patients exhibited normal karyotypes. All patients had a normal karyotype in phytohemagglutinin stimulated peripheral blood cells.

Patients no. 1 and 2 with an abnormal karyotype had both anemia and elevated plasma B_{12}-concentrations.

The colony growth capacity in all the patients examined showed a median value of 356 (range 140 to 1,029) on day 7 for microclusters, 220 (range 13 to 343) for macroclusters, and 75 (range 0 to 438) for colonies (Table 3). On day 10, the median value was 80 for colonies (range 4 to 242). No obvious difference could be observed between the patients with systemic mastocytosis and those with urticaria pigmentosa. In comparison with the control group the number of colonies was nearly twice as numerous while the cluster counts were of the same order of magnitude. The largest number of clusters was reached after a seven-day culture. An increased number of clusters was found in patients no. 4, 6, 8, and 13. The number of colonies reached a peak after seven days of culture for seven patients, four of whom showed an increased number in comparison with the control group. Six patients had a larger number of colonies on day 10, but all had values within the reference values. Only patient no. 11 had defective colony growth.

The morphology in May-Grünwald-Giemsa stained clusters and colonies could be evaluated in patients no. 1, 3, 4, 7, 9, and 13. All patients exhibited cells with features similar to mast cells, especially with regard to the cell size and the

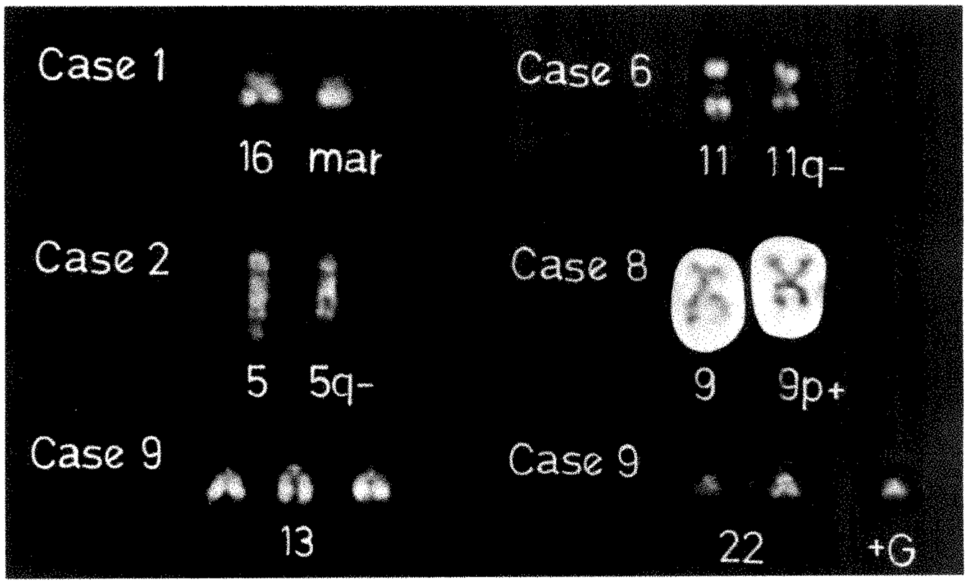

Fig 1. Bone marrow chromosomes, pairs with abnormalities in patients no. 1, 2, 6, 8, and 9.

heavy content of basophilic granules; however, further evaluation is necessary. Three of the five patients with chromosome abnormalities showed an abnormal in vitro growth pattern for granulocytic-macrophage stem cells.

DISCUSSION

Disorders with mast cell proliferation include a wide variety of manifestations, from benign infiltration of the skin, urticaria pigmentosa, to the malignant course seen in mast cell leukemia.[19] An intriguing connection between both myelo- and lymphoproliferative disorders has been discussed in case reports.[3,4]

This is the first report on a small series of patients with mastocytosis investigated by cytogenetic analysis. Chromosome abnormalities in bone marrow cells were found in 36% of the patients, which is a higher proportion than in healthy subjects.[5,20] In myeloproliferative disorders the incidence of abnormalities varies from 85% in patients with chronic granulocytic leukemia with the Ph^1 chromosome to ~15% in patients with polycythemia vera close to the diagnosis.[5,20,21] Some patients with chronic myeloid leukemia develop basophilia, and in a series[22] of patients with chronic myeloid leukemia the chromosome abnormality iso(17q) in addition to the Ph^1 abnormality, was related to high values of basophils. This abnormality, however, was not found in the present series of patients with mastocytosis. The abnormalities 5q− and 11q− found in two patients are also common abnormalities in myeloid disorders and in myelodysplastic syndromes.[23,24]

In seven patients, the in vitro colony growth pattern of bone marrow cells showed an increased number of clusters and/or colonies similar to findings recently reported by Denburg et al.[25] They found an increased number of colony-forming units in peripheral blood from patients with systemic mastocytosis. This pattern is more like the pattern found in chronic myeloid leukemia,[26] than that found in myelodysplastic syndrome with defective or no colony forming capacity.[15,27] An increased number of histamine positive granulocytic colonies from blood has been found in patients with systemic mastocytosis and chronic myeloid leukemia.[28] It would have been desirable to identify the cell type that contained the chromosome abnormalities. However, techniques for such identification were not available to us.

The occurrence of chromosome aberrations or increased growth capacity was similar in patients with urticaria pigmentosa and systemic mastocytosis. There was no obvious relationship between the cytogenetic results and the colony growth seen in this small series. However, three patients had both an abnormal karyotype and abnormal growth capacity, yet they still exhibited normal peripheral blood values.

All the patients with urticaria pigmentosa had normal hemoglobin, leukocyte, and platelet concentrations, as has been described in earlier reports.[1] In the group with systemic mastocytosis, one patient had anemia and thrombocytosis, and another had anemia and eosinophilia. These findings are in agreement with those in the reports on larger numbers of patients.[1,29] These two patients also had clones with chromosome abnormalities, as well as an increased plasma B_{12} concentration, a common finding in myeloproliferative disorders.

Bone marrow cells from our patients with mastocytosis showed chromosome aberrations and an abnormal in vitro colony growth similar to findings in myeloproliferative disorders and thus supports the idea of an association between these disorders. The hypothesis that mast cells derive from a hematopoietic origin is supported by observations obtained with bone marrow mast cells, grown in long-term culture from a patient with mastocytosis.[7] An increased number of bone marrow mast cells has been reported in preleukemic syndromes.[30] Experimental data suggest that the production of granulocyte-macrophage colony stimulating factor can be activated in tumorigenic mast cell lines derived from Abelson murine leukemia virus-transformed hematopoietic cells.[31] This observation may be one of the possibilities to explain the increased growth capacity seen in some of our patients.

We intend to follow-up this group of patients with repeated examinations, both with regard to their cytogenetic evolution and their colony growth pattern. The preliminary observation, in particular that mast cells grow from the bone marrow of patients both with systemic mastocytosis and urticaria pigmentosa, needs to be confirmed with other methods.

Rearrangement of the T Cell Receptor γ-Chain Gene in Childhood Acute Lymphoblastic Leukemia

By Akio Tawa, Stephen H. Benedict, Junichi Hara, Nobumichi Hozumi, and Erwin W. Gelfand

We analyzed rearrangements of the T cell receptor γ-chain (T_γ) gene as well as rearrangements of the T cell receptor β-chain (T_β) gene and immunoglobulin heavy-chain (IgH) gene in 68 children with acute lymphoblastic leukemia (ALL). All 15 patients with T cell ALL showed rearrangements of both T_β and T_γ genes. Twenty-four of 53 non-T, non-B ALL patients (45%) showed T_γ gene rearrangements and only 14 of these also showed T_β gene rearrangements. Only a single patient rearranged the T_β gene in the absence of T_γ gene rearrangement. The rearrangement patterns of the T_γ gene in non-T, non-B ALL were quite different from those observed in T cell ALL, as 20 of 23 patients retained at least one germline band of the T_γ gene. In contrast, all T cell ALL patients showed no retention of germline bands. These data indicate that rearrangement of the T_γ gene is not specific for T cell ALL. Further, the results also suggest that T_γ gene rearrangement precedes T_β gene rearrangement. The combined analysis of rearrangement patterns of IgH, T_β, and T_γ genes provides new criteria for defining the cellular origin of leukemic cells and for further delineation of leukemia cell heterogeneity.

HUMAN LYMPHOCYTES characteristically express distinct surface antigens and on this basis childhood acute lymphoblastic leukemia (ALL) has been subdivided into three major groups: T cell ALL, B cell ALL and non-T, non-B ALL based on the failure to express either T cell associated antigens, including the sheep erythrocyte receptor or surface immunoglobulin.[1] Reactivities with several antibodies associated with cells of B lineage suggested that most non-T, non-B ALL are B cell in origin; this has been confirmed by studying rearrangements of immunoglobulin genes.[2-6] Molecular cloning of the gene encoding the T cell receptor β-chain (T_β)[7] has more recently provided additional opportunities to study lineage commitment at the DNA level.[8-10]

On the basis of such studies, doubt has been cast on the lineage specificity of Ig heavy chain (IgH) gene rearrangements for B cells[11-13] and the specificity of T_β gene rearrangements in T cells.[10,14-16] Although exceptions to the rule are rare, there are nevertheless several descriptions of IgH gene rearrangement in T cell malignancies[11,13] and acute myelogenous leukemia.[12,17] Perhaps more striking was our finding that in 39 patients with non-T, non-B ALL who had rearranged IgH genes, ten had rearrangement of the T_β gene as well.[15]

Lymphoblastic leukemia is regarded as a monoclonal expansion of lymphocytes at specific stages of differentiation. The analyses of Ig and T_β gene rearrangements have offered new information about normal lymphocyte differentiation.[2,3,14,15,18,19] Recently, two groups isolated cDNA clones for the human T cell receptor γ-chain (T_γ) gene and demonstrated T_γ gene rearrangements in T cell lines and T cell malignancies.[20-22] Some data suggest that T_γ genes are rearranged and transcribed in the very early stage of T cell differentiation before T_β genes,[23-25] and T_γ transcripts have only been found in cytotoxic T cells.[24,26] Waldmann et al[10] reported that clonal T cells had rearranged T_γ genes, whereas the B cell populations, including those with T_β gene rearrangement, did not have rearrangement of this gene complex. To determine the lineage specificity of T_γ gene rearrangements, we analyzed leukemic cells from 15 patients with T cell ALL and 53 patients with non-T, non-B ALL derived from cells of B lineage. We examined the relationship between surface antigen expression and, IgH, T_β, and T_γ gene rearrangements, in order to determine whether the T_γ gene undergoes rearrangement before T_β gene rearrangement and to define specific rearrangement patterns in T cell and non-T, non-B ALL.

METHODS

Bone marrow cells. Bone marrow samples were obtained at the time of diagnosis and before initiation of treatment. Cell morphology was examined by Wright-Giemsa staining and cytochemistry. The percentage of leukemic cells in bone marrow samples was >85%. Mononuclear cells were separated by Ficoll-Hypaque gradient centrifugation. Analysis of cell surface markers using a panel of monoclonal antibodies, sheep erythrocyte-rosette formation and surface and cytoplasmic immunoglobulin were carried out as described previously.[4,27,28]

DNA preparation and Southern blot analysis. High molecular weight DNA was extracted from the mononuclear cells of each patient. DNA was digested with the restriction endonucleases *Eco*RI or *Bam*HI. Digested DNA was size-fractionated by agarose-gel electrophoresis and transferred to nitrocellulose filters. The filters were hybridized to nick-translated or randomly primed ^{32}P-labeled probes.[29]

Gene probes. The human IgH gene probe was an *Eco*RI fragment that contained the constant region of μ ($C\mu$, 1.3 kb *Eco*RI fragment). The $C\mu$ probe identified a 19 kb *Bam*HI fragment[4] in germline DNA. A *Bgl*II-*Eco*RV fragment of the T_β cDNA clone YT-35 was used as a T_β constant region gene probe ($C\beta$, 0.8 kb *Bgl*II-*Eco*RV fragment). The $C\beta$ probe detected a germline 24 kb *Bam*HI fragment containing both β1 and β2 and 11 kb and 4 kb *Eco*RI fragments containing β1 and β2, respectively.[15] These probes

have been described elsewhere.[4,15] The T_γ constant region probe was a *Pst*I-*Bam*HI genomic fragment (0.3 kb) containing DNA located 5′ to the *Bam*HI restriction site in exon 1 of the $C\gamma 1$ gene and hybridizing to both $C\gamma 1$ and $C\gamma 2$ (Fig 1). With *Eco*RI, the $C\gamma$ probe recognizes 5.4 kb ($C\gamma 1$) and 7 kb ($C\gamma 2$) germline bands. Using *Bam*HI, the $C\gamma$ probe recognizes 21 kb and 15 kb for $C\gamma 1$ and $C\gamma 2$, respectively. The $J\gamma$ probe was a *Hind*III-*Eco*RI genomic fragment (0.7 kb). The $J\gamma$ probe recognizes $J\gamma 1.3$ and $J\gamma 2.3$[30] fragments of 1.8 kb and 3.3 kb, respectively with *Eco*RI, and 21 kb and 15 kb, respectively, with *Bam*HI. The $C\gamma$ and the $J\gamma$ probes recognized identical *Bam*HI fragments.[20-22] $C\mu$ germline clones were kindly provided by Drs T.H. Rabbitts and G. Matthyssens,[31] YT-35 by Dr T.W. Mak,[7] the $C\gamma$ probe by Dr J.G. Seidman,[21] and the $J\gamma$ probe by Dr T.H. Rabbitts.[20]

There are at least five joining segment genes ($J\gamma 1.1$, $J\gamma 1.2$, $J\gamma 1.3$, $J\gamma 2.1$, and $J\gamma 2.3$) and two constant region genes ($C\gamma 1$ and $C\gamma 2$) in the human germline $T\gamma$ genome.[20-22] Following *Eco*RI digestion, the $C\gamma$ probe can recognize only the deletion of germline bands but can not detect a change of fragment size accompanying $T\gamma$ gene rearrangement, since as shown in Fig 1, there are *Eco*RI restriction sites between $J\gamma 1.3$ and $C\gamma 1$ as well as between $J\gamma 2.3$ and $C\gamma 2$.[21,22] For this reason, estimates of non-germline configuration were confirmed using the $J\gamma$ probe.

RESULTS

We analyzed surface markers and DNA from cells of 68 patients with ALL. Fifteen of 68 patients were diagnosed as having T cell ALL and the remaining 53 were classified as non-T, non-B ALL, based on studies using a panel of monoclonal antibodies, E-rosette formation, and staining for cytoplasmic and surface immunoglobulin. Among the 53 patients classified as non-T, non-B ALL, three groups could be distinguished: CALLA-negative–ALL, 6 patients; CALLA-positive–ALL, 35 patients; and cytoplasmic μ-chain–positive pre-B ALL, 12 patients.

T cell ALL. Thirteen of the 15 T cell ALL patients demonstrated the normal germline configuration of the IgH gene; two patients had rearrangements of one allele and a germline configuration of the other, as described previously.[32] Following *Bam*HI and *Eco*RI digestion, all 15 DNA samples had rearrangements of the T_β gene: nine patients had rearrangements of both alleles, and in six patients one allele was rearranged and the other deleted. Results of these studies are summarized in Table 1.

Figure 2 shows the patterns of T_γ gene rearrangements in these 15 patients. Using the $C\gamma$ probe, DNA samples from all T cell ALL patients were analyzed after *Eco*RI restriction endonuclease digestion. The normal germline configuration is shown in lane G (Fig 2A) as a 5.4 kb ($C\gamma 1$) band and a 7 kb ($C\gamma 2$) band. None of the T cell ALL patients retained germline configuration of both alleles. The majority of patients (12 of 15) demonstrated deletion of the 5.4 kb band and retention of the 7.0 kb band (lane 1). In three of 15 patients, the intensity of the 5.4 kb band was sufficiently lower than the 7.0 kb band (lane 2) to suggest deletion of one of the 5.4 kb bands. This was confirmed by densitometry of patient compared with control samples. Because the $C\gamma$ probe can recognize only deletions using *Eco*RI, 11 of the patients were reevaluated using the $J\gamma$ probe with *Eco*RI. Results with the $J\gamma$ probe were entirely consistent with the $C\gamma$ results. That is, samples that showed deletion of $\gamma 1$ with the $C\gamma$ probe showed no γ_1 germline with the $J\gamma$ probe and the number of rearranged bands identified by the $J\gamma$ probe was the same as seen with a *Bam*HI cut and the $C\gamma$ probe. Two (patients no. 11 and 15) of the three patients showing single allele deletion of γ_1 with the $C\gamma$ probe and *Eco*RI were re-examined with the $J\gamma$ probe. Both patients showed retention of germline band and a single rearranged band presumably γ_2.

Following *Bam*HI digestion of normal cell DNA and hybridization with the $C\gamma$ probe, the germline configuration consists of two bands, 21 kb and 15 kb (Fig 2B, lane G). In each of 12 T cell ALL samples digested with *Bam*HI, one of three patterns demonstrated in Fig 2B was observed and the rearrangement patterns are summarized in Table 1. Lane 1 (Fig 2B) shows one rearranged band; one patient had this pattern. Eight patients had two rearranged bands (lane 2), and three patients (patients no. 3, 11, and 15) had three rearranged bands (lane 3). An *Eco*RI cut probed with the $J\gamma$ probe showed a singe rearranged $\gamma 2$ band in these patients. Analysis of the T_β locus also did not show three non-germline bands. The observation of three non-germline bands using *Bam*HI and the $C\gamma$ probe is therefore of interest. Extra

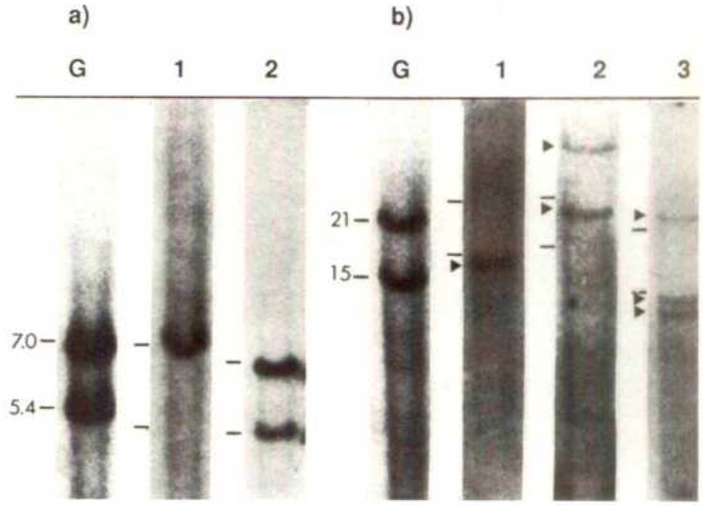

Fig 2. The rearrangement patterns of T_γ gene in T cell ALL patients (identified in Table 1). (A) *Eco*RI digestion. Lane G shows the germline control, lane 1 the sample from patient no. 4, and lane 2 the sample from patient no. 15. (B) *Bam*HI digestion. Lane G shows the germline control, lane 1 the sample from patient no. 10, lane 2 the sample from patient no. 4, and lane 3 the sample from patient no. 15. The germline positions obtained on the same gel with control DNA are indicated by lines and rearranged bands are indicated by arrows on the gels. The gels are not aligned because the studies were carried out at different times. Blots were probed with the Cγ probe.

bands of this nature usually suggest polymorphism of the DNA, clonal evolution of the leukemia, or that the leukemic cells had an abnormal karyotype. Karyotypic analysis was not available for these patients. Since *Eco*RI separates Jγ1.3 and Jγ2.3 from the other Jγ loci,[30] it is possible that Jγ1.1, Jγ1.2, Jγ2.1, or some as yet described Jγ locus was involved in the non-germline band detected by *Bam*HI.

Non-T, non-B ALL. All 53 DNA samples from patients in the non-T, non-B ALL group showed rearrangements of the IgH gene. Fifteen of 53 DNA samples showed rearrangement of the T_β gene following *Bam*HI and *Eco*RI digestion. We analyzed 39 patients' DNA for Tγ gene rearrangement after both *Eco*RI and *Bam*HI digestion, ten after only *Bam*HI digestion, and four after *Eco*RI digestion using the Cγ probe. The rearrangement patterns following *Eco*RI digestion are shown in Fig 3A. Of the 43 samples analyzed, 30 demonstrated germline configuration (Fig 3A, lane G). Three patients showed complete deletion of the 5.4 kb band (lane 1), whereas in eight patients a 5.4 kb band of decreased intensity relative to control was detected (lane 2) suggesting deletion of one of the 5.4 kb bands. In two patients a third pattern not observed in T-ALL was demonstrated consisting of a 7.0 kb band of decreased intensity compared with that of the 5.4 kb band (lane 3), suggesting deletion of one of the 7.0 kb Cγ2 bands. Such a deletion might suggest chromosomal abnormality.

Figure 3B shows the patterns of T_γ gene rearrangement after *Bam*HI digestion. Twenty-six of 49 samples analyzed retained the germline configuration (Fig 3B, lane G). In the remaining 23 patients, six different patterns of rearrangement were observed. Two patients had a single rearranged band (lane 1) and one patient showed two rearranged bands without germline bands (lane 2). Four patients manifested two rearranged bands with a 15 kb Cγ2 germline band (lane 3). As illustrated for the patients in lanes 1 through 3, the rearranged band in each case was ∼18 kb. Five patients demonstrated one rearranged band accompanied by both 21 kb and 15 kb germline bands (lane 4). Ten patients had one

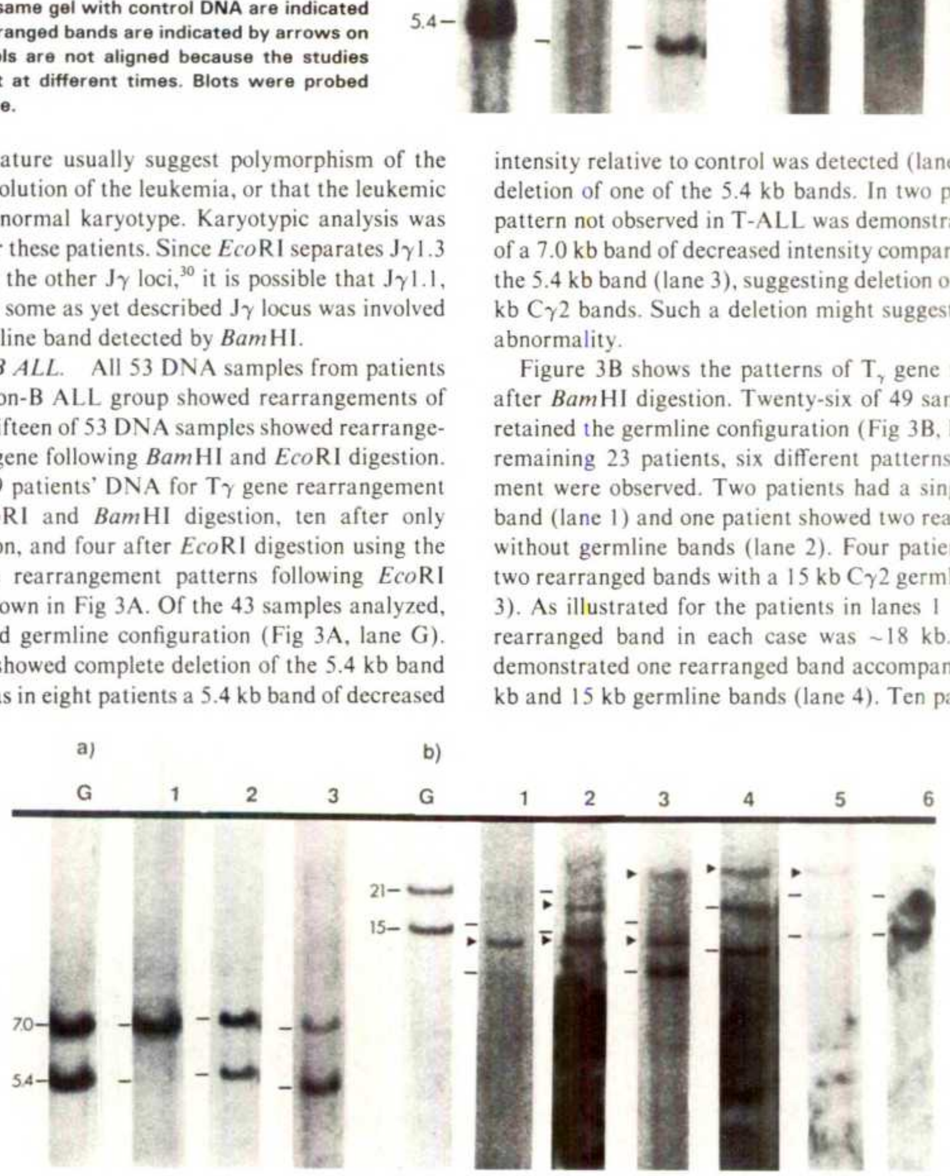

Fig 3. The rearrangement patterns of T_γ gene in non-T, non-B ALL patients (identified in Table 2). (A) *Eco*RI digestion. Lane G shows germline configuration and represents the sample from patient no. 35, lane 1 from patient no. 26, lane 2 from patient no. 38, and lane 3 from patient no. 33. (B) *Bam*HI digestion. Lane G shows germline configuration and represents the sample from patient no. 40 (not shown in Table 2), lane 1 from patient no. 25, lane 2 from patient no. 27, lane 3 from patient no. 20, lane 4 from patient no. 35, lane 5 from patient no. 19, and lane 6 from patient no. 18. The germline positions obtained on the same gel with control DNA are indicated by lines and rearranged bands are indicated by arrows on the gels. The gels are not aligned because the studies were carried out at different times. Blots were probed with the Cγ probe.

rearranged and one germline band (lane 5). Only one patient had the pattern shown in lane 6, namely, one 15 kb Cγ2 germline band with deletion of the 21 kb Cγ1 band. DNA samples from 27 patients were hybridized with the Jγ probe following *Bam*HI digestion. Identical results were obtained.

Overall (Table 2), we observed T_γ gene rearrangement in 24 of 53 (45%) non-T, non-B ALL patients. Twelve (of 39) samples showed non-germline configuration of the T_γ gene after both *Eco*RI and *Bam*HI digestion. In eight patients who manifested a rearranged band following *Bam*HI digestion, there was a germline configuration following *Eco*RI digestion (indicating rearrangement in Cγ1). One patient (of four) analyzed following only *Eco*RI digestion and two (of ten) patients following only *Bam*HI digestion showed T_γ genes in a non-germline configuration. Following *Bam*HI digestion, the germline bands identified by the Cγ probe are quite large and this size could mask small rearrangements. For this reason, *Eco*RI cuts of 27 cases were probed with the Jγ probe.[30] No additional rearrangements were found. Twelve patients that were germline using the Cγ probe for *Eco*RI and *Bam*HI cuts were re-examined with the Jγ probe and found to be germline (not shown). Fifteen patients (designated in Table 2) who were found to be rearranged with *Bam*HI and/or deleted using *Eco*RI and the Cγ probe were re-examined with the Jγ probe. In 13 of these cases, the same number of rearranged bands seen with *Bam*HI and the Cγ probe was observed with *Eco*RI and the Jγ probe thus confirming the results in Table 2. Figure 4 presents representative results of these studies. Using *Eco*RI and Cγ probe, patient 27 was found (Table 2) to have deleted both γ_1 alleles and using *Bam*HI, two rearranged bands were observed, presumably γ_2. In Fig 4, lane 1, these results were confirmed using *Eco*RI and the Jγ probe; two rearranged bands were observed. Faint germline bands were contributed by contaminating nonleukemic cells. Patient no. 36 was found (Fig 3, Table 2) to have deleted a single γ_1 allele using the Cγ probe and *Eco*RI, and to have two rearranged bands (presumably one γ_1 and one γ_2) using *Bam*HI. In lane 2 of Fig 4, patient no. 36 had two rearranged bands and a γ_2 band retained, the same as with *Bam*HI. Patient no. 39 was not previously examined with the Cγ probe and *Eco*RI. However, using the Cγ probe and *Bam*HI we observed γ_1 and γ_2 in germline and one rearranged band (Table 2). These results were confirmed (Fig 4, lane 3) using the Jγ probe and *Eco*RI. In two patients (patients no. 21 and 35) with *Bam*HI rearrangements, no rearrangement was seen using the Jγ or Cγ to probe an *Eco*RI cut. This suggests usage of Jγ1.1, Jγ1.2,[31] or unknown Jγ1 loci that may be located upstream of Jγ1.3.[30]

Of the 24 patients with T_γ gene rearrangement, 14 (26%) also showed rearrangements of the T_β gene. Among the 29 patients who showed a germline configuration of the T_γ gene, 28 were also in germline for the T_β gene. There was one

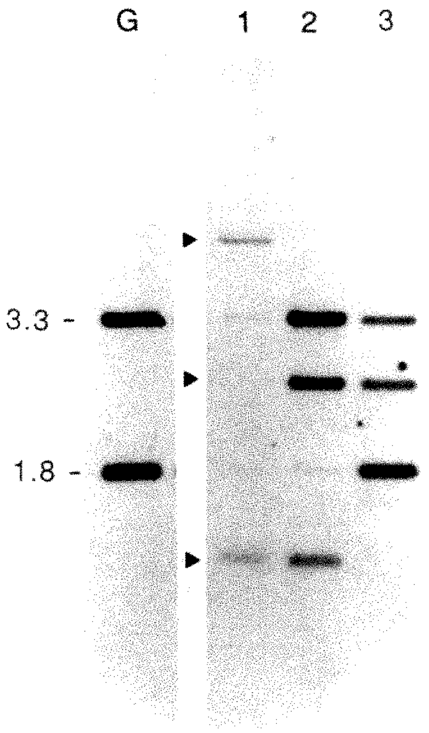

Fig 4. Rearrangement patterns of the T_γ gene examined with the Jγ probe in non-T, non-B ALL. DNA was digested with *Eco*RI and blots probed with the Jγ probe. Lane G shows the germline bands of 3.3 Kb (γ_2) and 1.8 Kb (γ_1). Representative patients presented were patient no. 27 (lane 1), patient no. 36 (lane 2), and patient no. 39 (lane 3).

patient, a single exception, who demonstrated a rearrangement of one allele and deletion of the other allele of the T_β gene, but with retention of the germline configuration of the T_γ gene after both *Eco*RI and *Bam*HI digestion. The patterns of T_β and T_γ gene rearrangement in this patient were identical when DNA was studied both at the time of diagnosis and several months later at the time of relapse.

DISCUSSION

We analyzed leukemic cell DNA from 68 children with lymphoblastic leukemia for IgH, T_β, and T_γ gene rearrangement. All 15 patients with T cell ALL showed rearrangements of both the T_γ and T_β genes. Thus, as reported previously for T_β gene rearrangements in T cell ALL,[8-10] T_γ gene rearrangements are also characteristic for T lineage cells. The patterns of rearrangement did not correlate with any particular pattern of T cell antigen expression. However, just as rearrangements of the T_β gene are not restricted to cells of T lineage,[10,14-16] we now show that rearrangement of the T_γ gene is similarly not restricted to cells of T lineage.[33] In the present study, 38% of the 68 patients examined with ALL had both IgH and T_γ gene rearrangement and 24% had both IgH and T_β gene rearrangements.

Three separate studies have shown that 8% to 11% of lymphoid malignancies demonstrate both IgH and T_β gene rearrangement.[10,14-16] This combination of immunoglobulin and T cell receptor gene rearrangement may be a result of neoplastic transformation or may occur during normal lymphocyte differentiation. Several studies reporting IgH gene rearrangement and expression in mouse thymocytes and lymphocytes[34,35] suggest that this combined gene rearrangement may occur in normal cells. In this case, the combined gene rearrangement may reflect common molecular mechanisms leading to immunoglobulin and T cell receptor gene rearrangement. This concept is consistent with the observation that immunoglobulin heavy and light chain gene segments and T cell receptor β gene and γ gene segments have similar recombination recognition sequences,[36-42] and with the evidence[43] indicating that both B and T cells use a common recombinase system in the mouse. If this concept applies to human lymphoid tumors, a common recombinase may lead to rearrangement of both immunoglobulin and T cell receptor genes in lymphoid malignancies.

There are two constant region genes (Cγ1 and Cγ2) in the human germline T cell receptor γ-chain genome.[20-21] Based on recent studies,[20-22,42] constant region probes recognize 5.4 kb and 7.0 kb *Eco*RI germline fragments containing Cγ1 and Cγ2, respectively and also identify 21 kb and 15 kb *Bam*HI germline fragments containing Cγ1 and Cγ2, respectively. In 15 T cell ALL patients, 12 had no 5.4 kb *Eco*RI fragment containing Cγ1, and the other three probably had only one Cγ1 allele, judged by the intensity of the 5.4 kb band. Moreover, all T cell ALL samples digested with *Bam*HI did not contain any of the two germline fragments containing Cγ1 and Cγ2. These results suggest that in the majority of T cell ALL, T_γ genes have undergone rearrangement to the γ^2 gene of both alleles. Quertermous et al reported that most T cell malignancies showed biallelic Cγ1 deletion with *Eco*RI digestion and had no germline band hybridized to a J region probe with *Eco*RI digestion.[22] Our results are consistent with these findings.

Surprisingly, 45% of non-T, non-B ALL patients rearranged the T_γ gene and similar to our previous study, 26% rearranged the T_β gene.[15] Among the 24 non-T, non-B ALL patients with T_γ gene rearrangement, only three (patients no. 25, 26, and 27) showed the same rearrangement patterns as those observed in T cell ALL. The other patients retained a 15 kb germline band containing Cγ2 with *Bam*HI digestion and five patients (patients no. 21, 32, 34, 35, and 39) had two germline bands indicating at least one allele in germline configuration. The intensity of the germline band argued against the possibility of its being due to contamination by normal cells. In addition, 17 of 20 patients had no residual germline bands of IgH or T_β genes. Our data and those of others[22] suggest that biallelic γ^2 rearrangement is characteristic for T cell ALL and retention of germline γ^2 is the rule in non-T, non-B ALL.

Most B lineage malignancies have both IgH gene alleles rearranged[2,6] and almost all T lineage cell malignancies show biallelic T_β gene rearrangement.[9,10,16] In contrast, B lineage malignancies with rearrangement of both alleles of the T_β gene, or T lineage cell malignancies with rearrangement of both alleles of the IgH gene are rare; in most cases, there is one residual germline allele of the IgH or T_β gene.[11,13,15,16,32] The rearrangement patterns for these three genes in our 68 patients are summarized in Table 3. These data indicate the difficulty in assigning lineage based solely on the rearrangement pattern of a single gene. As illustrated in Table 3, the further examination of three rearranging genes indicate the complex heterogeneity of childhood ALL.

Some reports have suggested that the rearrangement and transcription of T_γ, T_β, and T cell receptor α chain genes during T cell ontogeny is sequential.[23-25,44-46] To determine whether T_γ gene rearrangement precedes T_β gene rearrangement, we analyzed the relationship between T_γ and T_β gene rearrangement in 68 ALL patients. All 15 T cell ALL patients and 14 of 53 non-T, non-B ALL patients showed rearrangements of both T_γ and T_β genes, and 28 of 53 non-T,

Table 3. Rearrangement Patterns of IgH Gene, T_β Gene, and T_γ Gene in 68 Patients with ALL

		T Cell ALL	Non-T, Non-B ALL
IgH Gene	G*	13	0
	G/R	2	12
	R	0	41
T_β Gene	G	0	38
	G/R	0	7
	R	15	8
T_γ Gene†	G	0	29
	G/R	0	20
	R	14	3

*G denotes germline configuration, G/R, rearrangement with a germline allele, and R, rearrangement without a germline allele.

†Patients no. 1 and 31 were not included, since T_γ gene rearrangement was not analyzed following *Bam*HI digestion.

non-B ALL patients showed germline configuration of both genes. Ten non-T, non-B ALL patients with germline configuration of the T_β gene showed rearrangements of the T_γ gene, and there was only one patient who showed germline configuration of the T_γ gene and rearrangement of the T_β gene. It is possible that non-T, non-B leukemic cells are not appropriate for drawing conclusions about T cell gene rearrangements in normal cells. Nevertheless, these results are similar to the observations of others[23-25] and are consistent with the hypothesis that the T_γ gene undergoes rearrangement before rearrangement of the T_β gene.

ACKNOWLEDGMENT

We are indebted to the members of the Division of Hematology/Oncology for providing patient specimens, to A. Goldstein for surface marker studies, and to Drs P. Doherty, G. Mills, and M. Chan for their helpful discussions. Drs J. Seidman, T. Mak, T. Rabbitts, G. Matthyssens, and P. Leder kindly provided the T_γ, T_β, and Ig probes.

In Vitro Interaction of Recombinant Tumor Necrosis Factorα and All-Trans-Retinoic Acid With Normal and Leukemic Hematopoietic Cells

By Andreas Tobler, Reinhold Munker, Daniel Heitjan, and H. Phillip Koeffler

Both human recombinant tumor necrosis factor alpha (TNFα) and all-*trans*-retinoic acid (RA) inhibit the in vitro clonal growth of human myeloid leukemic cells. We investigated the in vitro interaction of TNFα and RA with normal and a variety of leukemic myeloid cells. With the promyelocytic HL-60 cells, TNFα ($\geq$2.5 U/mL) in combination with RA synergistically inhibited clonal growth; TNFα at lower concentrations ($\leq$1 U/mL) plus RA (10^{-9} mol/L) were antagonistic in their inhibition of growth. The ability of RA (10^{-8} mol/L) plus TNFα (2.5, 5 U/mL) to enhance differentiation of HL-60 cells paralleled their ability to inhibit clonal growth of these cells. In addition, RA (10^{-9} to 10^{-7} mol/L) increased the number of TNFα receptors on HL-60 cells 1.3- to 1.7-fold without changing the affinity for the TNFα receptor. With the more immature KG-1 myeloblasts, concentrations of TNFα >10 U/mL synergistically interacted with RA to inhibit clonal growth; at lower concentrations of TNFα (<10 U/mL), RA appeared to inhibit the expected effect of TNFα. KG-1 cells were not induced to differentiate with either agent alone or in combination. With four of nine leukemic patients, TNFα in combination with RA (10^{-7} mol/L) inhibited leukemic clonal growth to a greater extent than each agent alone. No marked effect of the combined treatment was seen in two other patients. The RA reversed the inhibitory action of TNFα on normal human granulocyte-macrophage colony forming cells (GM-CFC) and on clonal growth of leukemic cells from three patients. Our study suggests that TNFα and RA interact in a complex manner with normal and leukemic hematopoietic cells.

TUMOR NECROSIS factor alpha (TNFα) is a protein produced by myeloid cells. The TNFα was originally identified in the serum of endotoxin treated mice who were previously sensitized with bacillus Calmette-Guerin.[1] Human and murine TNFα recently have been purified, and the genes coding for these cytokines have been cloned and expressed.[2-4] Initial in vitro studies suggested that TNFα might be preferentially cytotoxic to certain malignant cells as compared with their normal counterpart (for a review, see ref. 5). We and others recently demonstrated that low concentrations of human recombinant TNFα effectively suppressed clonal growth in soft agar of cells from a variety of human myeloid leukemic cell lines and leukemic cells from patients.[6-8] In contrast, in the presence of granulocyte-macrophage colony stimulating factor (GM-CSF) clonal growth of normal human myeloid progenitor cells (GM-CFC) was inhibited only at much higher concentrations.[6,7,9] Studies further revealed that TNFα induces HL-60 to differentiate towards monocytes/macrophages.[6,7,10-12]

Retinoids in vitro effectively inhibited clonal growth and induced differentiation of myeloid leukemic cells harvested from patients and cell lines.[13-17] By contrast, retinoids stimulated clonal growth of normal human myeloid progenitor cells.[14,18] A logical extension of these studies was to investigate the combined in vitro effect of all-*trans*-retinoic acid (RA) and TNFα on clonal proliferation and differentiation of both human myeloid leukemic cells and normal human GM-CFC.

MATERIALS AND METHODS

Chemicals. The RA was a generous gift from M. Sherman (Hoffmann-La Roche, Inc, Nutley, NJ). Stock solution of 2.5 × 10^{-3} mol/L RA was prepared in 100% ethanol and stored at −20°C under a nitrogen atmosphere for no longer than 14 days. Before use, dilutions were made in phosphate-buffered saline (PBS) to the final concentrations of 1 × 10^{-7} to 1 × 10^{-9} mol/L. The concentrations of ethanol (<0.04%) had no influence on colony formation in control plates as compared with culture plates not containing ethanol. All experiments were performed in subdued light. The TNFα was generously provided by Dr M. Shepard (Genentech Inc, San Francisco). The stock solution (1 mg corresponds to 3.7 × 10^7 U; 1 U corresponds to 27 pg) was kept at 4°C in a sealed container. Before use, TNFα was diluted in alpha modified minimum essential medium (Flow Laboratories, Inc, Rockville, MD) plus 10% fetal calf serum (FCS) (Irvine Scientific, Santa Ana, CA) to final concentrations of 10,000 to 0.5 U/mL.

Cell preparations. The human myeloid cell lines HL-60 (passage 35, mean doubling time 32 hours)[19] and KG-1 (passage 30, mean doubling time 48 hours)[20] were maintained in culture T flasks (Miles Lab. Naperville, IL) containing alpha medium and 10% FCS. The cells were incubated in a humidified atmosphere with 7% CO_2. The medium was changed twice a week. All experiments were performed in the logarithmic growth phase of the cells. Normal human bone marrow cells were obtained from informed, healthy volunteers. Likewise, peripheral blood or bone marrow samples from leukemia patients were obtained after informed consent. The bone marrow or peripheral blood cells were layered over Ficol-Hypaque (density 1.077 g/mL) (Sigma Chemical Co, St Louis) and centrifuged for 40 minutes × 450 g. The light density, mononuclear cell fraction was washed twice in PBS and resuspended in alpha medium plus 10% FCS. Leukemia cells from all patients with chronic myelogenous leukemia (CML) contained the Philadelphia chromosome.

Colony formation assay by two layer agar technique. The colony formation assay was performed as previously described.[13,14] Briefly, an underlayer was plated in 1-mL portions in 35-mm petri

dishes (Miles) containing 0.5% agar, alpha medium, 16% FCS and the various additives (TNFα, RA), and CSF. As a source of CSF, conditioned medium (CM) obtained from a human T lymphocyte cell line (Mo) (Mo-CM) was used at concentrations of 1.5% to 2.5%.[21] The overlayer (1-mL) contained cells, alpha medium, 16% FCS, antibiotics and 0.3% agar. The HL-60 promyelocytic leukemia cells form colonies without CSF. The KG-1 myeloblastic leukemia cells (early passage), normal human bone marrow and leukemic cells from patients required CSF for clonal growth. The culture dishes were incubated at 37°C in a humidified atmosphere with 7% CO_2 for ten to 13 days. Colonies (>40 cells) were counted using an inverted microscope.

Cytochemistry. For nitroblue tetrazolium reduction (NBT), a total of 1×10^6 cells/mL were incubated in an equal volume of 1.25 mg NBT (Sigma), 17 mg bovine albumin (Sigma), and 10^{-7} mol/L 12-*O*-tetradecanoylphorbol 13-acetate (Consolidated Midland, New Rochelle, NY) in alpha medium plus 10% FCS for 30 minutes at 37°C. Cytospin slides of the cells were stained with safranin (Difco Laboratories, Inc, Detroit) and the number of cells containing reduced blue black formazan deposits was counted.[14] For α-naphtyl acetate esterase (ANAE) the cells were stained according to routine hematologic methods,[22] kindly performed by Dr F. Naeim (Department of Pathology, UCLA). Morphology was assessed by Giemsa staining. In each of the various experiments at least 200 cells were examined. Cell viability was >90% in all experimental procedures, as determined by trypan blue exclusion.

Monoclonal antibodies, indirect immunofluorescence. The monoclonal antibodies anti–leu-M3 and Y2FITC (mouse IgG2) were obtained from Becton-Dickinson (Mountain View, CA). Anti–leu-M3 reacts with 70% to 90% of normal human peripheral blood monocytes and has marginal reactivity with peripheral blood granulocytes. Y2FITC was used as isotypic control to define background staining. Analyses were performed on EPICS C flow cytometer (Coulter Electronics, Hialeah, FL), as described.[24]

Binding of ^{125}I-TNFα by HL-60 cells. The TNFα was iodinated by the Iodogen method as described.[24] Briefly, 10 μg of purified recombinant protein was incubated for ten minutes at 4°C in an Iodogen (Pierce, Rockford, IL) coated glass tube with 1 mCi of ^{125}I-TNFα (Amersham Corp, Arlington Heights, IL). Free iodide was separated from TNFα on a Sephadex G-25 column. The HL-60 cells were incubated with ^{125}I-TNFα (10^4 to 9×10^5 cpm) at 23°C for 90 minutes in alpha-medium, 10% FCS, and 20 mol/L Hepes (Sigma), washed extensively and the cell pellets counted in a Beckman gamma-counter. Previous experiments by us showed that at 23°C the peak of specific binding was reached at 45 minutes.[25] Nonspecific binding was determined by incubating the cells with a 100-fold excess of unlabeled TNFα. The specific activity of ^{125}I-TNFα was determined with a self-displacement experiment in which KG-1 cells were incubated with 0.4 to 10 μg unlabeled TNFα in the presence of $4 \times 10^4 - 5 \times 10^5$ cpm ^{125}I-TNFα and found to be 4.2×10^5 cpm/μg. Scatchard curves, the receptor number per cell and the affinity constants of binding were calculated with a computer program as described.[25] Under reducing conditions, iodinated recombinant TNFα gave a single band of the approximate mol wt of 17,000 on a 12% SDS-PAGE gel.[25] Under nonreducing conditions and longer exposure an additional faint band at ~34,000 daltons was observed (<2% of the intensity of the 17,000 band), indicating that little TNFα aggregates in vitro. Further, iodinated TNFα retained for over 2 months its biologic activity as measured by the inhibition of colony formation of HL-60 cells.

Statistical methods. Dose response curves were fit for each target (HL-60, KG-1 cells) and for each anti-tumor drug (RA, TNFα) by weighted least squares logistic regression.[26,27] At each percent inhibition, we computed a combination index (CI) for the additive (mutually exclusive binding) model using the method of Chou and Talalay.[27] We computed a standard error for CI (SE[CI]) using the delta method.[28] Drug combinations resulting in a given percent inhibition were said to be synergistic if CI + SE(CI) < 1, antagonistic if CI-SE(CI) > 1, and additive if CI + SE (CI) = 1. Cooperation between the drugs was also assessed by computing the fractional inhibitory concentration and its SE for each test concentration. These computations were based on the isobol method as described.[29] The effect of adding RA to TNFα compared with TNFα alone in the leukemic patients was assessed by fitting a model linear in the logs of the data. Significance was determined by comparing the effects to its standard error, which results in normal *z* statistics.

RESULTS

We examined the effect of the combination of TNFα (0.5 to 100 U/mL) and RA (10^{-8}, 10^{-9} mol/L) on clonal growth of the HL-60 promyelocytic cell line (Fig 1A). The TNFα and RA showed a dose-dependent interaction. Statistical analyses of the data (see Materials and Methods) showed that concentrations of TNFα ≥ 2.5 U/mL in combination with RA (10^{-8}, 10^{-9} mol/L) synergistically inhibited clonal growth of HL-60 cells. Evidence for an antagonistic interaction of TNFα and RA was observed at TNFα concentrations up to 1 U/mL when combined with 10^{-9} mol/L RA. Similar interpretations of the results were obtained when the isobol method of analysis was applied.

In an attempt to determine possible mechanisms of this enhanced inhibitory effect of TNFα and RA in HL-60 cells, several experiments were performed. The ability of TNFα plus RA to induce differentiation of HL-60 to mature cells was studied by examining the capability of these cells to reduce NBT (Fig 1B). At the concentrations tested (5 and 2.5 U/mL for six days), TNFα alone induced a mean 24% ±

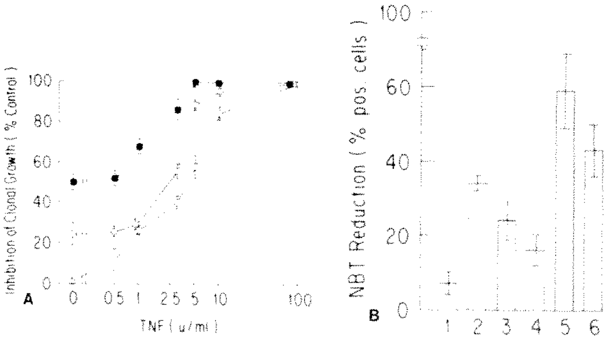

Fig 1. **(A) Dose response curves of inhibition of clonal growth of HL-60 cells by TNFα and RA. The cells were incubated with different concentrations of TNFα without (○) or with RA 10^{-8} mol/L (■) or 10^{-9} mol/L (□). Results are expressed as a mean percentage (±SD) of clonal growth inhibition in culture dishes containing the additives as compared with the control plates without additives. Three independent experiments were performed with triplicate dishes per point. Control plates contained a mean of 226 to 353 colonies per 1.5×10^3 plated cells. (B) Effect of TNFα and RA on induction of differentiation of HL-60 cells as measured by NBT reduction. Cells were incubated six days with different concentrations of TNFα and/or RA, harvested, and measured for NBT reduction. Data represent the means ± SD of three independent experiments done in duplicate flasks. 1, control (no TNFα, no RA); 2, RA (10^{8} mol/L); 3, TNFα (5 U/mL); 4, TNFα (2.5 U/mL); 5, TNFα (5 U/mL) plus RA (10^{-8} mol/L); 6, TNFα (2.5 U/mL) plus RA (10^{-8} mol/L).**

6% (±SD) and 16% ± 4% (±SD) of the HL-60 cells to reduce NBT, respectively. The RA alone (10^{-8} mol/L) induced differentiation of a mean 34% ± 3% (±SD) of HL-60 cells. Exposure of HL-60 cells for six days to TNFα (5 U/mL) plus RA (10^{-8} mol/L) significantly ($P < .001$) increased the number of these cells that reduced NBT (mean 59% ± 8% [±SD]) compared with the effect of each agent alone (mean 24% ± 6% [±SD] and 34% ± 3% [±SD] for TNFα and RA, respectively). Absolute numbers of HL-60 cells of one representative experiment were ($\times 10^6$/mL): control, 1.2; TNFα 5 U/mL, 0.6; TNFα 2.5 U/mL, 0.85; RA (10^{-8} mol/L), 0.75; TNF 5U/mL plus RA, 0.4; TNF 2.5 U/mL plus RA, 0.5. Lower concentrations of TNFα (0.5, 1.0 U/mL) in combination with RA (10^{-8} mol/L) showed no increase in the number of NBT positive cells, as compared with cells treated with RA alone; and TNFα alone showed no effect on NBT reduction at these concentrations (data not shown).

To determine the pathway of differentiation, HL-60 cells were exposed to TNFα plus RA (5 U/mL and 10^{-8} mol/L × 6 days, respectively) or to each agent alone (Table 1). Morphologically, 17% of the cells treated with RA alone showed granulocytic like differentiation; TNFα in combination with RA increased the number of differentiated cells to 62% with 20% of the cells showing morphological features of granulocytic-like cells and 42% having metamyelocytic- or monocytic-like appearance. In the presence of TNFα alone, 12% of the cells showed monocytic-like differentiation. No adherence was observed in cells treated with either TNFα alone or TNFα plus RA. Cytochemical analyses revealed that exposure to TNFα plus RA increased the number of ANAE positive cells to 35%, as compared with 15% ANAE positive cells when treated with TNFα alone, respectively. Fifteen percent of these cells (cultured with TNFα plus RA) were morphologically differentiated but were ANAE negative. Cytofluometric analyses showed that the combination of RA and TNFα increased the percentage of HL-60 cells expressing leu M3 (antigen expressed on monocytes but not granulocytes) to 24%, as compared with 15% and ≤2% in cells treated with TNFα or RA, respectively. Together, these results suggest that HL-60 cells when cultured with RA plus TNFα differentiate towards a mixed population of monocytic- and granulocytic-like cells.

Table 2. Binding Characteristics of ^{125}I-TNF α on HL-60 Cultured With RA

RA-dose	No. of Experiments	Receptors/Cell (Mean ± SD)	K_D of TNF Receptors (pmol/L)
0	n = 3	776 ± 39	42 ± 6
10^{-9}mol/L	n = 1	999	46
10^{-8}mol/L	n = 2	1201 ± 208*	64 ± 15
10^{-7}mol/L	n = 1	1338	54

HL-60 cells were cultured for five days in the presence of various concentrations of RA and then assessed for specific TNFα binding as described in Materials and Methods.

*$P \leq .05$ (determined by Student's t test).

The effect of RA on the expression of the TNFα receptors by HL-60 cells was examined as measured by the binding of ^{125}I-labeled recombinant human TNFα (Table 2 and Fig 2, for a representative Scatchard plot). The HL-60 cells were incubated for five days with several concentrations of RA (10^{-9} to 10^{-7} mol/L) and number of TNFα receptors per cell was determined. The wild type HL-60 cells expressed a single class of high affinity receptors (mean 776 ± 40 [±SD] receptors with a K_D binding affinity of 42 pmol/L). The RA increased expression of the number of TNFα receptors without a marked change in the affinity constants of binding of TNFα (1.3-, 1.6-, and 1.7-fold increase for cells cultured with 10^{-9} mol/L, 10^{-8} mol/L, and 10^{-7} mol/L RA, respectively as compared with wild-type HL-60 cells).

The effect of clonal growth of the combination of TNFα (1 to 1,000 U/mL) and RA (10^{-8} mol/L) was further studied using cells of the human myeloblastic line, KG-1, which are more immature than HL-60 cells and do not undergo differentiation in the presence of RA[14] (Fig 3). Clonal growth of KG-1 cells in early passages is dependent on CSF.[20] The KG-1 cells were less sensitive than HL-60 cells to the inhibitory action of TNFα (50% clonal inhibition [ED_{50}] at 15 U/mL for KG-1 cells as compared with 3.5 U/mL for HL-60 cells). By contrast, KG-1 cells were more sensitive than HL-60 cells to inhibition of growth by RA (ED_{50} 4×10^{-9} mol/L and 1×10^{-8} mol/L, respectively).[14] The combination of TNFα and RA resulted in various effects on clonal growth of KG-1 cells. The TNFα showed synergism with RA (10^{-8} mol/L) in the inhibition of clonal growth only at concentrations ≥10 U/mL. At lower concentrations of TNFα (<10 U/mL), the two agents were antagonistic in their inhibition of clonal growth of KG-1 cells. The TNFα

Table 1. Differentiation of HL-60 Cultured With TNFα and RA

Treatment (6 d)					
RA (10^{-8} mol/L)	TNFα (5 U/mL)	No. of Cells ($\times 10^6$/mL)	Morphology (Percent Differentiated Cells)	ANAE (Percent Positive Cells)	Leu-M3 (Percent Positive Cells)

HL-60 cells were cultured for six days with TNFα and/or RA and analyzed as described in Materials and Methods. Similar results were obtained in three independent experiments.

Abbreviations: ANAE, α-naphthylacetate esterase; RA, retinoic acid; TNFα, recombinant tumor necrosis factor α.

*Granulocytic-like cells.

†Monocytic-like cells.

‡Twenty percent granulocytic-like cells; 42% with metamyelocytic or monocytic features.

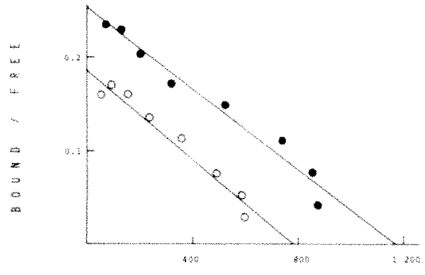

Fig 2. Scatchard plot of specific TNFα binding to HL-60 cells. HL-60 cells were cultured for five days either in the presence of RA (10^{-8} mol/L (●) or in the absence of RA (control) (○). 0.8 × 10^6 cells were then incubated with 10,000 to 900,000 cpm of ^{125}I-TNFα for 90 minutes at 23°C. Correlation coefficients were R = 0.986 for the control samples, and R = 0.980 for the RA-treated samples.

(2.5, 5.0 U/mL) and RA (10^{-8} mol/L) alone or in combination were not able to induce differentiation of KG-1 cells as determined by morphology and NBT-reduction (data not shown).

Diverse responses on clonal growth of leukemic cells freshly obtained from patients were observed when combinations of TNFα (1 to 10,000 U/mL) and RA (10^{-7} mol/L) were tested (Fig 4). The diagnoses are listed in the legend of Fig 4. In six of nine patients (no. 1 through 6) both RA and TNFα alone inhibited clonal growth to various degrees. With patients no. 1 through 4, the TNFα in combination with RA showed on average a greater inhibition of leukemic clonal growth ($P \leq .05$) as compared with TNFα alone. In two patients (no. 5 and 6), RA appeared to reduce the effect of TNFα at some but not all TNFα concentrations. In three patients (no. 7 through 9) TNFα alone inhibited leukemic growth, whereas RA alone stimulated leukemic growth; and when combined with TNFα, RA markedly decreased ($P \leq .05$) the inhibitory action of TNFα.

Further studies investigated the effect of the combination of TNFα and RA on GM-CFC (Fig 5). Normal human myeloid progenitor cells were ~2,800 times less sensitive to the inhibitory action of TNFα than HL-60 cells (ED_{50} at 10,000 U/mL and 3.5 U/mL TNFα, respectively) when CM from a human T lymphocyte cell line (Mo-CM) was used as a source of CSF. The RA alone (10^{-7} mol/L) enhanced GM-CFC formation ~1.6-fold. The addition of RA (10^{-7} mol/L) to the culture dishes containing TNFα (1 to 10,000 U/mL) either partially or completely reversed the inhibitory effect of TNFα on formation of GM-CFC. For example, at a concentration of 1,000 U/mL TNFα, a mean 40% ± 6% (±SD) of the GM-CFC were inhibited as compared with control plates; with the addition of 10^{-7} mol/L RA to plates containing 1,000 U/mL TNFα, GM-CFC formation was

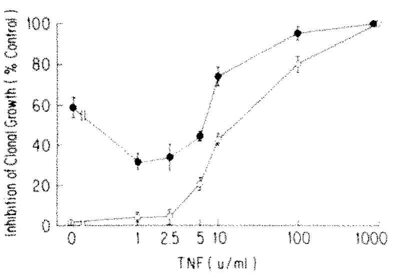

Fig 3. Dose-response curve of the combined effect of TNFα and RA expressed as an inhibition of clonal growth of the myeloblastic leukemic cell line KG-1. Cells were incubated with either TNFα alone (○) or with TNFα and RA 10^{-8} mol/L (●). Data of three independent experiments are expressed as described in the legend of Fig 1A. Control plates containing CSF alone had a mean of 92 to 126 colonies per 3 × 10^3 KG-1 cells.

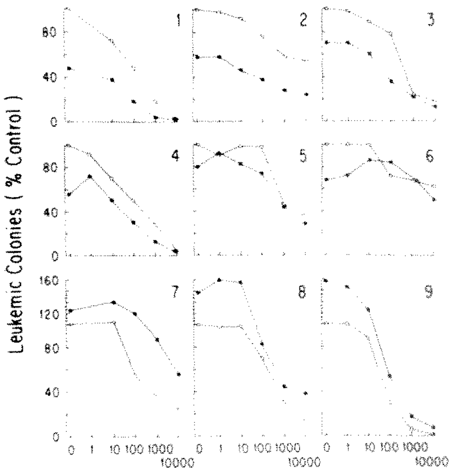

Fig 4. Effect of TNFα and RA on the clonal growth of myeloid cells from nine leukemic patients. The low density mononuclear cells were cultured in the presence of 1.5% Mo-conditioned medium as a source of CSF. TNFα was added either alone (○) or at different concentrations in combination with RA 10^{-7} mol/L (●) to the culture plates. Patients were diagnosed as follows: no. 2, 4, and 5 as CML; no. 3, 7, and 8 as CML in myeloid blast crisis; no. 1 as AML (FAB M2) in relapse; no. 9 as therapy-related AML, no. 6 as CMML. Control dishes containing CSF alone had the following mean numbers of colonies per 2 × 10^5 plated cells: no. 1, 891; no. 2, 46; no. 3, 180; no. 4, 39; no. 5, 469; no. 6, 23; no. 7, 158; no. 8, 206; no. 9, 81.

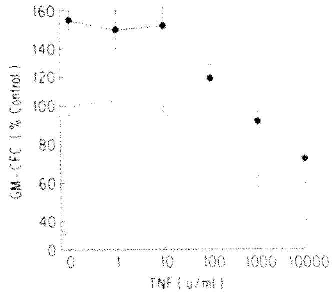

Fig 5. Effect of TNFα and RA on the clonal growth of normal human GM-CFC. Cells were incubated with different concentrations of TNFα without (○) or with RA 10^{-7} mol/L (●) and 1.5% Mo-conditioned medium as a source of CSF. Results are expressed as a mean percentage (±SD) GM-CFC compared with control plates containing CSF alone (no TNFα or RA). Note that RA plus TNFα curve shows the number of GM-CFC in plates containing RA and 0 to 10,000 U/mL TNFα. Control plates having CSF alone had a mean of 167 to 206 colonies per 2 × 10^5 plated bone marrow cells. Each experiment was performed with three different donors in triplicate plates per point.

nearly the same as control plates (mean 92% ± 6% [±SD] of control).

DISCUSSION

Our study shows that TNFα and RA interact in a complex manner with leukemic cell lines, leukemic cells from patients and normal human bone marrow cells. With HL-60 cells, TNFα ($\geq$2.5 U/mL) and RA mainly synergistically inhibited clonal growth (Fig 1A). However, evidence for an antagonism was seen at lower concentrations of TNFα ($\leq$1 U/mL) and RA (10^{-9} mol/L). At these concentration, RA seemed to reduce the expected inhibition of TNFα on clonal growth inhibition of HL-60 cells. The more immature myeloblastic KG-1 cells were less sensitive than HL-60 cells to the inhibitory action of TNFα alone, and only higher concentrations of TNFα ($\geq$10 U/mL) showed a synergistic interaction with RA (Fig 3). At <10 U/mL TNFα, antagonism was seen. A phase I trial with TNFα in cancer patients showed that after intravenous injection of 100 μg/mol/L^2, peak serum levels of 8,000 pg/mL (~300 U/mL) were reached with acceptable toxicity.[30] Our study with HL-60 and KG-1 cells shows that TNFα had synergistic interactions with RA at concentrations of both TNFα and RA that can be achieved in vivo.[30,31]

Recent studies demonstrated that TNFα induced HL-60 cells to differentiate towards monocytes/macrophages.[6,7,10-12] The RA in vitro induced HL-60 and leukemic cells from some patients to differentiate towards granulocytes.[15,16] The ability of the combination of TNFα and RA to enhance differentiation of HL-60 cells (Fig 1B) suggests that part of the synergism between TNFα and RA to inhibit clonal growth might be explained by their combined ability to increase the number of HL-60 cells that differentiate into mature nondividing cells. A previous study by us showed that TNFα preferentially inhibited growth of colonies containing granulocytes rather than macrophages or macrophage/granulocyte colonies.[6] This suggested that the combination of TNFα and RA may have selectively enhanced differentiation along the granulocytic pathway. However, analyses by morphology, cytochemistry and antigen expression showed that the combined treatment with TNFα and RA resulted in differentiation of HL-60 cells along both the macrophage and granulocyte pathway (Table 1), confirming previously reported data.[32]

The TNFα probably mediates its action through binding to specific receptors present on the surface of the cell.[5] Normal and leukemic hematopoietic cells express receptors for TNFα.[7,25,33] The RA (10^{-9} – 10^{-7} mol/L) moderately increased the number of TNFα receptors expressed on HL-60 cells (1.3- to 1.7-fold) as compared with wild-type HL-60 cells, but did not alter the binding affinity of the TNF receptors for their ligand in these cells (Fig 2, Table 2). Studies recently showed that γ-interferon (γ-IFN) increased the number of TNFα receptors on several human carcinoma cell lines, on murine L929 fibroblasts, and on the myeloid U937 cells.[24,33-35] Similar to the combination of TNFα and RA, TNFα plus γ-IFN had an increased cytotoxic/cytostatic effect as compared with each agent alone on human carcinoma cell lines, myeloid leukemia cell lines and leukemic cells from patients,[6,7,11,33,36,37] suggesting that increased cellular expression of the TNFα receptor may explain the enhanced responses. However, recent studies by us as well as others found no direct correlation between the number of receptors expressed on cells of various myeloid lines and their sensitivity to the growth inhibitory effects of TNFα.[7,25,33] Furthermore, TNFα was effective in clonal growth inhibition at concentration well below the saturation of its receptor (<10% occupancy).[7,25,33] Together, these results suggest that expression of increased numbers of TNFα receptors induced by RA is unlikely to account for the greater sensitivity of HL-60 cells and that mechanisms distal to TNFα binding to its receptor might be responsible for the enhanced cytotoxic/cytostatic effect of TNFα in combination with RA.

Various types of responses were observed on clonal growth inhibition of leukemic cells from patients. Both RA and TNFα alone inhibited clonal growth of leukemic cells of the majority of the patients, in agreement with previous studies.[6,13,14] However, RA alone also stimulated clonal growth of three of nine leukemic patients (no. 7 through 9). Two of the patients had CML in myeloid blast crisis (no. 7 and 8), and one had therapy-related AML (no. 9). Similarly, previous studies reported stimulation of leukemic clonal growth in selected patients.[38,39] The combination of TNFα plus RA showed a greater clonal growth inhibition compared with TNFα alone in some patients (no. 1 through 4); whereas in other patients (no. 5 through 9), RA either reduced or even reversed the inhibitory effect of TNFα. This suggests that in selected patients, RA may not enhance the inhibitory effect of TNFα, but possibly may protect leukemic growth from the inhibitory action of TNFα.

Our study confirms previous studies that retinoids enhance in vitro clonal growth of normal human myeloid progenitor cells.[14,18] The TNFα alone inhibited clonal growth of normal human GM-CFC only at much higher concentrations (ED$_{50}$ ~10,000 U/mL) as compared with leukemic clonal growth of both HL-60 cells (ED$_{50}$ 3.5 U/mL) and the majority of clonogenic leukemic cells harvested from patients (Fig 5). The combination of TNFα and RA had less growth inhibitory effect than TNFα alone on normal GM-CFC. This suggests that RA may have a protective effect on the TNFα-mediated inhibition of normal GM-CFC, and theoretically may allow higher concentrations of TNFα to be given without suppressing normal hematopoiesis.

Although RA inhibited in vitro clonal growth of myeloid leukemic cells of the majority of patients, in vivo RA usually had a therapeutic effect limited to patients with acute promyelocytic leukemia[40-43] and selected patients with the myelodysplastic syndrome.[31,44-47] Phase I and II trials with TNFα for AML are ongoing. In vivo animal studies are warranted to investigate further the complex interaction of TNFα and RA on normal and leukemic hematopoiesis and to help identify patients who may benefit from this combined treatment.

ACKNOWLEDGMENT

We would like to thank Suzanne Bookstaver and Regina Simon for their excellent secretarial help; Drs Michael Sherman and Michael Shepard for generously providing all-*trans*-retinoic acid and recombinant human TNFα, respectively.

Evidence That Plasma Lipoproteins Inhibit the Factor VIIa-Tissue Factor Complex by a Different Mechanism Than Extrinsic Pathway Inhibitor

By Shinichi Kondo and Walter Kisiel

Factor VIIa participates in blood clotting by activating factor X and/or factor IX by limited proteolysis. The proteolytic activity of factor VIIa is absolutely dependent on a lipoprotein cofactor designated tissue factor. We have examined the ability of purified preparations of human plasma high density, low density and very low density lipoproteins, as well as apolipoproteins A-I and A-II, to inhibit the factor VIIa-tissue factor mediated activation of either factor X or factor IX before and after treatment of the lipoprotein preparation with polyclonal antibody directed against partially-purified human plasma extrinsic pathway inhibitor (EPI). In the absence of anti-EPI IgG, HDL, LDL, VLDL, and apolipoprotein A-II noncompetitively inhibited factor X activation by factor VIIa-tissue factor with apparent Ki values of 3.39 µmol/L, 124 nmol/L, 33 nmol/L, and 10.5 µmol/L, respectively. Apolipoprotein A-I had no effect on this reaction. The inhibitory activity of HDL, LDL, VLDL, and apolipoprotein A-II in this reaction was unaffected by the presence of high levels of anti-EPI IgG. In the absence of exogenous factor Xa, none of the lipoproteins studied inhibited the activation of factor IX using the tritiated peptide release assay. In the presence of added factor Xa (1 nmol/L), LDL and VLDL, but not HDL and apolipoprotein A-II, inhibited the activation of factor IX by factor VIIa-tissue factor. This inhibition was completely blocked by prior incubation of the lipoprotein with anti-EPI IgG indicating association of EPI with these particles. Taken collectively, our data indicate that HDL, LDL, and VLDL, at or below their plasma concentration, each selectively inhibits the factor VIIa-tissue factor mediated activation of factor X by a mechanism that appears to be distinct from extrinsic pathway inhibitor. These lipoproteins may not only play a role in the regulation of extrinsic blood coagulation, but may also selectively promote the activation of factor IX by factor VIIa-tissue factor in vivo at low tissue factor concentrations.

© 1987 by Grune & Stratton, Inc.

FACTOR VII is a trace, vitamin K-dependent glycoprotein that circulates in blood as a zymogen to a serine protease, factor VIIa. Single chain human factor VII is converted to factor VIIa through the cleavage of a single internal peptide bond located at Arg$_{152}$-Ile$_{153}$.[1] The resultant two-chain factor VIIa activates either factor X or factor IX only in the presence of a lipoprotein cofactor designated tissue factor. In contrast to the three other activated vitamin K-dependent coagulation factors (factor IXa, factor Xa, and thrombin), factor VIIa is not effectively inhibited by antithrombin III.[2-5] The physiological mechanism whereby the factor VIIa-tissue factor complex is regulated in hemostasis is poorly understood.

In 1981, Carson[6] reported that plasma high density lipoproteins inhibit the activation of factor X by factor VIIa-tissue factor. More recently, several laboratories[7-12] have identified a novel mechanism for the inhibition of factor VIIa-tissue factor involving the copresence of factor VIIa, tissue factor, factor Xa, and a 35 to 40 kilodaltons (kDa) plasma protein initially isolated from a plasma lipoprotein fraction[8-10] and more recently purified to homogeneity from serum-free conditioned medium from Hep G-2 cells.[11-12] In this mechanism, extrinsic pathway inhibitor (EPI) presumably recognizes a ternary complex of factor VIIa-tissue factor-factor Xa and inhibits further activation of factor X and/or factor IX.[9,12] In addition, the active site of factor Xa appears to be essential for this inhibition to occur.[9,12] The association of EPI with the plasma lipoprotein fraction suggested that Carson's data concerning the inhibition of factor VIIa-tissue factor by HDL may have resulted, in large part, from contamination by EPI.[9] However, a recent report by Carson indicates that the inhibitory activity of HDL resides totally in the apolipoprotein A-II portion of this lipoprotein.[13] In the latter study, apolipoprotein A-II was purified to homogeneity by gel permeation column chromatography in the presence of 3 mol/L guanidine hydrochloride, a procedure that would in all likelihood resolve the apolipoprotein from contaminating EPI. In this report, we show that purified preparations of human plasma HDL, LDL, VLDL, and apolipoprotein A-II inhibits the factor VIIa-tissue factor mediated activation of factor X with Ki values at or below their respective plasma concentrations. None of these lipoprotein preparations demonstrated inhibitory activity against factor VIIa-tissue factor when factor IX was used as the substrate in the absence of added factor Xa. In the presence of factor Xa, however, LDL and VLDL demonstrated inhibitory activity with factor IX as the substrate and this activity was completely abolished following incubation of the lipoprotein with immunoglobulin raised against partially-purified EPI. In contrast, treatment of each lipoprotein (HDL, LDL, and VLDL) with this antibody had no effect on the ability of the lipoprotein to inhibit the activation of factor X by a complex of factor VIIa-tissue factor.

MATERIAL AND METHODS

Materials. Bz-Ile-Glu-Gly-Arg-p-nitroanilide (S-2222) was obtained from Helena Laboratories, Beaumont, TX. Sodium dodecyl sulfate (SDS) was obtained from British Drug House, Poole, England. Bovine serum albumin (fatty acid-free), Tris (Trizma base), potassium bromide, polyoxyethylene sorbitan monolaurate (Tween 20), Triton X-100, and sodium deoxycholate were obtained from Sigma, St Louis. Acrylamide, N, N'-methylene bisacrylamide, N, N, N', N'-tetramethylene diamine, Coomassie Brilliant Blue G-250, Protein Assay Dye Reagent Concentrate, Affi-Gel 10, and Affi-Gel 15 were products of Bio-Rad, Richmond, CA. Sodium Boro [^{3}H] hydride (21.6 C/m mol) was purchased from Amersham Corporation, Arlington Heights, IL. Rabbit anti-human apolipoprotein B antiserum was obtained from Calbiochem-Behring, La Jolla, CA. Sheep anti-human apolipoprotein A-I and sheep anti-human apolipoprotein A-II were purchased from Boehringer Mannheim, Indianapolis. SDS High Mr protein standard kit was a product of Pharmacia, Piscataway, NJ. All other chemicals were the best grade available from commercial sources.

Human brain cephalin (mixed phospholipids) was prepared according to Bell and Alton.[14] Human brain tissue factor apoprotein was prepared essentially according to Broze et al.[15] In this procedure, 25 g of human brain acetone powder were resuspended in 500 mL of 0.05 M Tris-HCl (pH 7.5) containing 0.1 mol/L NaCl, 0.1% NaN$_3$, 5 mmol/L EDTA, and 2 mmol/L DFP and stirred for one hour at room temperature. The mixture was centrifuged at 12,000 g for 1.5 hours at 20°C. The supernatant was discarded and the pellet was resuspended in 500 mL TBS/2% Triton X-100/0.1% NaN$_3$ and stirred at room temperature for one hour. This suspension was centrifuged at 30,000 g at 4°C for 75 minutes. The supernatant was adjusted to 10 mmol/L CaCl$_2$, stirred at room temperature for 30 minutes, and incubated overnight at 4°C. A precipitate that formed during incubation was removed by centrifugation at 40,000 g for one hour at 4°C, and the supernatant subsequently concentrated by ultrafiltration to ~40 mL. The crude tissue factor concentrate was again centrifuged (48,000 g; one hour; 4°C) and the pellet discarded. The supernatant was applied at room temperature to tandem columns of glycine-ethyl ester-Affi-Gel (2.6 × 5 cm) and human factor VII-Affi-Gel (1.6 × 2 cm) at a flow rate of 10 mL/h. Following a wash of both columns with 50 mL of TBS/10 mmol/L CaCl$_2$/2% Triton X-100, the glycine ethyl ester-Affi-Gel column was removed and the factor VII-Affi-Gel column was eluted with TBS/20 mmol/L EDTA/2% Triton X-100. Fractions containing tissue factor activity were pooled and stored at 4°C. Using this procedure, ~80% of the tissue factor activity eluted in the unadsorbed fraction of factor VII-Affi-Gel column, while the remaining 20% was recovered in the EDTA-eluant. The low yield of purified TF apoprotein was consistently observed whether factor VII (15 mg) was coupled to 4 mL of Affi-Gel 15 or 4 mL activated CH-Sepharose (Pharmacia). Examination of affinity-purified human tissue factor apoprotein by SDS-PAGE revealed two major bands with mol wt values of 61,000 and 47,000 in the presence or absence of reducing agents. As revealed by gel slicing experiments, tissue factor coagulant activity was confined exclusively to the 47,000 Mr band. The affinity-purified tissue factor apoprotein was relipidated as described[15] with the exception that human brain mixed phospholipids were used instead of rabbit brain phospholipids.

A DEAE Affi-Gel Blue purified rabbit immunoglobulin preparation that neutralized extrinsic pathway inhibitor activity was generously provided by Drs Warn-Cramer and Rapaport, University of California, San Diego. The EPI antigen used for immunization was purified ~1000-fold from the total lipoprotein fraction of human plasma by a combination of gel filtration, ion exchange chromatography and preparative SDS-PAGE, and contained both Mr variants of EPI, significant amounts of apolipoprotein E and minor amounts of apolipoprotein A-II and apolipoprotein A-IV (S. Rapaport, personal communication, December, 1986). Anti-EPI IgG formed a single, faint precipitin band in Ouchterlony double diffusion experiments when allowed to react with either a purified preparation of HDL or apolipoprotein A-II, but failed to form any detectable precipitin band when allowed to react with various concentrations of either LDL, VLDL, or apolipoprotein A-I.

Human factor X, factor VII, and factor IX were partially purified from therapeutic plasmapheresis plasma by a combination of barium citrate adsorption and elution and DEAE-Sepharose CL-6B chromatography essentially as described.[16] Factor VII obtained from DEAE-Sepharose chromatography was purified to homogeneity by immunoaffinity chromatography as described.[1] Single-chain factor VII was activated to two-chain factor VIIa by factor Xa as described.[1] The factor X pool obtained from DEAE-Sepharose chromatography was further purified on a column of dextran sulfate agarose (5.0 × 45 cm) equilibrated at 4°C with 0.025 mol/L sodium citrate (pH 7.4)/1 mmol/L benzamidine. Proteins were eluted in a linear NaCl gradient composed of 2 L of equilibrating buffer and 2 L 0.025 mol/L sodium citrate (pH 7.4)/1M NaCl/1 mmol/L benzamidine. This DSA column effectively resolved factor X from protein S, prothrombin, protein C, and factor IX. The factor X obtained from DSA chromatography was homogeneous as judged by SDS-PAGE. However, this preparation was found to be contaminated with low density lipoproteins and high density lipoproteins as evidenced by positive immunoprecipitates with monospecific antisera against apolipoprotein B and apolipoprotein A-I/A-II. Consequently, the DSA-factor X pool was purified to homogeneity by preparative polyacrylamide gel electrophoresis as described elsewhere.[17] Alternatively, lipoproteins were effectively separated from DSA factor X by gel filtration chromatography in Sephadex G-150 equilibrated with TBS/1 mmol/L Benzamidine. Both preparations of purified factor X appeared as single bands on 10% SDS-gels, and were negative for immunoreactive apolipoprotein B and apolipoprotein A-I/A-II. Factor X was activated by incubation with an insolubilized preparation of RVV-X as described.[18] The factor IX obtained from DSA chromatography was separated from contaminating lipoproteins and purified to homogeneity by immunoaffinity chromatography using a column containing murine monoclonal antibody to human factor IX (A-7) coupled to Affi-Gel 10.[19] The affinity column was equilibrated with 0.02 mol/L Tris-HCl (pH 7.2)/0.15 mol/L NaCl/20 mm MgCl$_2$/1 mmol/L benzamidine and the adsorbed factor IX was eluted from the column with 0.02 mol/L Tris-HCl (pH 7.2)/0.15 mol/L NaCl/1 mmol/L benzamidine/20 mmol/L EDTA. Human factor VII (14.6 mg) was coupled to 4 mL packed volume of Affi-Gel 15 at RT for two hours. The coupling reaction was performed in 0.1 mol/L Hepes (pH 7.5), and residual, unreacted sites on the Affi-Gel 15 were subsequently blocked with glycine ethyl ester (0.1 mol/L final concentration).

Sodium dodecyl sulfate polyacrylamide gel electrophoresis. SDS-PAGE was performed according to Laemmli[20] using a 2.5% concentrating gel and a 3% to 15% linear gradient polyacrylamide resolving gel. Gels were stained for one hour in 0.1% Coomassie Blue G-250/50% methanol/10% acetic acid and diffusion destained in 10% methanol/10% acetic acid.

Various assays. Human factor VII, factor X, and factor IX were assayed by standard one-stage assays using hereditary deficient plasmas as substrates.[3,21,22] The coagulant activity of relipidated tissue factor apoprotein was measured by incubating 100 μL of diluted tissue factor with 100 μL of normal pooled human plasma for 30 seconds, followed by the addition of 100 μL of 25 mmol/L calcium chloride. In this system, 2 ng of relipidated tissue factor apoprotein produced a clot in ~50 seconds. The protein concentrations of factor X, factor VII, factor VIIa, tissue factor apoprotein, and purified plasma lipoproteins were determined by the dye binding assay as described by Bradford[23] using bovine serum albumin as the reference protein.

The inhibition of the factor VIIa-tissue factor mediated activation of factor X by plasma lipoproteins was determined in a modified two-stage amidolytic assay originally described by Seligsohn et al.[24] In this assay, 50 μL of tissue factor (0.34 nmol/L in apoprotein) was incubated for 15 minutes in a polystyrene tube at 37°C with 50 μL of either buffer control (TBS/BSA) or various concentrations of lipoproteins in TBS/BSA. To this system was added 50 μL of factor VIIa (0.16 nmol/L), 50 μL of human factor X (27 to 228 nmol/L) and 25 μL of calcium chloride (50 mmol/L). Incubation at 37°C was continued for exactly one minute after the addition of $CaCl_2$, and at this time 25 μL of EDTA (300 mmol/L) was added to stop the activation reaction. One hundred microliters of the incubation mixture was removed and added to 700 μL of S-2222 (192 μmol/L) in 0.05 mol/L Tris-HCl/0.15 mol/L NaCl (pH 8.3) in a cuvette. The absorbance at 405 nm was continuously recorded using a Beckman Model 25 spectrophotometer equipped with a strip chart recorder. Factor Xa concentrations were interpolated from a standard curve of ΔA_{405}/min *v* factor Xa concentration (Fig 1).

The inhibition of the factor VIIa-tissue factor mediated activation of factor IX by plasma lipoprotein was determined in a modified tritiated activation peptide release assay originally described by Zur and Nemerson.[25] This assay was constructed the same as the chromogenic assay except the tritiated factor IX (21 to 803 nmol/L) was substituted for factor X and the final incubation volume was increased to 450 μL. At appropriate intervals, 100 μL subsamples of the incubation mixture were transferred to polypropylene tubes containing 200 μL of 50 mmol/L EDTA/50 mmol/L benzamidine/TBS and kept on ice. At the end of the incubation period, 150 μL of ice-cold 15% trichloracetic acid (TCA) was added to each subsample and this mixture centrifuged five minutes in a Beckman microfuge B. Duplicate samples of each supernatant were counted in a Packard Tri-Carb scintillation counter. In our system, the factor IX activation progress curve plateaued when 31% of the total counts were released as TCA soluble material. We assume that this level of TCA soluble counts represents complete activation of [^3H]-factor IX, and used this value to calculate the moles of factor IX temporally activated.

Tritium labeled factor IX was prepared by the modification of Van Lenten and Ashwell.[26] In our hands, the specific radioactivity of tritiated factor IX was 0.9 × 10^5 cpm/μg, and the biological activity of labeled factor IX was 67% of nonlabeled preparations. Kinetic parameters were determined from three individual experiments using the nonlinear, nonweighted, least square fitting to a hyperbola.[27]

The molar concentrations of plasma lipoproteins used in this assay were calculated from the observed protein mass concentration by the dye-binding assay,[13] and from published values of the weight percentage of apolipoprotein in each lipoprotein[28] as well as the mol wt of the intact lipoprotein.[29] In the case of VLDL, where ranges of mol wt are reported (10 to 80 × 10^6), a mean value was assumed. Specific mol wt values used in this study for VLDL, LDL, and HDL were 50 × 10^6, 2.3 × 10^6, and 1.75 × 10^5 Da, respectively.

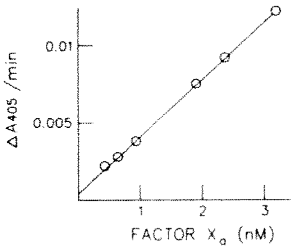

Fig 1. **Human factor Xa amidolytic assay standard curve.**

Isolation of plasma lipoproteins and apolipoproteins A-I and A-II. HDL, LDL, and VLDL were isolated from plasma obtained from a fasted normolipemic donor by sequential preparative ultracentrifugation essentially as described by Havel et al.[30] Ultracentrifugation was carried out in a Beckman model L5-75 preparative ultracentrifuge at 15°C. Briefly, nine parts of blood were mixed with one part of an anticoagulant cocktail containing 0.13 mol/L sodium citrate, 0.02% sodium azide, and 50 mmol/L EDTA. Following centrifugation to remove blood cells, the plasma was adjusted to 1 mmol/L in PMSF and 10 mmol/L benzamidine. Chylomicrons were removed from plasma by centrifugation at 78,000 g for 150 minutes in an SW-40 rotor. Subsequently, the VLDL was floated following centrifugation of the infranate at 105,000 g for 22 hours in a 50 Ti fixed angle rotor. LDL and HDL were floated sequentially after density adjustment of the infranates to 1.063 and 1.21, respectively, by the addition of either stock salt solution (NaCl/KBr; density = 1.346) or solid KBr.[30] LDL was floated at 105,000 g for 22 hours, while HDL was floated at 105,000 g for 48 hours. VLDL was refloated at least one time at d = 1.0063 g/mL by centrifugation for 22 hours at 105,000 g. LDL was refloated sequentially at d = 1.063 g/mL and d = 1.050 g/mL to remove contaminating HDL. Despite recentrifugation at d = 1.21 g/mL, the HDL preparation revealed the presence of contaminating apolipoprotein B by immunoassay that could not be removed by readjustment of the HDL solution to d = 1.063 (by dialysis) and subsequent refloatation. Accordingly, low levels of immunoreactive LDL were quantitatively removed from the HDL preparation by passage of the HDL through a column of rabbit anti-Apo B-IgG-protein A-Sepharose. Each purified lipoprotein preparation was dialyzed extensively against TBS/0.02%

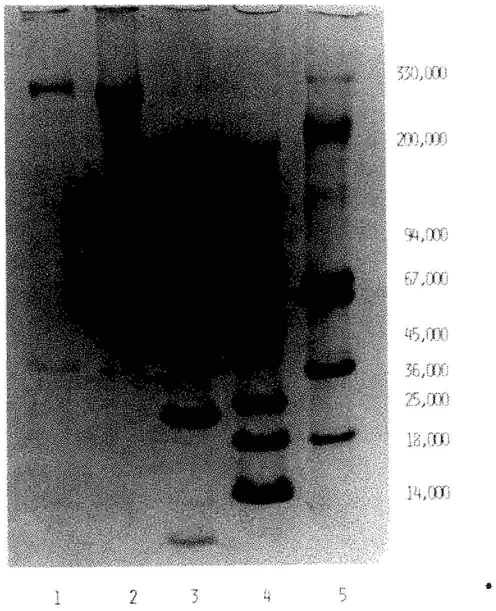

Fig 2. **SDS-PAGE of human plasma lipoproteins on a 3% to 15% polyacrylamide gradient gel. Lanes: 1, VLDL, 6 μg; 2, LDL, 8 μg; 3, HDL, 15 μg; 4, mol wt standards (Myosin, 200,000; phosphorylase b, 94,000; bovine serum albumin, 67,000; ovalbumin, 45,000; chymotrypsinogen, 25,700; β-lactoglobulin, 18,400; lysozyme, 14,300); 5, mol wt standards (thyroglobulin, 330,000; ferritin, 220,000; albumin, 67,000; catalase, 60,000; lactic dehydrogenase, 36,000; apoferritin, 18,500). All samples were electrophorized after reduction with 10% 2-mercaptoethanol.**

NaN_3 and stored at 4°C. When examined by SDS-PAGE,[20] unreduced preparations of VLDL exhibited a major band at 300 kd, LDL a major band at 280 kd, and HDL a major band at 24 kd (Apo A-I) and a minor band at 15 kd (Apo A-II). Reduction with 5% 2-mercaptoethanol had no effect on the Mr of VLDL or LDL (Apo B), whereas the 15 kd band in HDL decreased to ~7 kd. The 24 kd (Apo A-I) band was also unaffected by reduction (Fig 2). By Ouchterlony double diffusion analysis, the VLDL and LDL preparations appeared immunologically pure and showed no precipitation band against rabbit anti-apolipoprotein A-I/A-II. Similarly, the HDL preparations were free of immunoreactive apolipoprotein B, and formed a single precipitin arc against rabbit anti-apolipoprotein A-I/A-II.

A mixture of apolipoproteins A-I/A-II was isolated from HDL by the following procedure. Two milliliters of HDL (1.22 mg/mL) were dialyzed exhaustively against 50 mmol/L Tris-HCl (pH 7.5) and subsequently lyophilized. The lyophilized lipoprotein (plus Tris) was extracted four times with 15 mL of chloroform: methanol (2:1) at 0°C (ice-water bath). The final pellet was dried under N_2 and solubilized in 1.5 mL TBS/40 mmol/L sodium deoxycholate (DOC). This solution was diluted with 50 mL TBS in order to reduce the DOC concentration to below its critical micelle concentration (0.9 mmol/L)[31] and the resulting solution dialyzed exhaustively against TBS at 4°C. The retentate was subsequently concentrated to 2 mL by ultrafiltration (YM-10 membrane). Apolipoproteins A-I and A-II were isolated as described.[32] Shortly after delipidation by chloroform:methanol (2:1), the HDL was dissolved in 3 mol/L guanidine hydrochloride/TBS and applied to Sephacryl S200 column chromatography (1.5 × 170 cm) equilibrated with the same buffer. Column chromatography was repeated once to achieve homogeneity (Fig 3). Purified apolipoproteins were dialyzed against TBS/0.02% NaN_3 and concentrated by ultrafiltration (YM10; Amicon, MA).

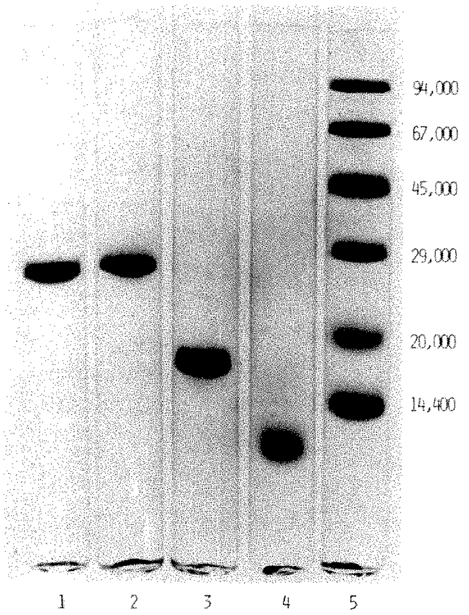

Fig 3. SDS-PAGE of human apolipoprotein A-I and A-II. Lanes: 1, nonreduced Apo A-I, 12 μg; 2, reduced Apo A-I, 12 μg; 3, nonreduced Apo A-II, 14 μg; 4, reduced Apo A-II, 14 μg; 5, mol wt standards (phosphorylase b, 94,000; bovine serum albumin, 67,000; ovalbumin, 45,000; carbonic anhydrase, 29,000; soybean trypsin inhibitor, 20,000; α-lactalbumin, 14,400).

RESULTS

Validity of the coupled amidolytic assay. The two stage coupled amidolytic assay was used to determine the inhibitory effect of purified plasma lipoproteins on factor Xa generation by a complex of factor VIIa and tissue factor. The assay was standardized with respect to tissue factor concentration, factor X concentration, factor VIIa concentration and incubation time such that the rate of factor Xa generation was first-order and linear. In our system, factor Xa production was linear between factor VIIa concentrations of 2.5 and 35 pmol/L and tissue factor concentrations between 6.8 and 78 pmol/L during a one-minute incubation period. At these reactant concentrations, linear production of factor Xa was consistently preceded by a lag period of ~30 seconds similar to that reported by Silverberg et al[33] using the radiolabeled activation peptide release assay. Tissue factor was routinely incubated with either lipoproteins or apolipoproteins for 15 minutes at 37°C before the addition of factor VIIa, factor X, and $CaCl_2$; however, incubation times of two to 15 minutes produced the same effect. The tissue factor and factor VIIa final concentrations selected for these experiments were 75 pmol/L and 35 pmol/L, respectively. The tissue factor concentration actually represents the molar concentration of tissue factor apoprotein assuming a mol wt of 47,000 Da. As mentioned earlier, our tissue factor apoprotein preparation revealed two bands by SDS-PAGE with mol wt values of 61,000 and 47,000 in roughly a 40:60 ratio (61,000:47,000) as judged from densitometry scans of the gels. To simplify our calculations, we are assuming that the 61,000 Mr species represents a contaminant and the concentration of tissue factor apoprotein has been expressed as the amount of the 47,000 Mr species by multiplying the total protein concentration by a factor of 0.6. The factor X preparation was homogeneous by SDS-PAGE and was free of lipoproteins, factor IX, factor Xa, and factor VII. No amidolytic activity could be detected when factor X was incubated with calcium in the presence or absence of tissue factor. In preliminary experiments designed to compare the activation of gel-filtered factor X *v* factor X purified by preparative electrophoresis, a significantly higher (twofold) Vmax was obtained using gel-filtered factor X. In addition, the specific coagulant activity of gel-filtered factor X was threefold higher than electrophoresis factor X (106 U/mg *v*

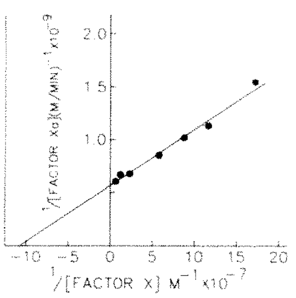

Fig 4. Lineweaver-Burk plot of the activation of factor X by factor VIIa-tissue factor. The range of factor X final concentrations used was 6 to 200 nmol/L.

30 U/mg) in an assay using RVV-X to activate the factor X. Accordingly, gel-filtered factor X was used for the inhibition studies using the amidolytic assay.

Using the above conditions, the kinetic parameters of the activation of human factor X by a complex of human factor VIIa-tissue factor were determined (Fig 4). The Km is 10.49 ± 4.88 nmol/L factor X. The Vmax is 1.67 ± 0.19 nmol l^{-1} min^{-1}, which yields a turnover number (Kp) of 50 $minutes^{-1}$. These kinetic parameters are in reasonably good agreement with those recently published for the activation of bovine factor X by purified preparations of bovine factor VIIa and bovine brain tissue factors.[34]

Construction of the peptide release assay. The peptide release assay for factor IX activation was constructed similar to the chromogenic assay for factor X activation. Tritium labeled factor IX activation peptide production was linear between factor VIIa concentrations of 4 to 27 pmol/L and tissue factor concentrations between 20 and 112 pmol/L up to 15 minutes incubation time.

The tissue factor and factor VIIa concentration selected for the inhibition experiments was 112 pmol/L and 27 pmol/L, respectively. The kinetic parameters for the activation of human factor IX by a complex of human factor VIIa-tissue factor are as follows: Km, 47.44 ± 24.76 nmol/L factor IX; Vmax, 0.439 ± 0.055 nmol l^{-1} min^{-1}, yielding a turnover number (Kp) of 16 min^{-1} (Fig 5).

Inhibition of factor X activation by purified plasma lipoproteins and apolipoproteins. Factor X activation was measured over the concentration range of 6 to 50 nmol/L factor X in the presence of varying levels of purified HDL, LDL, and VLDL. In control experiments where tissue factor was replaced with buffer, no activation of factor X was observed by factor VIIa in the presence of various concentrations of each lipoprotein. Each lipoprotein had no effect on factor Xa amidolytic activity in the range used to inhibit the factor VIIa-tissue factor catalyzed activation of factor X. In addition, each lipoprotein had no effect on the duration of the lag period preceeding the linear production of factor Xa in each system.

The results for the inhibition of factor X activation by HDL are shown in Fig 6 as a Dixon plot. The type of inhibition observed was distinctly noncompetitive, and the apparent inhibitor constant (Ki) for HDL was 3.39 μmol/L.

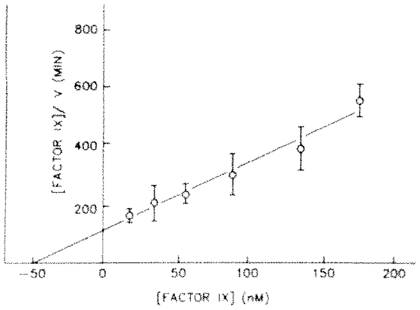

Fig 5. Hanes-Woolf plot of the activation of factor IX by factor VIIa-tissue factor. The range of factor IX final concentrations used was 14 to 179 nmol/L.

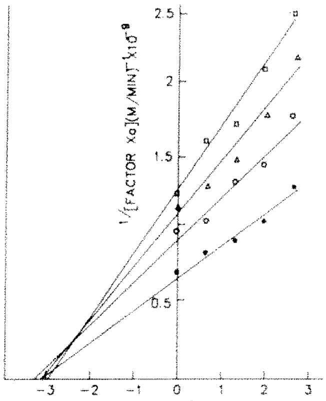

Fig 6. Dixon plot for the inhibition of factor X activation by HDL. The rate of factor X activation was determined in the coupled amidolytic assay as described in Materials and Methods. The factor X final concentrations used were: (●), 47.9 nmol/L; (○), 19.2 nmol/L; (△), 12.8 nmol/L; (□), 9.6 nmol/L.

The inhibition of factor X activation by LDL and VLDL also exhibited a noncompetitive type of inhibition. Ki values of 124 nmol/L and 33 nmol/L were obtained from Dixon plots (Figs 7 and 8) for LDL and VLDL, respectively. Delipidated HDL, containing a mixture of apolipoproteins A-I and A-II, exhibited the same type of inhibition (Ki = 5.5 μmol/L) and was essentially as effective as intact HDL in the inhibition of factor X activation (Table 1). Comparable experiments to assess the inhibitory potential of apolipoprotein B failed due to the insolubility of apolipoprotein B following chloroform:methanol extraction of LDL. The inhibitory activity, observed in a mixture of apolipoproteins A-I/A-II was subsequently shown to be due entirely to apolipoprotein A-II. Each apolipoprotein was purified to homogeneity by repetitive gel-filtration column chromatography in the presence of 3 mol/L guanidine hydrochloride. Purified apolipoprotein A-I failed to show any factor X activation inhibitory activity in our system at concentrations as high as 100 μmol/L (Table 1) whereas the apolipoprotein A-II noncompetitively

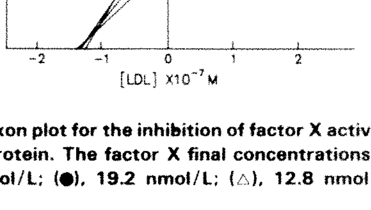

Fig 7. Dixon plot for the inhibition of factor X activation by low density lipoprotein. The factor X final concentrations used were: (○), 47.9 nmol/L; (●), 19.2 nmol/L; (△), 12.8 nmol/L; (▲), 9.6 nmol/L.

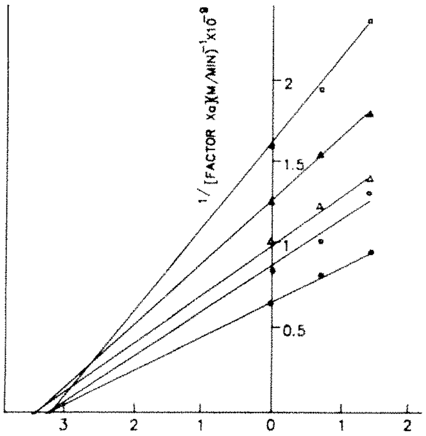

Fig 8. Dixon plot for the inhibition of factor X activation by very low density lipoprotein. The factor X final concentrations used were: (●), 47.9 nmol/L; (○), 19.2 nmol/L; (△), 12.8 nmol/L; (▲), 9.6 nmol/L; (□), 6.4 nmol/L.

inhibited the factor X activation reaction with an apparent Ki value of 10.5 μmol/L (Fig 9). The results of the inhibition of factor X activation by each lipoprotein and soluble apolipoprotein are shown in Table 1. The Ki values for each lipoprotein appear to be at or below their plasma concentration, assuming plasma concentrations of 13 μmol/L, 1.5 μmol/L, and 28 nmol/L for HDL, LDL, and VLDL, respectively.[29]

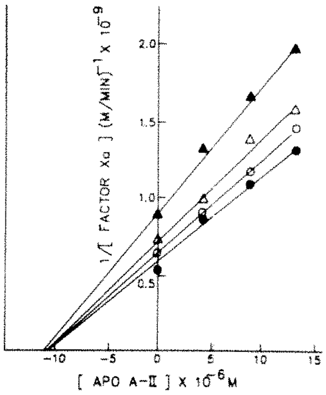

Fig 9. Dixon plot for the inhibition of factor X activation by apolipoprotein A-II. The rate of factor X activation was determined in the coupled amidolytic assay as described in Methods. The factor X final concentrations used were: (●), 68 nmol/L; (○), 45 nmol/L; (△), 34 nmol/L; (▲), 23 nmol/L.

Inhibition of factor IX activation by purified plasma lipoproteins and apolipoproteins. The activation of [^{3}H]-factor IX by a complex of factor VIIa-tissue factor was measured over the concentration range of 14 to 179 nmol/L factor IX in the presence of varying levels of two different preparations of lipoproteins and apolipoproteins. The results of quadruplicate measurements at a factor IX concentration of 179 nmol/L are shown in Table 2 for one preparation of each lipoprotein and apolipoprotein. In comparison with a control mixture, none of the lipoproteins or apolipoproteins tested inhibited this reaction in the absence of added factor Xa. One preparation of apolipoprotein A-II, however, produced a slight enhancement (twofold) of the rate of factor IX activation that appeared to be statistically significant (data not shown). This effect was not observed when factor X was the substrate using this particular apolipoprotein A-II preparation. Furthermore, the reason for the stimulating effect on the factor IX activation by this particular apolipoprotein A-II preparation is not known and additional studies are required to determine the reproducibility of this effect with several different preparations of apolipoprotein A-II. When the activation of factor IX by factor VIIa-tissue factor was conducted in the presence of added factor Xa (1 nmol/L final concentration), both VLDL and LDL inhibited this reaction suggesting the presence of EPI associated with these particles. Pretreatment of VLDL and LDL preparations with increasing concentrations of anti-EPI–IgG completely abolished the ability of VLDL and LDL to inhibit the activation of factor IX (Fig 10). Interestingly, these same incubation mixtures of VLDL–anti-EPI and LDL–anti-EPI inhibited the factor VIIa-tissue factor mediated activation of factor X using final concentrations of factor VIIa and tissue factor essentially identical to that used for the activation of factor IX (Fig 10). The slight recovery of inhibitory activity observed for LDL and VLDL in the factor IX activation system (Fig 10) probably reflects a condition of antibody excess relative to EPI concentration and the consequent solubilization of the antigen-antibody complex. Thus, these data strongly suggest that the apparent inhibition of factor IX activation by purified preparations of LDL and VLDL result from contaminating EPI in these lipoprotein preparations. In both cases, the expression of this inhibitory activity was dependent on the presence of exogenous factor Xa. In contrast, purified preparations of HDL and apolipoprotein

Table 1. Inhibition Constants of Plasma Lipoproteins and Apolipoproteins for the Activation of Factor X by Factor VIIa-Tissue Factor

Lipoprotein/Apolipoprotein	Ki
VLDL	33 nmol/L
LDL	124 nmol/L
HDL	3.4 μmol/L
Delipidated HDL	5.5 μmol/L
Apo A-I	>100 μmol/L
Apo A-II	10.5 μmol/L

Table 2. Effect of Purified Lipoproteins and Apolipoproteins on Factor IX Activation by Factor VIIa-Tissue Factor in the Presence and Absence of Added Factor Xa

Lipoprotein/ Apolipoprotein	Concentration (μmol/L)	Rate (nmol l^{-1} min^{-1}) (−Xa)	Rate (nmol l^{-1} min^{-1}) (+Xa)
Control	—	0.321 ± 0.046	0.292 ± 0.038
VLDL	0.024	0.298 ± 0.030	0.156 ± 0.039
LDL	0.185	0.329 ± 0.032	0.057 ± 0.015
HDL	2.7	0.294 ± 0.033	0.280 ± 0.068
Apo A-I	6.7	0.282 ± 0.075	0.294 ± 0.038
Apo A-II	24.8	0.297 ± 0.029	0.281 ± 0.040

Factor IX concentration, 179 nmol/L; factor Xa concentration, 1 nmol/L.

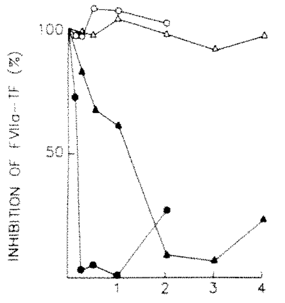

Fig 10. The effect of anti-EPI–IgG on the ability of LDL and VLDL to inhibit factor VIIa-tissue factor. LDL (△,▲) and VLDL (○,●) at a fixed concentration was incubated with increasing concentrations of anti-EPI–IgG for two hours at 37°C. An aliquot of this incubation mixture was tested for its ability to inhibit the activation of either factor X (open symbols) or factor IX (closed symbols) as described in Materials and Methods. Factor IX activation incubation mixture also contained 1 nmol/L factor Xa. The inhibition observed by each lipoprotein in the absence of anti-EPI–IgG (buffer control) was designated as the 100% value. LDL final concentration in each activation reaction was 150 nmol/L; VLDL concentration in each activation reaction was 40 nmol/L.

A-II, as well as LDL and VLDL preparations previously treated with immunoglobulin that neutralized EPI activity, markedly and specifically inhibited the activation of factor X by a complex of factor VIIa-tissue factor without demonstrating any apparent effect on the ability of factor VIIa-tissue factor to activate factor IX.

DISCUSSION

We have carried out experiments to assess the inhibitory properties of purified plasma lipoproteins on the activation reactions of factor X and factor IX by a complex of purified factor VIIa and human brain tissue factor. Our data clearly indicate that HDL, LDL, and VLDL effectively inhibit the activation of factor X by factor VIIa-tissue factor at or below their respective plasma concentrations (Table 1). Of these three lipoproteins, given their plasma concentrations and Ki values, the most effective inhibitor of this reaction would appear to be LDL.

With regard to HDL, our data confirm earlier reports by Carson that described inhibition of the bovine factor VIIa-tissue factor catalyzed activation of bovine factor X by purified human HDL and apolipoprotein A-II.[6,13] Both our data, and that of Carson,[13] suggest that a specific interaction between the Apo A-II and tissue factor occurs resulting in allosteric modifications of the tissue factor molecule.

Inasmuch as factor VIIa-tissue factor also activates factor IX in the test tube,[35] we examined whether or not the above lipoprotein preparations could inhibit the activation of factor IX at approximately the same enzyme-cofactor–substrate concentrations. Under these conditions, none of the lipoprotein preparations inhibited the activation of [^{3}H]-factor IX when present at a concentration that inhibited the factor X activation by 50%. When these incubation mixtures were supplemented with purified factor Xa (1 nmol/L), appreciable inhibition of factor IX activation was observed for the LDL and VLDL preparations. This factor Xa-dependent inhibition was, however, abolished on preincubation of LDL and VLDL with antibody raised against partially purified extrinsic pathway inhibitor. To our complete surprise, preincubation of LDL and VLDL with anti-EPI had no detectable effect on the ability of these lipoproteins to inhibit the activation of factor X by factor VIIa-tissue factor. Thus, these data provide suggestive evidence that LDL and VLDL inhibit the activation of factor IX by factor VIIa-tissue factor as a result of EPI associating and copurifying with these lipoprotein particles. On the other hand, HDL, LDL, and VLDL preparations appear to inhibit the activation of factor X by factor VIIa-tissue factor by a mechanism distinct from extrinsic pathway inhibitor. The precise mechanism whereby these lipoproteins selectively affect factor X activation without affecting factor IX activation is completely unknown. Presumably any proposed mechanism that involves either apolipoprotein exchange between lipoprotein and tissue factor, or the formation of a nonproductive complex between factor VIIa and lipoprotein would affect both reactions to the same degree. Furthermore, assuming our LDL and VLDL preparations were contaminated by EPI, we have no explanation as to why the inhibition of factor X activation by these lipoproteins was not diminished to any significant extent by prior incubation with anti-EPI–IgG. Presumably, sufficient nascent factor Xa was produced in our factor X activation system in a one-minute incubation period to form the factor VIIa-tissue factor-factor Xa ternary complex recognized by EPI present in the LDL and VLDL preparations prior to antibody treatment. Alternatively, in the event that the formation of this ternary complex was not instantaneous, the expression of EPI inhibitory activity may not have occurred under our experimental conditions. The possibility of a negative feedback reaction involving proteolysis of factor VIIa by newly formed factor Xa may play some role in the apparent inhibition of this reaction and cannot be excluded. However, in our experience, little, if any, proteolytic degradation of human factor VIIa by factor Xa was observed at a 1:100 factor Xa:factor VII ratio for one hour in the presence of mixed phospholipids and calcium (5 mmol/L). Whether or not degradation of factor VIIa by factor Xa is enhanced in the presence of tissue factor and/or lipoproteins remains to be determined.

Our findings, in addition to earlier reports[6,13] clearly underline the effectiveness of plasma lipoproteins to inhibit the activation of factor X in the test tube. Whether or not these reactions occur to any significant extent in vivo is unknown. Given the fact that the extrinsic pathway does not appear to be operative to any significant extent in hemophilic patients, the activation of factor IX by factor VIIa-tissue factor may be a very significant reaction in hemostasis. Indeed, experimental evidence indicates that the activation of factor X and factor IX by factor VIIa-tissue factor in human plasma proceeds at approximately the same rate.[7,36] It is tempting to speculate that lipoproteins may selectively promote the activation of factor IX by factor VIIa at low tissue factor concentrations through the inhibition of the factor X activation pathway. A description of the precise role, if any, that lipoproteins play in the regulation of extrinsic coagulation will obviously require several additional studies.

ACKNOWLEDGMENT

The authors are grateful to Drs Warn-Cramer and Rapaport for generously providing us with the anti-EPI-IgG preparation. The authors would also like to thank Ellen Choi for excellent technical assistance, and Adrienne Harkins for preparing the manuscript. The human therapeutic plasmapheresis plasma used in this study was generously provided by United Blood Services of Albuquerque.

CONCISE REPORT

Serum Transferrin Receptor as a New Index of Erythropoiesis

By Yutaka Kohgo, Yoshiro Niitsu, Hitoshi Kondo, Junji Kato, Nobuyasu Tsushima, Katsunori Sasaki, Michiaki Hirayama, Takaaki Numata, Takuji Nishisato, and Ichiro Urushizaki

Serum transferrin receptors were measured by a sandwich radioimmunoassay procedure in patients with iron deficiency anemia, autoimmune hemolytic anemia and aplastic anemia. The mean circulating transferrin receptor concentration of normal subjects and patients with iron deficiency anemia, autoimmune hemolytic anemia and aplastic anemia are 253 ± 82 ng/mL, 730 ± 391 ng/mL, 1,426 ± 1,079 ng/mL, and 182 ± 39 ng/mL, respectively. The values for those with iron deficiency anemia and autoimmune hemolytic anemia were significantly higher than that of normal controls and the values for those with aplastic anemia were lower than that of normal controls. After iron supplementation in iron deficiency anemia, the serum transferrin receptor values increased twofold over those of pretreatment values. This increase parallels an increase in peripheral reticulocytes. Therefore, the number of circulating transferrin receptors in anemic patients may reflect the level of bone marrow erythropoiesis and is a potentially useful new index for red cell production.

© 1987 by Grune & Stratton, Inc.

TRANSFERRIN receptor is a transmembrane glycoprotein that is expressed primarily on the surface of erythroid cells and delivers iron during proliferation and hemoglobin synthesis.[1,2] The receptor binds serum diferric transferrin and is endocytosed and transferred to acidosomes, in which inorganic iron is released into the cytosol and the remaining ligand and receptor is recycled back to the cell surface.[3] During this unique recycling process, transferrin receptor was found to be externalized as a form of multivesicular endosomes.[4,5] This externalization of transferrin receptors from the cell surface was first reported by Pan and Johnstone[4] using cultured sheep reticulocytes in vitro. The released receptors may potentially circulate in the serum. Recently, we established a quantitative method for measuring immunoreactive transferrin receptors by using two different monoclonal antibodies, OKT9 and B3/25[6] and found that immunoreactive transferrin receptor was detected at concentrations between 150 and 250 ng/mL. However, the clinical and pathophysiological significance of this circulating transferrin receptor is still obscure. In the present report, we evaluate the usefulness of circulating transferrin receptor as an index of erythropoiesis by measuring its serum level in patients with iron deficiency anemia, autoimmune hemolytic anemia, and aplastic anemia.

MATERIALS AND METHODS

Serum samples. Venous blood samples were taken from 38 normal adult males (age 18 to 72), 54 normal adult females (age 15 to 78), 41 patients with iron deficiency anemia, five patients with autoimmune hemolytic anemia, and five patients with aplastic anemia. The samples were collected before any treatments were started. Serial blood sampling was performed in ten patients with iron deficiency anemia and five patients with autoimmune hemolytic anemia for consecutive determination of serum transferrin receptor values. All serum samples were stored at −20°C until use.

Sandwich radioimmunoassay. Quantitation of immunoreactive serum transferrin receptors by a sandwich radioimmunoassay was performed as previously described.[6] Two monoclonal antibodies against the transferrin receptor, OKT9 and B3/25 were purchased from Ortho Diagnostic (Raritan, NJ) and Hybritech Inc (San Diego), respectively. Flat-bottomed polystyrene plates (Dynatech Lab, Alexandria, VA) were inoculated with 50 μL of OKT9 (10 μg/mL) overnight at 4°C. They were then washed and incubated for one hour at room temperature with 100 μL of phosphate buffered saline containing 1% bovine serum albumin (BSA, Sigma Chemical Co, St Louis) to prevent nonspecific binding. To each well in the plates, 40 μL of purified standard receptor (4 to 2,000 ng/mL) or serum samples was added. The standard transferrin receptors were obtained from human term placenta, which we reported previously.[5] The plates were then incubated another 18 hours at 4°C, washed, and overlayed with 40 μL of ^{125}I-labeled B3/25 (5×10^6 cpm/μg/0.5 mL). After additional incubation for 12 hours at 4°C, the plates were washed and the radioactivity of each well was determined. All samples were performed in triplicate. Radioiodination of proteins was carried out by the lactoperoxidase and glucose oxidase method using Enzymobeads (Bio-Rad, Richmond, VA).[7]

Assay for reticulocyte counts, hemoglobin concentration, serum iron, total iron binding capacity, and serum ferritin. Peripheral reticulocyte counts in 1,000 RBCs were determined by the method of Pappenheim.[8] Hemoglobin was measured by cyanomethemoglobin method.[9] Serum iron and total iron binding capacity (TIBC) were determined by the method of International Committee for Standardization in Haematology.[10,11] Serum ferritin was quantitated by SPAC ferritin kit (Daiichi Radioisotope Lab, Tokyo).[12]

Statistical analysis. Student's *t* test was used to assess the statistical significance of the results shown in the designated tables.

RESULTS

Serum transferrin receptor levels in normal subjects and patients with various anemias are shown in Table 1. The mean values for healthy males and females were 251 ± 94 ng/mL (mean ± 1 SD) (n = 38) and 256 ± 99 ng/mL (n = 54), respectively. No significant differences because of sex or age were observed. The mean values for nontreated patients with iron deficiency anemia and autoimmune hemolytic anemia were 730 ± 391 ng/mL and 1,426 ± 1,079 ng/mL, respectively, both of which were significantly higher than

Table 1. Serum Transferrin Receptor Levels in Normal Subjects and Patients With Iron Deficiency Anemia, Autoimmune Hemolytic Anemia, and Aplastic Anemia

Diagnosis	No. of Cases	Serum Transferrin Receptor (ng/mL)*	Range	*P* Value†
Normal subjects	92	253 ± 82	70-440	—
Male	38	251 ± 94	80-420	—
Female	54	256 ± 99	70-440	—
Iron deficiency anemia				
Before treatment	41	730 ± 391	100-1,700	<.001
During treatment	14	1,016 ± 326	460-1,800	<.001
After tretment	7	350 ± 147	160-520	NS
Autoimmune hemolytic anemia				
Before treatment	5	1,426 ± 1,079	400-3,010	<.05
After treatment	5	538 ± 150	380-750	<.01
Aplastic anemia	5	182 ± 39	140-240	<.02

In hemolytic anemia, the same five patients were studied before and after treatment with prednisolone.

*Data are expressed as mean ± 1 SD.

†Statistically significant difference from normal values by Student's *t* test.

those of normal subjects. On the other hand, the mean concentration for patients with aplastic anemia was 182 ± 39 ng/mL, which was significantly lower than that of normal subjects. During the iron supplementation in patients with iron deficiency anemia, the concentration increased up to 1,016 ± 326 ng/mL, while the absolute reticulocyte count increased from 2.42 ± 0.97 × $10^4/\mu L$ to 7.30 ± 4.09 × $10^4/\mu L$. Therefore, it seemed that the increase of serum transferrin receptor correlated well with the increase in reticulocytes. After the hemoglobin values were normalized by successful treatment with iron supplementation, the mean value returned to the normal range (350 ± 147 ng/mL) in association with the decreased reticulocyte counts (5.16 ± 1.61 × $10^4/\mu L$). In patients with autoimmune hemolytic anemia, the significant decrease of serum transferrin receptor was observed after effective therapy of prednisolone. The absolute reticulocyte counts before and after steroid therapy were 36.1 ± 6.4 × $10^4/\mu L$ and 15.7 ± 5.8 × $10^4/\mu L$, respectively, indicating that the decline of transferrin receptor in autoimmune hemolytic anemia paralleled the decrease of reticulocyte counts and the improvement of hemoglobin concentration.

Table 2 demonstrates the correlation between serum transferrin receptor values and other hematological parameters such as reticulocyte counts, hemoglobin concentration, TIBC, serum iron, and serum ferritin in patients with iron deficiency anemia and hemolytic anemia. There was a good correlation between serum transferrin receptor and reticulocyte counts in both conditions, suggesting that the increased serum transferrin receptor values may reflect the increase of reticulocytes and bone marrow erythroid cells. In patients with iron deficiency anemia, significant positive or negative correlations were observed between serum transferrin receptor and other markers such as TIBC, serum iron, and serum ferritin concentration, whereas no other correlations were observed in autoimmune hemolytic anemia.

The serial change of serum transferrin receptor values in a patient with iron deficiency anemia supplemented with intravenous (IV) iron administration and in a patient with autoimmune hemolytic anemia treated with prednisolone is shown in Fig. 1. Just after the initiation of iron supplementation, a transient increase of serum transferrin receptors was obtained, and thereafter the values increased again in association with increased reticulocyte counts and returned to normal levels with the improvement of anemia (Fig 1A). In a patient with hemolytic anemia, the serum transferrin receptor level also seems to parallel reticulocyte counts (Fig 1B).

DISCUSSION

We previously reported that immunoreactive transferrin receptor could be detected in human serum by a sandwich radioimmunoassay technique, although no clinical significance was elucidated.[6] In the present report, we measured the receptor concentration in various anemias and obtained the higher values in iron deficiency anemia and autoimmune

hemolytic anemia and lower values in aplastic anemia (Table 1). These values paralleled the peripheral reticulocyte counts (Table 2), suggesting that the serum transferrin receptors may reflect the turnover of transferrin receptors in erythrocyte progenitor cells in the bone marrow.

Since Jandl and Katz[13] first reported the presence of transferrin receptors on the reticulocyte surface, erythrocyte progenitor cells have been considered the main source of transferrin receptors in the body as well as syntrophoblasts of placenta and malignant tissues.[1] The overall dynamics of transferrin receptors has been extensively studied using the erythroleukemia cell line, K562[3], and the expression of transferrin receptors is thought to be regulated by the equilibrium between its recycling and synthesis. Receptor mRNA synthesis is increased with the addition of iron deficient serum and iron chelating agents in vitro.[14] Therefore, it is likely that the reticulocytes in iron deficiency anemia may possess more receptors than usual.

Good correlations between serum transferrin receptor value and markers such as TIBC, serum iron, and serum ferritin were present only in iron deficiency anemia but not in autoimmune hemolytic anemia (Table 2). This result may explain that there is a double effect in iron deficiency anemia, ie, iron deficiency and erythropoiesis. Actually, in autoimmune hemolytic anemia, which could exclude the effect of iron deficiency, there is no correlation with TIBC, serum iron or serum ferritin.

According to Pan and Johnstone,[4] the receptors of reticulocytes were shed and released into the medium. We also found the same phenomenon in K562 cells.[5] The shedding of transferrin receptor was inhibited by metabolic inhibitors such as cytochalasin B, colchicine, and sodium azide. The presence of ligand, on the other hand, increased this externalization. These results suggest that this externalization of receptor is a ligand-dependent and energy-dependent process. Therefore the measurement of shed circulating receptors in the serum seems to be a practical and efficient way for estimating erythrocyte transferrin receptor turnover. The lower levels in aplastic anemia reflect decreased erythropoiesis in the bone marrow. Interestingly, the biphasic increase of serum transferrin receptor levels was obtained in the clinical course of iron deficiency anemia during which IV iron was supplemented (Fig 1A). The transient increase was observed just after iron supplementation and the second increase was observed two to three days before the increase in reticulocytes. The first increase, just after iron supplementation, may be explained by the transient increase of receptor shedding according to the increase of serum diferric transferrin, which facilitates the internalization and recycling-shedding process of the receptors. On the other hand, the second increase paralleled the reticulocyte increase may reflect the increase of erythron, namely the accelerated division and proliferation of erythroid precursor cells by incorporation of iron into the cells. It is noteworthy that serum transferrin receptor appeared two to three days before the increase in reticulocytes. In patients with autoimmune hemolytic anemia, the serum transferrin receptor level also seems to parallel reticulocyte counts (Fig 1B) and the serial determination was useful for monitoring the activity of the bone marrow erythroid mass. Therefore, the measurement of serum transferrin receptor is a simple and rapid method for estimation of erythropoiesis, formerly estimated by reticulocyte counts or complicated ferrokinetic measurements such as plasma iron turnover (PIT) and percent red cell use (%RCU).[15] In conclusion, the measurement of circulating transferrin receptor in patients with various anemias may be a useful new index for estimating the bone marrow erythropoiesis.

CONCISE REPORT

Coordinate Glycosylation and Cell Surface Expression of Glycophorin A During Normal Human Erythropoiesis

By Michael R. Loken, Curt I. Civin, William L. Bigbee, Richard G. Langlois, and Ronald H. Jensen

The expression of two epitopes on glycophorin A (GPA) during erythroid development was examined on normal human bone marrow using quantitative flow cytometry. The highly correlated binding of two monoclonal antibodies, one sensitive and the other insensitive to glycosylation, indicated that the two epitopes were coordinately expressed during erythroid development. Both antigens reached a maximum expression during the early normoblast stage and were maintained at a constant amount per cell throughout further maturation to erythrocytes. These data suggest that glycosylation of GPA, as detected by antibodies recognizing blood group (M) and (N) antigens, does not increase during erythroid maturation.

©1987 by Grune & Stratton, Inc.

GLYCOPHORIN A (GPA) is the major sialoglycoprotein of the human erythrocyte membrane.[1,2] This protein is restricted to the erythroid lineage.[3] Cell surface expression of GPA is first detected at the erythroblast stage of development, after the cells can no longer form erythroid colonies.[3,4] GPA occurs in two allelic forms corresponding to the (M) and (N) antigens of the MN blood group.[5,6] The (M) and (N) antigens are identical except for two amino acid differences in the amino terminal region, but 0-linked tetrasaccharides in this region are required for the binding of many (M) and (N) specific antibodies.[7-9]

Biochemical analyses of cell lines (K562 and HEL) stimulated to undergo maturation and comparisons of abnormal with normal bone marrow suggested that GPA acquired an increased number of 0-linked tetrasaccharides when the erythroid cells matured.[10] These conclusions were supported by experiments using antibodies that detected (M) and (N) blood group antigens.[11]

In studying the expression of GPA during normal erythropoiesis, we showed that GPA reached maximal expression at the basophilic normoblast stage and remained in a constant amount per cell throughout further maturation to the erythrocyte.[4] The reported late glycosylation of GPA during erythrocyte development was difficult to explain in light of this invariance of amount of GPA on the maturing erythroid cells. Therefore, we investigated the correlated expression of two epitopes of GPA during erythropoiesis using monoclonal antibodies, one epitope was insensitive to glycosylation while the other required intact tetrasaccharides.

MATERIALS AND METHODS

Monoclonal antibodies. Anti-GPA (M) (9A3) binds only to type (M) glycophorin A while anti-GPA (M/N) (10F7) identifies both types (M) and (N) GPA.[12-14] Fluorescein isothiocyanate (FITC) was used to prepare directly conjugated 10F7.[15] Rat anti-mouse kappa phycoerythrin (PE) and isotype control IgG_1 FITC was obtained from Becton Dickinson Immunocytometry Systems, Mountain View, CA.[16]

Cell preparation and immunofluorescence. Bone marrow aspirates were obtained from three consenting normal adult volunteers. Collection of samples was performed after approval by the Institutional Review Board, as approved by the Department of Health and Human Services. The low-density leukocytes (1.077 g/mL) were stained using indirect immunofluorescent as described.[4] Briefly, 10^6 cells were incubated sequentially with anti-GPA(M), rat anti-mouse kappa PE, 10% normal mouse serum, and anti-GPA(M/N) FITC with a wash interspersed between each step. As a negative control an IgG_1 FITC monoclonal antibody with irrelevant specificity was used in place of the anti-GPA (M/N). The cells were fixed in 1% paraformaldehyde for later analysis.[17] Some bone marrow cells were incubated with 0.5 IU neuraminidase for one hour at 37°C (Sigma, St Louis) before immunofluorescence staining.[12] The data from three separate experiments gave identical results.

Flow cytometry. Quantitative fluorescence analyses were performed on a FACS 440 (Becton Dickinson) using the filter combinations previously described.[18] Linear amplifiers were used for the light scattering signals, while 4-decade logarithmic amplifiers were used for the fluorescence signals. A minimum of 20,000 events were collected in list mode with contour levels drawn at 2, 4, 8, 16, 32, 64, and 128.

RESULTS

All immunofluorescence analyses were performed by gating on either the "Lymph" or the "Blast" light scattering populations identified for normal bone marrow (Fig 1). No staining above background was found for either the anti-GPA (M) specific or the anti-GPA (M/N) binding antibody on cells which were in the "Gran" light scattering window (data not shown).

The indirect immunofluorescence staining with the anti-GPA (M) specific antibody used rat anti-mouse kappa PE as a second step. A distinct population of labeled cells was observed in both the "Lymph" and "Blast" light scattering windows (Fig 2A). The lack of staining with the negative control, IgG_1 FITC, indicated that there was complete blocking of the free valencies of the rat anti-mouse kappa PE by normal mouse serum used in the staining protocol.

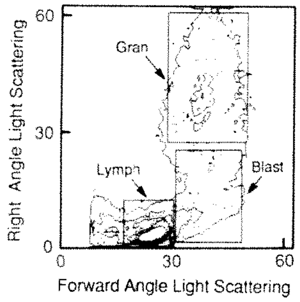

Fig 1. Correlation of forward and right angle light scattering of low density human bone marrow after immunofluorescence staining and fixation. Three populations of cells are identifiable in this plot:"Lymph" including lymphocytes, mature erythrocytes, and late normoblasts; "Blast" including early normoblasts, erythroblasts, monocytes, monoblasts, and myeloblasts; "Gran" exclusively neutrophil lineage from promyelocyte to mature neutrophil.[4] The fluorescence data in Fig 2 were gated on either the "Lymph" or "Blast" light scattering window. The differences observed between this light scattering pattern and that previously reported are a consequence of the fixation of the cells.[4]

When the anti-GPA (M) and anti-GPA (M/N) antibodies were used together to stain the sample, they bound to the same cells (Fig 2B). There were no cells that stained with the anti-GPA (M) (9A3) antibody that did not also bind the anti-GPA (M/N) (10F7) antibody and vice versa. In addition, there was a tight quantitative correlation of binding of the two antibodies on the cells (Fig 2B, "Blast"). The intensity of fluorescence of the anti-GPA (M) staining was the same whether or not the anti-GPA (M/N) was bound to the cells. These data suggest that the two antibodies identified the same antigen but bound at different epitopes[19] since they did not inhibit the attachment of the other antibody.

An aliquot of the same bone marrow preparation was treated with neuraminidase (which selectively removes sialic acid residues) before immunofluorescence labeling by the two anti-GPA antibodies. Binding of anti-GPA (M) was lost with the removal of the terminal sialic acid residues while no difference in intensity of anti-GPA (M/N) binding (Fig 2C). This illustrated the absolute requirement of the terminal sialic acids for the binding of the (M) specific antibody. This enzymatic treatment had no effect on the binding of the anti GPA (M/N) antibody.

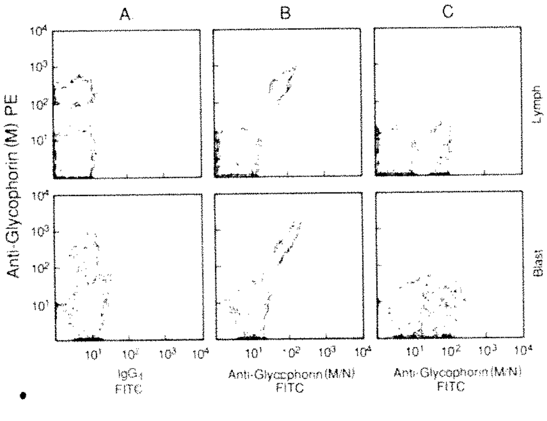

Fig 2. Correlation between anti-GPA (M) specific and anti-GPA (M/N) reactive monoclonal antibodies on normal human bone marrow. (A) Comparison of anti-GPA (M) specific antibody with a negative control of IgG, FITC. (B) Fluorescence analysis of marrow cells double labeled with anti-GPA (M) and anti-GPA (M/N) antibodies. (C) Fluorescence analysis of marrow cells treated with neuraminidase before labeling with both anti-GPA (M) and anti-GPA (M/N) antibodies.

DISCUSSION

Both of the anti-GPA monoclonal antibodies used in this study recognize the amino terminal peptide of the glycophorin A molecule with essentially no reactivity with glycophorin B.[12] The anti-GPA (M) specific antibody (9A3) requires the terminal sialic acid residues for binding, as shown previously on erythrocytes[12] and, in this study, on less mature erythroid lineage cells (Fig 2C). The binding of the anti-GPA (M/N) antibody (10F7) is unaffected by neuraminidase treatment, both on mature erythrocytes and on immature erythroid cells (Fig 2C).[12] Anti-GPA (M/N) also reacts with cells which lack all but the first carbohydrate residue of the tetrasaccharides on the GPA.[13] These data suggest that the anti-GPA (M/N) probably binds to a glycosylation insensitive site somewhat removed from the *N*-terminus.[12]

The highly correlated expression of the two epitopes shown in Fig 2B suggests that the two antibodies identify not only the same populations but that the two epitopes were coordinately expressed on those cells. Since all maturational stages of erythroid development are represented in the normal bone marrow, these data indicate that the two epitopes appear at the same time during erythroid maturation. Thus, GPA is sialated at the time that it is first expressed on the cell surface.

The morphological analysis of cells sorted on the basis of GPA intensity indicated that GPA first appears during the erythroblast stage.[4] Cells with intermediate amounts of GPA were >90% erythroblasts while those expressing maximal amounts of GPA were predominantly normoblasts. The less mature normoblasts were larger than the more mature cells and could be distinguished by light scattering differences. Since both the anti-GPA (M/N) and anti-GPA (M) epitopes follow the same pattern of expression during maturation, it can be concluded that there is no change in the sialic acid residues on these epitopes on GPA after the erythroblast stage. The anti-GPA (M/N) and the anti-GPA (M) epitopes both reach a maximum amount per cell and remain constant during further maturation of the cells to erythrocytes.

If there were glycosylation during the later normoblast stages of maturation, a discordance in immunofluorescence staining would be observed, as has been demonstrated with other erythroid cell surface antigens such as transferrin receptor and CD45 (common leukocyte antigen).[4]

The observations by Ekblom et al may have resulted from less precise quantitation of the binding of their monoclonal antibodies and their rabbit antiserum.[10,11] In addition, the flow cytometric experiments detected only cell surface antigens while immunofluorescence staining after fixation on a slide identified both cell surface and cytoplasmic antigens.[11]

CONCISE REPORT

tdic(9;12): A Nonrandom Chromosome Abnormality in Childhood B-Cell Precursor Acute Lymphoblastic Leukemia: A Pediatric Oncology Group Study

By Andrew J. Carroll, Susana C. Raimondi, Dorothy L. Williams, Frederick G. Behm, Michael Borowitz, Robert P. Castleberry, Michael B. Harris, Richard B. Patterson, D. Jeanette Pullen, and William M. Crist

In a review of 432 children with newly diagnosed acute lymphoblastic leukemia (ALL), we identified a new nonrandom translocation, tdic(9;12)(p1?1;p1?2), in the leukemic marrow cells of eight patients. Seven had hypodiploid karyotypes that lacked chromosomes 9 and 12 and contained a der(12), tdic(9;12); the eighth had a pseudodiploid karyotype with two normal 9 chromosomes, one normal 12 and the der(12), tdic(9;12). Abnormalities involving chromosomes other than 9 and 12 were noted in four of the eight patients. All cells with the tdic(9;12) expressed both the common ALL antigen and HLA-DR. Cytoplasmic immunoglobulin, a marker of pre-B ALL, was detected in one case with the tdic(9;12) but was absent in the other seven. Our results suggest that the tdic(9;12)(p1?1;p1?2) rearrangement is specifically associated with leukemic B cell precursors.

© 1987 by Grune & Stratton, Inc.

CHROMOSOMAL rearrangements have been identified as the single most important prognostic variable in childhood acute lymphoblastic leukemia (ALL).[1] Moreover, certain nonrandom rearrangements, including the t(4;11) in infants with undifferentiated acute leukemia, the t(8;14) in B cell ALL, the t(1;19) in pre-B cell ALL,[2,3] and the t(11;14) and t(10;14) in T cell ALL,[3,4] are associated with specific clinically and immunologically defined subclasses of ALL. Other chromosomal abnormalities often found in the blast cells of patients with ALL include the t(9;22),[5] 6q−[5] and a deletion or rearrangement of 9p[6-9] and of 12p.[10,11] These structural abnormalities are usually found in pseudodiploid karyotypes and are seen less frequently in other ploidy groups. We have reviewed the cytogenetic features of 432 children with newly diagnosed ALL and have found a new nonrandom translocation, tdic(9;12)(p1?1;p1?2), in the leukemic B cell precursors of eight patients, seven of whom had hypodiploid karyotypes.

MATERIALS AND METHODS

Patients. A total of 432 consecutive cases of ALL with fully banded chromosomes were available for review. Their distribution according to referral center was: St Jude Children's Research Hospital, 187 cases studied between 1984 and 1986; University of Alabama at Birmingham (UAB), 100 cases studied between 1979 and 1985; and the Pediatric Oncology Group (POG) 8600 study, 145 cases in which marrow specimens were shipped to the UAB cytogenetics laboratory for chromosome analysis between January and June 1986. All patients were advised of the procedures and attendant risks, in accordance with institutional guidelines, and informed consent was obtained in each instance.

Immunologic characterization. After separation on a Ficoll-Hypaque gradient, the leukemic marrow cells were evaluated by standard techniques for surface immunoglobulins (sIg),[12] cytoplasmic immunoglobulins (cIg),[13] and receptors for sheep erythrocytes.[14] In cases of pre-B cell or B cell ALL, >10% of the blasts expressed either cIg or sIg. A case was considered E-rosette positive if >40% of the blasts formed heat stable E-rosettes. Surface antigens, including CALLA (CD10), B1 (CD20), and HLA-DR, were determined by indirect immunofluorescence or, in some cases, by microcytotoxicity assays with use of heteroantisera, as previously described.[15] In the cytotoxicity assays, 20% reactivity above control was considered positive in immunofluorescence.

Chromosome analysis. Bone marrow samples from the 187 patients studied at St Jude Hospital were processed directly according to the method of Williams et al.[16] Samples from the 100 patients seen at UAB were either processed directly or placed in short-term culture, or both.[9] Samples from the 145 POG patients were placed in RPMI 1640 supplemented with 15% fetal calf serum and shipped overnight to the UAB cytogenetics laboratory. On arrival, they were subjected to short-term (24 hour) culture.[9] Routine methods were used for culture harvest, slide preparation, and GTG-banding. Karyotypic designations were assigned according to the International System for Human Cytogenetic Nomenclature.[17]

RESULTS

Three hundred twenty-eight (76%) of the 432 cases studied had a cytogenetically abnormal clone, eight of which (Table 1) showed a translocation involving chromosomes 9 and 12. The resulting derivative chromosome appeared to be dicentric with breakpoints tentatively assigned at 9p11 and 12p12; consequently, the rearrangement was designated tdic(9;12)(p1?1;p1?2)(Fig 1). We are aware that, on close examination of the derivative chromosomes shown in Fig 1, it could be reasonably suggested that the chromosome breakpoints are slightly different in each of the three cases. While we cannot rule out case to case variation in breakpoints, it is also possible that the apparent differences are the result of contracted chromosomes since we observed a similar degree

8	20	75	46,XY,−12,+der(12),tdic(9;12)(p11;p12)(60%)/45,XY,−8,−9,−12+der(8),t(8;9)(p23;q13),+der(12),tdic(9;12)(p11;p12)(15%)

of variation between metaphases from individual patient cultures. The fact that the alternate derivative chromosome, containing the remaining short-arm material from chromosomes 9 and 12, was absent in all eight cases supports our contention that the translocation results in a dicentric chromosome. Furthermore, C-banding demonstrated the presence of the 9qh region on the der(12) chromosome in each of the three cases examined in this manner. Seven cases were hypodiploid, lacking a 9 and a 12 chromosome, and contained a der(12),tdic(9;12). The eighth case had a pseudodiploid karyotype with two normal 9 chromosomes, one normal 12 and the der(12),tdic(9;12). Abnormalities involving chromosomes other than 9 and 12 were noted in four of the eight cases. One case had two cytogenetically abnormal clones, both with the tdic(9;12). The proportions of cytogenetically normal cells in each case ranged from 5% to 80%.

Table 2 lists the clinical and laboratory findings in the eight cases with the tdic(9;12). Blast cells uniformly expressed both CALLA and HLA-DR. In five of seven cases in which it was determined, blast cells also expressed CD20 (B1). In seven cases the blast cells were morphologically classified as FAB L1. Cytoplasmic Ig was detected in one case. With the possible exception of male predominance (M:F ratio, 7:1), there were no obvious variations in clinical features that would distinguish these patients from the larger group with B cell precursor ALL lacking the tdic(9;12). Leukocyte counts ranged from 2.9 to 132 × 10^9/L and ages from 3 to 16 years. Three patients had extramedullary disease at the time of the diagnosis.

DISCUSSION

These results suggest that a rearrangement involving the short arms of chromosomes 9 and 12, tdic(9;12)(p1?1;p1?2) is an acquired, nonrandom chromosome abnormality with a frequency of ~2% among children with ALL. It appears to be limited to cases of B cell precursor ALL, specifically those

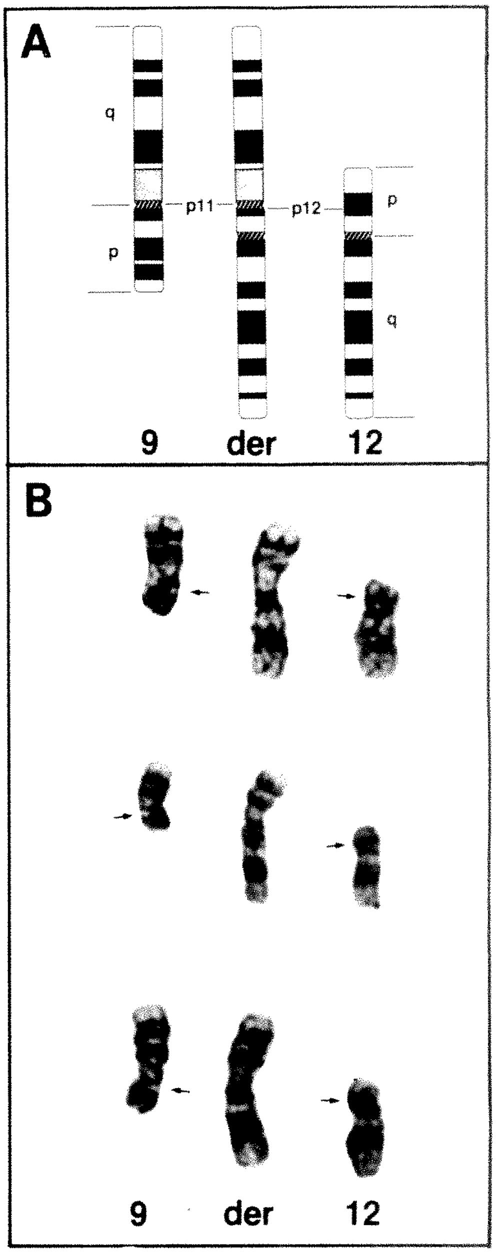

Fig 1. The tdic(9;12)(p1?1;p1?2) associated with B cell precursor ALL. (A) Diagram showing the G-banded pattern of the derivative (der) chromosome and normal homologues involved in the tdic(9;12). (B) Representative partial karyotypes from three different patients with the tdic(9;12). Top, case no. 1; middle, case no. 6; and bottom, case no. 8. The arrows indicate the approximate positions of the breakpoints.

characterized by CALLA, HLA-DR, and usually CD20 expression, a phenotype seen in 25% to 30% of cases of ALL in children. It may occur much more frequently in boys, as has been noted for chromosome 9p abnormalities in ALL.[6,7,9]

We are aware of only two other reports of a similar 9;12 translocation. The LAZ 221 cell line, established from the peripheral blood of a patient with "null" cell ALL, was characterized as having a karyotype of 45,XX,−9,−12,

Table 2. Clinical and Laboratory Findings for the Eight Cases With tdic(9;12)

Case No.	FAB Type	Age(yr)	Sex	WBC (× 10/L)	Hb (mg/dL)	Immunophenotype	Cell Markers CALLA	HLA-DR	B1	Extramedullary Disease
1	L1	3	M	2.9	4.1	Common	+	+	+	−
2	L1	16	M	6.1	12.3	Common	+	+	+	−
3	L1	15	M	19.0	11.2	Common	+	+	+	+
4	L1	4	M	15.1	8.7	Common	+	+	−	−

Abbreviation: NT, not tested.

+t(9q12q).[18] In a review of 70 cases of ALL, Heerema et al[19] identified a child whose blast cell karyotype was 45,XY,−9,−12,+der(12),t(9;12)(q1;p13). Further examination of this case indicated that the abnormality was the same as that in our eight cases (N.A. Heerema, personal communication, January 1987).

Deletions or rearrangements involving the short arm of chromosome 9 or the short arm of chromosome 12 seem to be equally common among children with ALL, with each occurring in ~10% newly diagnosed cases.[6-11] Thus, the tdic(9;12) may define a distinct subgroup of patients who could be included in either or both of these cytogenetic categories. In fact, cases no. 2, 5, and 6 were previously included in reports describing 9p or 12p abnormalities.[8-11] In addition, cases no. 3 through 5 were included in a report[20] concerning hypodiploidy and its association with treatment outcome in childhood ALL.

Many nonrandom chromosomal translocations associated with chronic or acute leukemia involve breakpoints at or near the assigned loci for genes encoding proteins that affect cell growth. In view of the fact that the c-Kirsten-*ras* 2 oncogene has been mapped to 12p11.1-p12.1,[21] molecular studies of cases with the tdic(9;12) appear warranted.

The clinical significance of the tdic(9;12) is uncertain since so few patients with the abnormality have been reported and the follow-up times for most of them are short. Nevertheless, all eight patients described in this report attained complete remission and remain free of leukemia for 5 to 36 months (median, 10 months). Previous reports indicating that the presence of a chromosomal translocation[1] or hypodiploidy[20] confers a poor prognosis suggest that patients with the tdic(9;12) are at increased risk for treatment failure; however, longer follow-up is required to substantiate this impression.

CONCISE REPORT

Host Origin of the Human Hematopoietic Microenvironment Following Allogeneic Bone Marrow Transplantation

By Joseph Laver, Suresh C. Jhanwar, Richard J. O'Reilly, and Hugo Castro-Malaspina

The origin of marrow stromal cells post allogeneic bone marrow transplantation (BMT) was studied. Two groups of patients receiving HLA-identical marrow grafts from sex mismatched siblings were included in the study: the first group (eight patients) received conventional marrow grafts and the second group (ten patients) received stromal cell and T cell depleted grafts. All patients showed hematopoietic engraftment with donor cells. Marrow aspirates obtained from these patients were used to establish stromal layers in long-term marrow cultures (LTMC) for 4 to 6 weeks. In both groups, karyotype analysis of nonhematopoietic cultured stromal cells showed host origin even as late as day 760 posttransplantation. Immunofluorescence methods using monoclonal antibodies against components of fibroblasts, macrophages, and endothelial cells, showed that the composition of stromal layers was similar to those obtained from normal controls. Our data indicate that marrow stromal progenitors capable of proliferation are nontransplantable and do not originate from a hematopoietic-stromal common progenitor.

© 1987 by Grune & Stratton, Inc.

AN INTACT hematopoietic microenvironment is required for successful engraftment of donor hematopoietic stem cells.[1] The origin (host *v* donor) of this marrow compartment following bone marrow transplantation (BMT) is still controversial. Keating et al[2] reported that the microenvironment becomes progressively of donor origin, while other studies assessing stromal cell subpopulations suggested a host origin.[3,4] Donor origin would imply that stromal engraftment is required for successful marrow transplantation, whereas host origin would imply that the indigenous stroma remains functionally active following preparatory pretransplant treatment. In case of host origin, the design of new aggressive cytoreductive protocols should consider the effects of such therapy on the marrow microenvironment. Since failure or delay of hematopoietic reconstitution might be due to an impaired marrow microenvironment, it is important to determine the origin of these cells. A better understanding of the origin of marrow stromal cells can be reached by comparative analysis of stromal and hematopoietic reconstitution in recipients of stromal cell-containing and stromal cell-depleted marrows. The latter marrow grafts that are depleted of stromal cells by soybean lectin agglutination,[5] provide a unique model for studying the transplantability and the origin of stromal cells following BMT. In this study, we have addressed these questions by using chromosomal analysis of cultured marrow microenvironmental cells derived from patients who had received either conventional or stromal depleted marrow grafts from HLA-identical donors, and showed host origin in all instances.

MATERIALS AND METHODS

Patients. Eighteen patients who received allogeneic marrow grafts from sex mismatched HLA identical siblings were studied. After informed consent was obtained, patients were prepared for transplantation with hyperfractionated total body irradiation and cyclophosphamide (except one patient with severe aplastic anemia who received total lymphoid irradiation and cyclophosphamide).[6] Eight patients received conventional grafts and ten received marrows depleted of stromal progenitors and T cells. The separation method, involving soybean agglutination and E-rosetting (SBA), was originally used to eliminate T cells[7] and was subsequently found to deplete stromal progenitors as well.[5]

Long-term marrow cultures. Bone marrow aspirates post-BMT were obtained at 14 to 760 days in the conventional group and 14 to 563 days in the SBA separated group. Long-term cultures of human marrow (LTMC) were established according to the method of Gartner and Kaplan[8] with some modifications.[9] Briefly, 20×10^6 marrow buffy coat cells in 10 mL of LTMC medium were inoculated into T-25 tissue culture flasks. Cultures were then gassed with 5% CO_2 in air and incubated at 33°C. The LTMC medium consisted of supplemented McCoy's 5A medium containing 12.5% horse serum, 12.5% FCS and 10^{-6} mol/L hydrocortisone sodium succinate (Calbiochem-Behring, La Jolla, CA). At weekly intervals, half the supernatant medium and suspension cells were removed and replaced with fresh LTMC medium. The development of marrow stromal layers was assessed every seven days under a phase contrast inverted microscope and the percentage of the flask surface covered by the stromal interlocking network was visually estimated and recorded.

To evaluate the composition of the adherent stromal cells in culture we used immunofluorescence methods using antibodies to components of fibroblasts (collagen type III and fibronectin), endothelial cells (factor VIII related antigen), and macrophages (monocyte surface molecules recognized by 63D3 and 61D3 mouse monoclonal antibodies), as previously described.[9]

Cytogenetic studies. To assess the origin of hematopoietic and stromal cells, chromosomal analysis of fresh bone marrow cells and trypsinized LTMC stromal cells was performed using quinacrine dihydrochloride staining (Q-banding).[10] The binomial distribution was used to calculate the probability to identify donor stromal cells derived from LTMC.

RESULTS

The eighteen patients included in this study showed engraftment with donor hematopoietic cells. Hematopoietic cells remained of donor origin throughout the study period. In contrast, chromosomal analysis of cultured stromal cells in 4 to 6-week-old LTMC showed host origin in recipients of either unmodified (group 1) or stromal cell depleted marrow grafts (group 2) (Tables 1 and 2). In both groups the composition of stromal layers in LTMC derived from marrows obtained over day 35 of the BMT was similar to that seen in normal controls and included fibroblasts, lipid-containing cells, macrophages, and 5% to 10% endothelial cells (Table 3). In group 1, 311 stromal metaphases were studied. All, including 158 over day 100 post-BMT, showed host origin. In group 2, 367 metaphases including 273 over day 100 post-BMT were studied showing host stromal origin. It is unlikely that the presence of donor stroma was missed as the probability to do so is extremely low. For instance, if the frequency of donor stromal cells was 5%, the probability that none would be identified in a random sample of over 300 metaphases is <0.1%. Furthermore, in our laboratories we have been able to identify as low as 3% mosaicism in marrow specimens obtained after marrow transplantation.

DISCUSSION

The data presented show the host origin of cultured marrow stromal cells obtained from patients successfully transplanted with allogeneic grafts. These findings suggest that chemoradiotherapy used for myeloablation does not fully ablate marrow stromal progenitors. Achievement of successful hematopoietic engraftment in these patients indicates that the host microenvironment plays an important role in the posttransplant period: In the early stages it provides favorable conditions for hematopoietic engraftment, and later it reconstitutes a functional microenvironment capable of sustaining hematopoiesis. Since the reconstitution of the marrow microenvironment requires proliferation of stromal

Table 3. Cellular Composition of Stromal Layers in Long-Term Marrow Culture

	Relative Frequency*	
Cell Type	Stromal Layers Derived From Post-BMT Marrows	Stromal Layers Derived From Normal Marrows
Fibroblast	+ + + +	+ + + +
Adipocyte	+ +	+ +
Endothelial cell	+	+
Macrophage	+ + +	+ + +

The cellular composition was assessed by immunofluorescence staining with antisera against type III collagen and fibronectin for fibroblasts, and against factor VIII-related antigen for endothelial cells, as well as monoclonal antibodies recognizing monocytic antigens and by light microscopy for adipocytes. The presence and relative amount of different cell types were assessed semiquantitatively by grading their frequency from + to + + + +: +5% to 10%; + +, 11% to 25%; + + +, 26% to 50%; + + + +, 50%.

*Cultures were initiated with 20 × 10^6 marrow cells per flask and after six weeks of incubation adherent layers were examined for their cellular composition.

progenitors it is important to determine the origin of stromal cells capable of undergoing mitosis.

Our results showing host origin of proliferating marrow microenvironmental cells following BMT suggest that stromal progenitors are nontransplantable. The apparent discrepancy between our results and those reported by Keating et al[2] can be explained by the differences in the techniques used to assess cultured stromal cells and the type of cells analyzed by these methods. We used chromosomal analysis, which determines the origin of stromal cells capable of undergoing mitosis, whereas Keating by determining the presence of the Y-body chromosome analyzed nondividing cells (cells in interphase). Identifying donor derived macrophages that are abundantly present in stromal layers with the Y-body method could lead to the incorrect conclusion that stromal cells post BMT are of donor origin. In contrast, chromosomal analysis assesses only cells undergoing mitosis and excludes differentiated nondividing cells such as macrophages. Using karyotype analysis, other investigators have also shown that certain stromal elements, such as marrow fibroblasts and reticulofibroblastoid cells, are of host origin following allogeneic unmodified marrow grafts.[3,4] Analogous discrepancy exists regarding the origin of stromal cells in patients with clonal hematopoietic disorders such as chronic myelocytic leukemia. This, once again, can be explained by the different cell populations used for study (dividing *v* nondividing cells). Chromosomal analysis has demonstrated that stromal cells do not originate in the malignant clone[3,11] whereas G6PD studies[12] of nondividing cells in patients heterozygous for types A and B of the enzyme, have suggested that stromal cells arise from the malignant hematopoietic clone.

In addition to the nontransplantability of marrow stromal cells, our data are against the notion of a common hematopoietic-stromal progenitor. Marrow transplantation with SBA separated grafts provides a unique model to answer whether stromal and hematopoietic cells share a common progenitor. Following BMT, a microenvironment of donor origin could develop through two possible mechanisms: (1) engraftment with a common stromal-hematopoietic progenitor giving rise to both marrow compartments, or (2) engraftment with a transplantable stromal progenitor that gives rise only to stromal cells and not to hematopoietic cells. Conventional marrow grafts containing stromal and hematopoietic progenitors cannot discriminate between these two mechanisms, whereas marrow grafts depleted of stromal progenitors by eliminating the second possibility can be used to test the first mechanism. Our results with stromal depleted marrow grafts showing engraftment with donor hematopoietic cells without the emergence of donor stromal cells, rule out the hypothesis that stromal and hematopoietic cells share a common progenitor.

ANNOUNCEMENTS

AMERICAN BOARD OF INTERNAL MEDICINE
1988 SUBSPECIALTY EXAMINATIONS IN HEMATOLOGY

Registration Period: January 1, 1988-April 1, 1988
Examination Date: November 1, 1988

For information and application form, contact: Registration Section, American Board of Internal Medicine, 3624 Market Street, Philadelphia, PA 19104.

ONCOLOGY PRACTICE 1988: A PERSPECTIVE

January 31-February 6, 1988
Snowmass, Colorado

For further information, contact: Stephen E. Jones, MD, Charles A. Sammons Cancer Center, Room 4800, Baylor University Medical Center, 3500 Gaston Ave, Dallas, TX 75246. Phone: (214) 820-2021.

CLINICAL HEMATOLOGY AND ONCOLOGY

February 15-17, 1988
San Diego Princess Resort, San Diego, CA

This conference, to be held in San Diego, CA, is designed for hematologists, oncologists, internists, pediatricians, and pathologists interested in the diagnosis and management of hematologic and oncologic disorders. An outstanding faculty from across the country has been assembled to discuss various aspects of these fields, to aid clinicians in sorting out the important from the trivial, and to help identify those recent advances which will withstand the test of time. 24 hours Cat. I.

The conference is sponsored by Scripps Clinic and Research Foundation, La Jolla, CA. The program chairman is Bernard A. Babior, MD, PhD.

For further information, contact: Bonny Mower, Department of Academic Affairs, Box 400S, Scripps Clinic and Research Foundation, 10666 N Torrey Pines Rd, La Jolla, CA 92037. Telephone: (619) 457-8556.

SUBJECT INDEX

ABMTs, *see* Autologous bone marrow transplantations
ABO matching for platelet transfusions to refractory patients, 23-30
Abortions, hypofibrinogenemia and recurrent, associated with 7p-;12q translocation, 921-925
Acquired idiopathic sideroblastic anemia (AISA), cytogenetics of B cell involvement in, 1003-1005
Acquired idiopathic siberoblastic anemia (AISA), progenitor cells, cytogenetics and cytochemistry of, 1367-1372
Acquired immunodeficiency syndrome, *see* AIDS
Actin filaments
  depolymerization of, by serum, 524-530
  PMN, stimulated and primed by PAF, 1921-1927
  polymerization of, and its relationship to locomotion and chemokinetic response in maturing promyelocytic leukemia cells, 363-367
Activated complement (C), CALLA/CD10-negative neutrophil chemotactic response to, 1624-1629
Activated platelets
  detection of, in whole blood with activation-dependent MoAbs and flow cytometry of, 307-315
  53,000-molecular weight lysosome-like granule protein exposed on surface of circulating, and MoAbs against, 838-845
  IgA recognizing neoantigen on GPIIa expressed on stored and, 16-22
  phorbol esters sensitizing platelets to activation by physiological agonists, 1373-1381
  surface expression of GPIIb/IIIa induced by, 475-483
Acute leukemia(s)
  with monocytic phenotype, *c-fos* expression in, 1450-1457
  See also specific forms of acute leukemias
Acute leukemia B cells, IL-2R expressed on, 954-959
Acute lymphoblastic (and lymphocytic) leukemia (ALL)
  childhood, *see* Childhood acute lymphoblastic leukemia
  genotype and phenotype analysis in, at first presentation and at relapse, 1079-1083

Acute lymphoblastic (*Continued*)
  hypermethylation of 5' region of CT gene in, 412-417
  infant, configuration of Ig and TRC genes in, 536-541
  Ph-positive, *see* Philadelphia-positive acute lymphoblastic leukemia
  recurrence of, in donor cells after allogeneic BMT associated with chromosome 6 long arm deletion, 1099-1104
  T cell, TRGγ diversity and mRNA expression in, 637-646
Acute lymphoblastic leukemia (ALL) cells, histone H1° synthesized by, 1203-1207
Acute lymphoblastic leukemia (ALL) B cell precursors, proliferation of, induced by L-BCGF, 132-138
Acute lymphoblastic leukemia (ALL) CALLA-positive cells, phenotypic differences and similarities between normal marrow CALLA-positive B cell precursors and, 814-821
Acute megakaryoblastic leukemia with Down's syndrome, *c-sis* gene expression in cells of patient with, 368-371
Acute myeloblastic (and myelocytic) leukemia (AML)
  childhood, GF requirements of, 192-199
  chromosome 5 long arm deletion in, 1707-1708
  hypermethylation of 5' region of CT gene in, 412-417
  immunophenotyping of, using MoAbs and alkaline phosphatase-antialkaline phosphatase technique, 83-90
  MRD in, leukemic cell distribution during, 1073-1078
  Ph-positive, c-*abl* expression in, 1584-1588
  t(7p−;11p+) involving short arm of chromosomes 7 and 11 associated with, 1654-1658
Acute myeloblastic leukemia (AML) blast cells, effects of rIL-3, rGM-CSF, and rG-CSF on, 657-663
Acute myeloblastic leukemia (AML) cells, secretion of IL-1 by, inducing endothelial cells to secrete CSFs, 1218-1221
Acute myeloblastic leukemia (AML) progenitor cells, IL-3 stimulating, 333-336
Acute nonlymphoblastic (and nonlymphocytic) leukemia (ANLL)
  childhood, clinical significance of low levels of MPO positivity in, 51-54
  following etoposide and cisplatin therapy for NSCLC, 1412-1417
  minimally differentiated, 1400-1406
Acute promyelocytic leukemia (APL), localization of G-CSF gene of chromosome 17 proximal to t(15;17) breakpoint in, 330-332
Acyanotic congenital heart disease (CHD), childhood, siEP in, 822-826
Adenosine dialdehyde, and nitrous oxide inducing HL-60 differentiation, 1161-1164
Adenosine diphosphate, *see* ADP; ADP, platelets and
Adherent cells from LTMC transformed by SV40, 464-474
ADP (adenosine diphosphate), inhibition of GF-induced proliferation by ribosylation inhibitors of, 686-693
ADP (adenosine diphosphate), platelets and
  changes in phosphorylation of platelet proteins due to ADP, 511-515
  effects of calcium concentration on Fg and vWF ability to support platelet aggregation induced by ADP, 827-831
  FSBA interaction with ADP receptors on platelets, 796-803
  platelet aggregation induced by ADP dependent on conformation or availability of terminal γ chain sequence of Fg Paris I, 558-563
  platelet shape change and mobilization of cytoplasmic ionized calcium induced by ADP and mediated by distinct binding sites on platelets, 751-756
  vWF on platelet surface stimulated in plasma by ADP, 1363-1366
Adnexal lymphoid neoplasms, ocular, Ig and TCR β chain gene rearrangement in analysis of, 1519-1529
Adult(s) receiving fetal liver transplant, Epo production in, 542-545
Adult T cell leukemia (ATL), immunology and histology of, correlated with translocations, 1554-1564
Adult T cell leukemia (ATL) cells, IL-2-dependent expansion of, 1407-1411
Advanced non-small-cell carcinoma of the lung (NSCLC), ANLL following cisplatin-etoposide, regimen for, 1412-1417
Age
  defective synthesis of PAF by leukocytes in Zellweger patients related to, 460-463
  and neutrophil function, 1131-1135, 1838-1841
Aggregation
  of platelets, *see* Platelet aggregation
    RBC, 1572-1576

    RBC, 1572-1576

Aggressive lymphoma, chemotherapy in, 1394-1399
AIDS (acquired immunedeficiency syndrome)
  glycoprotein inhibitor of granulopoiesis associated with, 1267-1272
  hemophilia-associated, *see* Hemophilia-associated AIDS
  risk of, for recipients of blood components from donors subsequently developing, 1604-1610
  see also HIV
AISA, *see* Acquired idiopathic sideroblastic anemia
ALG (antilymphocyte globulin) for aplastic anemia, survival dependent on disease severity in, 1046-1052
Alkaline phosphatase-antialkaline phosphatase technique, immunophenotyping of AML using MoAbs and, 83-90
ALL, *see* Acute lymphoblastic (and lymphocytic) leukemia
Alloantibodies, Rh, antiidiotypic IgG crossreactive with, in RBC autoimmunity, 710-715
Allogeneic bone marrow transplantations (BMTs)
  following busulfan and cyclophosphamide regimen, 1382-1388
  host origin of hematopoietic microenvironment following, 1966-1968
  IgG subclass and antibacterial polysaccharide antibody deficiency after, 779-785
  recurrence of ALL in donor cells after, associated with chromosome 6 long arm deletion, 1099-1104
  therapy of severe aplastic anemia with, 1325-1330
Allogeneic bone marrow transplantations (BMTs) for CML
  gene rearrangements distinguishing pre- and post-BMT lymphoproliferative processes in, 882-885
  molecular analysis of relapse after, 873-876
  using unrelated donor, 877-881
Alloimmunization, and response to nonmatched platelet transfusions, 1727-1729
all-*trans*-retinoic acid (RA), interaction of rTNF-α and, with normal and leukemic hematopoietic cells, 1540-1546
Amino acid residues, Gly 911 and Glu 1,365, collagen-interactive domain of vWF between, 1577-1583
AML, *see* Acute myeloblastic (and myelocytic) leukemia
Anemia
  aplastic, *see* Aplastic anemia
  defective endocytotic vesicle membrane transport of iron in, 38-44
  monoclonal reconstitution of erythropoiesis in, 5FU in, 1758-1763
  sickle cell, HbF production in, 716-721; *see also* Sickle cell(s)
  sideroblastic, *see* Acquired idiopathic sideroblastic anemia

- ANLL, *see* Acute nonlymphoblastic (and nonlymphocytic) leukemia
- Antibacterial polysaccharide antibody, deficiency in, after allogeneic BMT, 779-785
- Antibody(ies)
  - antibacterial polysaccharide, deficiency in, after allogeneic BMT, 779-785
  - anti-HLA, assays for, 1495-1499
  - antiidiotype, in analysis of patient with CLL and LCL, 45-50
  - and antiidiotypic IgG crossreactive with Rh alloantibodies in RBC autoimmunity, 710-715
  - conformation-specific, plasma factor IX separated from HTLV-I or HIV by immunoaffinity chromatography with, 1312-1315

- B-CLL, *see* B cell chronic lymphocytic leukemia cells

B cell differentiation
  in close association with stromal cells in diffusion chambers, 1418-1424
  relationship between expression of T200 antigen and stages of, in resurgent BM hyperplasia, 1165-1172
B cell growth factor (BCGF), L-, proliferation of ALL B cell precursors induced by, 132-138
B cell growth factor (BCGF) receptor, expression of, and BCGF response of leukemic B cell precursor and B lymphoid progenitor, 1020-1034
B cell leukemia cells
  activation of 1193-1202
  c-fos expression in subsets of, 1450-1457
  IL-2R expressed on, 954-959
B cell precursor(s)
  leukemic, BCGF receptor expression and response of, 1020-1034
  phenotypic differences and similarities between normal marrow CALLA-positive, and CALLA-positive ALL cells, 814-821
  proliferation of ALL, induced by L-BCGF, 132-138
  survival of, in diffusion chamber cultures, 1418-1424
B-cell precursor acute lymphoblastic leukemia (ALL), childhood, tdic(9;12) translocaton in, 1962-1965
B cell prolymphocytic leukemia (B-PLL) cells, proliferation of, induced by PMA and native or rIFN-γ, 670-675
B cell stimulatory factor-1/interleukin 4 (BSF-1/IL-4), effects of, on hematopoietic progenitors, 254-263
BCGF, *see* B cell growth factor
bcr, *see* Breakpoint cluster region
Bernard-Soulier syndrome (BSS), pseudo-, as thrombocytopenia caused by autoantibody to GPIb, 428-431
b5, fixed, paraffin-embedded tissues, immunohistochemical characterization by BM-1 MoAb of, 1124-1130
Biopsies, pathologic BM, autofluorescent eosinophil granules in, 597-599
Biotinylated red blood cells (RBCs), survival and recovery of, 791-795
Black hereditary persistence of fetal hemoglobin (HPFH), types 1 and 2, 3′ ends of deletions of β globin gene in, 595-596
Blast cells
  AML, effects of rIL-3, rGM-CSF, rG-CSF on, 657-663
  rIL-3 and rGM-CSF compared in supporting colony formation of, 1343-1348
  See also specific types of blast cells
Blast crisis
  CML, breakpoints localized to specific regions of bcr during, 448-455
  t(3;21) associated with CML, 1338-1342
Blastic transformation in CML, loss of myeloid differentiation antigens preceding, 122-131
Bleeding time (BT) in vWD, 1354-1361
Blood group phenotype, S—s—U, δ glycophorin gene deletion in individuals homozygous for, 1830-1835
Blood product(s), laser-ultraviolet irradiation for inactivation of viruses in, 589-592
Blood product transfusions, risk of AIDS for recipients of, from donors subsequently developing AIDS, 1604-1610
BM, *see* Bone marrow
BM-1 MoAb, immunohistochemical characterization of 183-kD-myeloid-specific-DNA-binding protein in B5, fixed, paraffin-embedded tissues and BM aspirates by, 1124-1130
BMTs, *see* Bone marrow transplantations
B19 parvovirus, erythroid BM cells infected by, 384-391
Bone marrow (BM)
  autofluorescent eosinophil granules in pathologic biopsies of, 597-599
Bone marrow (BM) (*Continued*)
  flow cytometry of, showing normal B cell development, 1316-1324
  hyperplastic, relationship between expression of T200 antigen and stages of B cell differentiation in resurgent, 1165-1172
  immunohistochemical characterization of aspirates of, by BM-1 MoAb, 1124-1130
  injury to, induced by CAP, 1180-1185
  isolation, characterization, and localization of glycosaminoglycans in, 501-510
  See also entries beginning with element: Myelo-
Bone marrow adherent cells transformed by SV40, 464-474
Bone marrow (BM) CALLA-positive B cell precursors, normal, phenotypic similarities and differences between CALLA-positive ALL cells and, 814-821
Bone marrow (BM) cells, unfractionated, ABMT using, cryopreserved in DMSO and HES, 974-978
Bone marrow (BM)-derived megakaryocytic progenitors, effects of rIFN-α and rIFN-γ on, 1173-1179
Bone marrow (BM) erythroid cells, *see* Erythroid cells
Bone marrow (BM) granulocyte-macrophage colonies (CFU-GM), response of, to PGE_1, 1792-1796
Bone marrow (BM) matrix, HL-60 phenotype modulation by, 1119-1123
Bone marrow (BM) purging, *see* Bone marrow transplantations
Bone marrow transplantations (BMTs)
  allogeneic, *see* Allogeneic bone marrow transplantations
  autologous, *see* Autologous bone marrow transplantations
  for childhood ALL in second remission, 324-326
  clonogenic hematopoietic precursors in, 1425-1432
  haploidentical, for SCID, marrow treated with CT-2 MoAb and C following, 664-669
  for hematologic malignancies, mixed hematopoeitic chimerism after, 1331-1337
  γ-irradiation and busulfan compared in BM preparation for, and their effects on recovery of contact hypersensitivity, 1910-1920
  PB mononuclear cells response to IL-2 following, 1595-1603
  for Ph-positive ALL, 587-588
  second, in patients with aplastic anemia with cyclophosphamide and ATG conditioning regimen, 118-121
  See also Soybean lectin-separated marrow; T-cell depleted marrow
Botrocetin, vWF binding to GPIb induced by, 985-988
B-PLL (B cell prolymphocytic leukemia) cells, proliferation of, induced by PMA and native or rIFN-γ, 670-675
Breakpoint cluster region (bcr)
  breakpoints during blast crisis of CML localized in specific regions of, 448-455
  of chromosome 18q21, cytogenetics of lymphoma refined by, 1816-1823
  chromosome 22 breakpoint outside, in Ph-positive CML, 1659-1664
BSF-1/IL-4 (B cell stimulatory factor/1/interleukin 4), effects of, on hematopoietic progenitors, 254-263
BSS (Bernard-Soulier syndrome), pseudo-, as thrombocytopenia caused by autoantibody to GPIb, 428-431
Burkitt's leukemia, molecular analysis of, in two hemophilic brothers with AIDS, 1713-1717
Busulfan
  and cyclophosphamide regimen, allogeneic BMT following, 1382-1388
  in preparation of BM for BMTs and its effects of recovery of contact hypersensitivity, 1910-1920
BT (bleeding time) in vWD, 1354-1361

C (complement), elimination of MM stem cells with MM4 MoAb and, 1482-1489
c-*abl* protooncogene, expression of, in Ph-positive AML, 1654-1658
Cachectin, *see* Recombinant tumor necrosis factor-α
Calcitonin (CT) gene, hypermethylation of 5′ region of, in ALL and AML, 412-417
Calcium (Ca)
  cysteine protease activity in serum of patients with TTP dependent on, 1584-1588
  cytoplasmic, mobilization of, induced by ADP and mediated by distinct binding sites on platelets, 751-756
  effects of concentration of, on Fg and vWF ability to support ADP-induced platelet aggregation, 827-831
  epitope mapping of factor Va functional domains and evidence of its interaction with, 139-146
  permeability and concentration of, not impaired in β-thalassemia and HbC erythrocytes, 804-808
  TXA$_2$ formation on contact with platelets in medium with low concentration of, 647-651
Calcium (Ca) ionophore A23187, synergistic action of TPA and, on B-CLL cells, 1536-1542
CALLA/CD10-negative neutrophils, chemotactic response of, to activated C, 1624-1629
CALLA-positive acute lymphoblastic leukemia (ALL) cells, phenotypic similarities and differences between normal marrow CALLA-positive B cell precursors and, 814-821
CAP (chloramphenicol), BM injury induced by, 1180-1185
Carbohydrate-binding specificity of lymphocytes, 1842-1850
Carbohydrate moiety, role of, in vWF function, 608
Carrier detection
  of hemophilia A, factor VIII cDNA in, 351-355
  of hemophilia B, 1006-1013
Cations, K transport inhibited by divalent, in sickle RBCs, 1810-1815
CCHD (cyanotic congenital heart disease), childhood, siEP in, 822-826
cCLLa antigen, MoAbs against, in CLL, 457-463
cDNA (complementary deoxyribonucleic acid)
  lactoferrin, isolation of, from myeloid library and expression of mRNA during normal and leukemic myelopoiesis, 989-993
  β-spectrin, cloning and nucleotide sequence of, 915-920
  See also Restriction fragment length polymorphisms
CD1 antigen on thymus cells and leukemic T cells, 676-685
Cell differentiation, *see* Differentiation
CFCs (colony-forming cells), HPP- and/or LPP-, effects of rIL-3 on, 401-403
c-fos protooncogene
  expression of, in acute leukemias with monocytic phenotype and in subsets of B cell leukemias, 1450-1457
  transcriptionally active, in normal granulocytes, 456-459
CFU-GM, *see* Granulocyte-macrophage colonies
a-Chain, factor XIII, normal peripheral blood monocytes and liver as sites of synthesis of, 579-582
β and γ Chain gene rearrangement, *see* T cell receptor β chain gene rearrangement; T cell receptor γ chain gene rearrangement
γ Chain sequence of Fg Paris I, ADP-induced platelet aggregation depending on conformation of availability of terminal, 558-565
CHD (congenital heart disease), childhood cyanotic and acyanotic, siEP in, 822-826
Chemokinetics of locomotion in maturing promyelocytic leukemia cells, actin polymerization and, 363-367
Chemotactic factors, impaired induction of MAC-1 by, and abnormal stimulated adherence of NGs, 740-750
Chemotactic response of CALLA/CD10-negative neutrophils to activated C, 1624-1629
Chemotaxis, characterization of defective, in PMNs exposed to influenza virus, 251-255
Chemotherapy
  ABMT and high-dose, for resistant MM, 869-872
  in aggressive lymphoma, 1394-1399
  See also specific chemotherapeutic agents
Childhood acute lymphoblastic leukemia (ALL)
  B-cell precursor, tdic(9;12) translocation in, 1962-1965
  hypoploidy and prognosis of, 247-253
  in second remission, BMT for, 324-328
  TCR γ chain gene rearrangement in, 1933-1939
Childhood acute myeloblastic leukemia (AML), growth factor requirements of, 192-199
Childhood acute nonlymphoblastic leukemia (ANLL), clinical significance of low levels of MPO positivity in, 51-54
Childhood cyanotic and acyanotic congenital heart disease (CHD), siEP in, 822-826
Childhood non-Hodgkin's lymphoma (NHL), serum IL-2R levels related to advanced, and its poor outcome, 624-628
Childhood Philadelphia (Ph)-positive acute lymphoblastic leukemia (ALL)
  clinical and biologic hallmarks in, 948-953
  multipotential stem cell disease in, 1458-1461
Childhood thrombocytopenia, ^{111}In-oxine platelet survival in, 852-856
Chimerism, *see* Mixed blood chimerism
Chinese $\delta\beta$-thalassemia chromosome, β globin gene on, carrying promoter mutation, 1470-1474
Chloramphenicol (CAP), BM injury induced by, 1180-1185
Chromatography, immunoaffinity, with conformation-specific antibodies, plasma factor IX separated from HTLV-1 or HIV by, 1312-1315
Chromosome(s)
  Chinese $\delta\beta$-thalassemia, β globin gene on, carrying promoter mutation, 1470-1474
  See also Translocation(s) *specific chromosomes and entries beginning with term:* Philadelphia
Chromosome 5, long arm deletion of, 1705-1712
Chromosome 6, long arm deletion of, recurrence of ALL in donor cells after allogeneic BMT associated with, 1099-1104
Chromosome 7
  long arm deletion of, in myeloid disorders, 1349-1353
  t(7p−;11p+) involving short arm of, associated with AML, 1654-1658
Chromosome 11, t(7p−;11p+) involving short arm of, associated with AML, 1654-1658
Chromosome 11q23, identification of RFLP involving ETS-1 oncogene on, 327-329
Chromosome 17, localization of G-CSF gene on, proximal to t(15;17) breakpoint in APL, 330-332
Chromosome 18q21
  in diffuse and follicular lymphomas, 90-95
  refinement of lymphoma cytogenetics by major breakpoint region of, 1818-1823
Chromosome 22, breakpoint of, outside bcr in Ph-positive CML, 1659-1664
Chronic immune thrombocytopenic purpura (ITP), platelet-associated, and plasma anti-GP autoantibodies in, 1040-1052
Chronic lymphoblastic (and lymphocytic) leukemia (CLL)
  antiidiotype antibody in analysis of patient with Richter's syndrome and, 45-50
  B-, *see* B cell chronic lymphocytic leukemia cells
  MoAbs against cCLLa antigen in, 437-443

- Cytoplasmic calcium (Ca), mobilization of, induced by ADP and mediated by distinct binding sites on platelets, 751-756
- Cytoplasmic factor required for entry of *P. falciparum* into RBCs, 77-82
- Cytosine arabinoside (Ara-C), dCyd protecting normal progenitor cells from cytoxicity of, 568-571
- Cytosol of leukemic cells, 52-kD and 30-kD glucocorticoid receptor fragments produced by neutrophil elastase in, 860-868

- D-CSF (diffusible colony-stimulating factor), hematopoietic precursors response to, 1784-1789
- dCyd (deoxycytidine), normal progenitor cells protected by, from Ara-C cytoxicity, 568-571
- 1-Deamino-8-D-arginine vasopressin (DDAVP), proteolytic degradation of vWF after administration of, in normal individuals, 173-176
- Defensin in dense granules of neutrophils, 757-765

Deletions
  chromosome 5 long arm, 1705-1712
  chromosome 6 long arm, recurrence of ALL in donor cells after allogeneic BMT associated with, 1099-1104
  chromosome 7 long arm, in myeloid disorders, 1349-1353
  δ glycophorin gene, in individuals homozygous for S—s—U blood group phenotype, 1830-1835
  in HPFH, 1797-1803
  See also β Globin gene deletions
Dense granules of neutrophils, defensin in, 757-765
Dense tubular system of platelets, [^{3}H]arachidonic acid uptake in, 832-837
Deoxycytidine (dCyd), normal progenitor cells protected by, from Ara-C cytoxicity, 568-571
Deoxyribonucleic acid, *see* DNA
$1,25(OH)_2D_3$, *see* 1α,25-Dihydroxyvitamin D_3
Depolymerization of actin filaments by serum, 524-530
Dermatan Sulphate (DS), PA release induced by, 1858-1860
Diagnosis
  aplastic anemia, 1718-1721
  fetal, of hemophilia A with factor VIII cDNA, 531-535
  See also Carrier detection *and specific diagnostic techniques*
Differentiation
  B cell, *see* B cell differentiation
  bipotential, of KU-812, 612-619
  diploid myeloid leukemia cell line with granulocytic and monocytic differentiating capacity, 372-378
  HL-60, *see* HL-60 cell differentiation
  receptor-mediated monocytoid, or promyelocytic cells by TNF, 994-1002
Differentiation antigens, loss of, preceding blastic transformation in CML, 122-131
Differentiation marker of myelomonocytic lineage, oncoplacental protein SP_1 as, 1279-1283
Diffusible colony-stimulating factor (D-CSF), hematopoietic precursors response to, 1784-1789
Diffuse lymphoma, chromosome 18q21 gene rearrangement in, 90-95
1α,25-Dihydroxyvitamin D_3 [$1,25(OH)_2D_3$],
  lymphokine-mediated activation of oxidative metabolism of U937 cell line and phosphorylation of 48-kD respiratory burst-associated protein enhanced by, 1639-1644
  and receptor-mediated monocytoid differentiation of promyelocytic cells by TNF, 994-1002
Dimethylsulfoxide (DMSO), unfractionated cryopreserved cells in HES and, and used in ABMTs, 974-979
Dimorphism, factor IX, carrier detection of hemophilia B with immunoassay distinguishing, 1006-1013
Diploid myeloid leukemia cell lines with granulocytic and monocytic differentiating capacity, 372-378
Divalent cations, K transport inhibited by, in sickle RBCs, 1810-1815
DMSO (dimethylsulfoxide), unfractionated cryopreserved cells in HES and, and used in ABMT, 974-979
DNA (deoxyribonucleic acid)
  complementary, *see* cDNA
  183-kD-myeloid-specific-DNA-binding protein of, immunohistochemistry of, in B5, fixed, paraffin-embedded tissues and BM aspirates by BM-1 MoAb, 1124-1130
  synthesis of fibroblast, stimulated by eosinophils, 572-574
Donors, *see* Transfusions; Transplantations
Down's syndrome, acute megakaryoblastic leukemia with, *c-sis* gene expression in cells of patient with, 368-371
DS (Dermatan Sulphate), PA release induced by, 1858-1860
EBV, *see* Epstein-Barr virus
ECM, *see* Extracellular matrix
Elastase, neutrophil, 52-kD and 30-kD glucocorticoid receptor fragments produced by, in cytosol of leukemic cells, 860-868
ELISA (enzyme-linked immunoassay), plasma and platelet HLA in normal individuals measured by, 282-286
Elliptocytosis, hereditary, molecular determinants of clinical expression of, 766-772
Endocytotic vesicle membrane transport of iron in anemia, 38-44
Endothelial cells
  conversion of active to latent PAI-1 from, 1090-1098
  ECM of aortic, containing PAI-1, 721-728
  effects of flow cytometry on PMN adhesion to, 1284-1290
  IL-1 secretion by AML cells inducing, to secrete CSFs, 1218-1221
  interaction of, with sickle cells, sickle trait, mechanically injured, and normal RBCs, 152-157
Enzyme-linked immunoassay (ELISA), plasma and platelet HLA in normal individuals measured by, 282-286
Eosinophil(s)
  fibroblast DNA synthesis stimulated by, 572-574
  response of, to fMLP, 379-383
Eosinophil granules, deposition of autofluorescent, in pathologic BM biopsies, 597-599
Ep and Epo, *see* Erythropoietin
Epitope mapping of functional domains of factor Va with MoAbs, 139-146
Epstein-Barr virus (EBV), effects of, on peripheral blood cells, 516-523
Epstein-Barr virus (EBV)-carrying cell line, FL-18-EB, obtained from patient with follicular lymphoma, 1619-1623
E rosette-depleted bone marrow (BM), NK cells activated by IL-2 in BMTs with soybean lectin-separated and, 1893-1903
Erythroblastic leukemias, effects of GM-CSF and Ep on leukemic erythroid colony formation in, 965-973
Erythrocytes, *see* Red blood cell(s)
Erythroid cells
  infected by B19 parvovirus, 384-391
  precommitted, enriched in Friend erythroleukemia cell cultures, 1565-1571
Erythroid phenotype of HEL cells, 1764-1772
Erythroid progenitors, rGM-CSF action on, 1867-1871
Erythroleukemia cells
  effects of GM-CSF and Epo on formation of, in erythroblastic leukemias, 965-973
  Friend, precommitted erythroid cells enriched in cultures of, 1565-1571
Erythropoiesis
  glycosylation and expression of glycophorin A during, 1959-1961
  monoclonal reconstitution of, in anemia, 5-fluorouracil in, 1758-1763
Erythropoietin (Ep; Epo)
  effects of GM-CSF and, on leukemic erythroleukemia cell colony formation in erythroblastic leukemias, 965-973
  production of, in adult recipients of fetal liver transplants, 542-545
  regulation of production of, in hepatoblastoma cell line, 1904-1909
  serum immunoreactive, in childhood cyanotic and acyanotic CHD, 822-826
  serum transferrin receptor as index of, 1955-1958
Erythropoietin (Epo) mRNA (messenger ribonucleic acid), renal, physiologic regulation and tissue localization of, 316-323

Etoposide-cisplatin regimen, ANLL following, for advanced NSCLC, 1412-1417
ETS-1 oncogene, identification of RFLP involving, on chromosome 11q23, 327-329
Extracellular matrix (ECM)
  of aortic endothelial cells containing PAI-1, 721-728
  of heparan sulfate, non-anticoagulant heparin species inhibiting degradation of, mediated by heparanase, 551-557

FACS (fluorescence-activated cell sorting), megakaryocyte purification by, 1735-1742
Factor III (tissue factor; tissue thromboplastin), HTF1-788 MoAb inhibiting, 490-493
Factor V, regulation of, by neutrophil protease, 846-851
Factor Va, epitope mapping of functional domains of, with MoAbs, 139-146
Factor VIIa-tissue factor complex inhibited by plasma lipoproteins, 1947-1954
Factor VIII binding domain, localization of, on 34-kD fragment of *N*-terminal portion of vWF, 1679-1682
Factor VIII cDNA in carrier detection and prenatal diagnosis of hemophilia A, 531-535
Factor IX
  carrier detection of hemophilia B with immunoassay distinguishing dimorphism of, 1006-1013
  plasma, HTLV-1 or HIV separated from, by immunoaffinity chromatography with conformation-specific antibodies, 1312-1315
Factor Xa, epitope mapping of functional domains of factor Va and evidence of its interaction with, 139-146
Factor XI, defective cross-reacting material in, in patients with deficient, 31-37
Factor XII (Hageman factor), and coagulation-kinin pathway in, 1-15
Factor XIIa, anti-plasma prekallikrein MoAb inhibiting prekallikrein activation by, 1053-1062
Factor XIII a-chain, normal peripheral blood monocytes and liver as sites of synthesis of, 579-582
Fc receptor-specific clearance, ITP with impaired, of reticuloendothelial system in homosexuality, 392-395
Feline leukemia virus (FePV-FAIDS), transmission and pathogenesis of, 1880-1892
Fetal diagnosis of hemophilia A with factor VIII cDNA, 531-535
Fetal hemoglobin (HbF)
  black hereditary persistence of, types 1 and 2, 3′ ends of deletions of β globin gene in, 595-596
  influence of hydroxyurea on, 1824-1829
  production of, in SCA, 716-721
Fetal liver transplantation, adult recipients of, production of Epo by, 542-545
Fg, *see* Fibrinogen, platelet aggregation and Fibrinogen-platelet binding
Fibrin
  monomer of, inducing binding of vWF to glycocalicin portion of GPIb, 1589-1594
  TGs in vascular cells and tissues as alternate pathway for stabilization of, 702-709
Fibrin I polymer, regulation of action of thrombin on, in prethrombotic state, 347
Fibrinogen (Fg), platelet aggregation and
  effects of calcium concentration on Fg ability to support ADP-induced aggregation, 827-831
  platelet disaggregation and, dependent and independent of Fg, 222-226
Fibrinogen (Fg) Paris I, ADP-induced platelet aggregation depending on conformation or availability of terminal γ chain sequence of, 558-563
Fibrinogen (Fg)-platelet binding
  arginyl-glycyl-aspartic acid sequences and, 110-115
  surface expression of GPIIb/IIIa related to, 475-483
Fibrinolytic system
  molecular defects in, in prethrombotic state, 347-348
  and pathway of coagulation in plasma, 5-6
  response of, to tPA, 564-567
Fibroblast DNA, synthesis of, stimulated by eosinophils, 572-574
Fibronectin (FN) in platelet adhesion and thrombus formation on subendothelium and collagen surfaces, 1437-1442
15;17 translocation [t(15;17)], localization of G-CSF gene on chromosome 17 proximal to breakpoint of, in APL, 330-332
52-kD glucocorticoid receptor fragments produced by neutrophil elastase in cytosol of leukemic cells, 860-868
53,000-molecular weight lysosome-like granule protein exposed on surface of circulating activated platelets, 838-845
Filter blockage in vWD, 1354-1361
FL-18 (lymphoma cell lines) and FL-18-EB (Epstein-Barr virus-carrying cell line) from patient with follicular lymphoma, 1619-1623
Flow cytometry
  of BM showing normal B cell development, 1316-1324
  detection of activated platelets in whole blood using, 307-315
  in detection of hairy cells using MoAbs, 1063-1068
  effects of, on PMN-endothelial cell adhesion, 1284-1290
Fluorescence-activated cell sorting (FACS), megakaryocyte purification by, 1735-1742
5′-*p*-Fluorosulfonylbenzoyladenosine (FSBA)
  interaction of, with ADP receptor on platelets, 796-803
  as weak platelet agonist, 751-756
5-Fluorouracil (5FU), monoclonal reconstitution of erythropoiesis in anemia and, 1758-1763
fMLP (formyl-methionyl-leucyl-phenylalanine), eosinophil response to, 379-383
FN (fibronectin) in platelet adhesion, and thrombus formation on subendothelium and collagen surfaces, 1437-1442
Follicular lymphoma
  chromosome 18q21 gene rearrangement in, 90-95
  FL-18 and FL-18-EB obtained from patient with, 1619-1623
Formation-resistant antigen, Ki-B3 detecting, on normal and neoplastic B cells, 629-636
Formyl-methionyl-leucyl-phenylalanine (fMLP), eosinophil response to, 379-383
fos protooncogene, *see: c-fos* protooncogene
IVS-1 sequence of β globin gene, mutation in, causing β thalassemia, 147-151
14;18 translocation [t(14;18)], histology of NHL carrying, 444-447
48-kD respiratory burst-associated protein, phosphorylation of, enhanced by $1,25(OH)_2D_3$, 1639-1644
Friend erythroleukemia cells, precommitted erythroid cells enriched in cultures of, 1565-1571
FSBA, *see* 5′-*p*-Fluorosulfonylbenzoyladenosine
5FU (5-fluorouracil), monoclonal reconstitution of erythropoiesis in anemia and, 1758-1763
Full-term infants, development of coagulation system in, 156-172
Functional domains, epitope mapping of factors Va and Xa with MoAbs, 139-146

Gamma globulin, *see* IgG
G-CSF, *see* Granulocyte colony-stimulating factor

- Gene(s)

  - carrier detection of, 1006-1013
  - immunologic aberrations, seroconversion rates, and seropositivity to HIV in, 276-281, 786-790
- Hemostatic system
  - markers of, in pathophysiology of prethrombotic state, 343-350
  - *See also* Platelets *specific coagulation factors and entries beginning with element:* Thromb-
- HEP G2 cells, effects of warfarin on synthesis and secretion of prothrombin in, 773-778
- Heparin, non-anticoagulant species of, inhibiting degradation of ECM heparan sulfate mediated by heparanase, 551-557
- Hepatoblastoma cells and cell lines, regulation of Epo production in, 1904-1909
- Hereditary antithrombin III (ATIII) deficiency, genetics of, 1273-1278
- Hereditary elliptocytosis (HE), molecular determinants of clinical expression of, 766-772
- Hereditary persistence of fetal hemoglobin (HPFH)
  - deletions in, 1797-1803
  - types 1 and 2, 3′ ends of deletions of β globin gene in black, 593-596
- Hereditary pyropoikilocytosis, molecular determinants of clinical expression of, 766-772
- Hereditary thrombotic disorders, 345-347
- Herpes virus, effects of, on peripheral blood T lymphocytes, 516-523
- HES (hydroxyethyl starch), unfractionated cells cryopreserved in DMSO and, and used for ABMT, 974-979
- Heterologous cells, δ globin gene from patients with homozygous δ^0-thalassemia functioning normally on transient expression in, 809-813
- High-dose chemotherapy, ABMT and, for resistant MM, 869-872
- High-dose intravenous gamma globulin (IV IgG), effects of, on responses to single-donor platelets in patients refractory to platelet transfusions, 1433-1436
- High-proliferative potential colony-forming cells (HPP-CFCs), effects of rIL-3 on, 401-403
- Histology
  - of NHL and ATL correlated with translocations, 1554-1564
  - of NHL carrying 14;18 translocation associated with additional nonrandom chromosome changes, 444-447
- Histone H1°, synthesis by ALL cells but not by normal lymphocytes, 1203-1207
- HIV (human immunodeficiency virus)
  - detection of antigen to, and specific antibodies to core and envelope proteins of, in serum of patients infected with, 575-578
  - plasma factor IX separated from, by immunoaffinity chromatography with conformation-specific antibodies, 1312-1315
  - immunologic aberrations, seroconversion rates, and seropositivity to, in hemophilia A and B, 276-281, 786-790
  - ITP with impaired Fc receptor-specific clearance of reticuloendothelial system and, 392-395
  - transmission and pathogenesis of feline, 1880-1892
  - *See also* AIDS
- HLA antigens
  - in leukemia, 227-232
  - plasma and platelet, in normal individuals, measured by ELISA, 282-286

HLA matching for platelet transfusions to refractory patients, 23-30
HL-60 cell(s)
  proliferation and expression of oncogene of, 1233-1244
  rTNF regulating *c-myc* expression in, 200-205
HL-60 cell differentiation, 1234-1237
  induced by N_2O and adenosine dialdehyde, 1161-1164
HL-60 cell phenotype, BM matrix modulation of, 1119-1123
HL-T cell line expressing terminal transferase and secreting suppressor activity, 1151-1160
hMulti-CSF, *see* Interleukin 3
H_2O_2 (hydrogen peroxide), PMA-induced production of, in macrophages increased by exposure to γ-irradiation, 694-701
Hodgkin's disease (HD)
  antigen receptor gene rearrangement in, 96-105
  Ig gene rearrangement in tissues involved in, 186-191
Homing receptors of lymphocytes, 1842-1850
Homosexuality
  ITP with impaired reticuloendothelial system Fc receptor-specific clearance in, 392-395
  See also AIDS; HIV
Homozygous δ^0-thalassemia, δ globin gene from patients with, functioning normally on transient expression in heterologous cells, 809-813
HPFH, *see* Hereditary persistence of fetal hemoglobin
HPP-CFCs (high-proliferative potential colony-forming cells), effects of rIL-3 on, 401-403
HTF1-788 MoAb inhibiting tissue factor, 490-493
HTLV-I (human T cell leukemia virus type I)
  adsorption of, to various target cells, 1303-1311
  colony assay for transformation of, 432-436
  IL-2 dependent on T cells from patient with T-CLL and not infected with, 1069-1071
  plasma factor IX separated from, by immunoaffinity chromatography with conformation-specific antibodies, 1312-1315
HTLV-II (human T cell virus type II), colony assays for transformation of, 432-436
Human immunodeficiency virus, *see* HIV
Human T cell leukemia viruses, *see* HTLV-I; HTLV-II
Hydrocortisone (HC), effects of, on hematopoietic progenitor cell growth, 1611-1618
Hydrogen peroxide (H_2O_2), PMA-induced production of, in macrophages increased by exposure to γ-irradiation, 694-701
4-Hydroperoxycyclophosphamide (4-HC)
  correlation between CFU-GM content of BM graft and time to hematologic reconstitution following autologous BMT with marrow purged with, 271-275
  variability in activity during purging for ABMT, 1490-1494
Hydroxyethyl starch (HES), unfractionated cells cryopreserved in DMSO and, and used for ABMT, 974-979
Hydroxyurea, effects of, on HbF production, 1824-1829
Hypermethylation of 5′ region of CT gene in AML, 412-417
Hyperplasia, BM, relationship between expression of T200 antigen and stages of B cell differentiation in resurgent, 1165-1172
Hypofibrinogenemia, recurrent abortion associated with 7p−;129 translocation and, 921-925
Hypoploidy, and poor prognosis in childhood ALL, 247-253

Idiopathic sideroblastic anemia, *see* Acquired idiopathic sideroblastic anemia
IFN, *see* Interferon
Ig (immunoglobulin) gene, configuration of, an infant ALL, 536-541
Ig (immunoglobulin) gene rearrangement
  in analysis of ocular adnexal lymphoid neoplasms, 1519-1529
  in tissues involved in HD, 186-191
IgA (immunoglobulin A) monoclonal antibody (MoAb), recognizing neoantigen on GPIIa expressed on stored and activated platelets, 16-22
IgG (immunoglobulin G; gamma globulin)
  antiidiotypic, in analysis of patient with CLL and LCL, 45-50
  deficiency in subclasses of, after ABMT, 779-785
  effects of high-dose IV, on responses to platelet transfusions in refractory patients, 1433-1436
IgG (immunoglobulin G) lupus anticoagulants, specificity and mechanisms of action of, 69-76
IgM (immunoglobulin M), membrane, and activation of leukemic B cells, 1193-1202
IL, *see specific interleukins*
Immune thrombocytopenic purpura (ITP)
  chronic, platelet-associated and plasma anti-GP autoantibodies in, 1040-1052
  with impaired reticuloendothelial system Fc receptor-specific clearance in homosexuality, 392-395
  See also Thrombocytopenia
Immunoaffinity chromatography with conformation-specific antibodies, plasma factor IX separated from HTLV-I or HIV by, 1312-1315
Immunoglobulins, *see entries beginning with acronym:* Ig
Immunohistochemistry of 183-kD myeloid-specific-DNA-binding protein in B5, fixed, paraffin-embedded tissues and BM aspirates by BM-1 MoAb, 1124-1130
Immunologic aberrations, HIV seropositivity, seroconversion rates and, in hemophilia B, 276-281
Immunology of NHL and ATL correlated with translocations, 1554-1564
Immunophenotyping
  of AML using MoAbs and alkaline phosphatase-antialkaline phosphatase technique, 83-90
  of new pre-B cell component in plasma cell myeloma, 932-942
Immunoreactive erythropoietin (Ep), serum, in childhood cyanotic and acyanotic CHD, 822-826
Incidence
  of aplastic anemia, 1718-1721
  of hemophilia-associated AIDS, geographic differences in, 1208-1213
Infant(s), full-term, development of coagulation system in, 165-172
Infant acute lymphoblastic leukemia (ALL), configuration of Ig and TCR genes in, 536-541
Influenza virus, characterization of defective chemotaxis in PMNs exposed to, 351-355
Inherited conditions, *see entries beginning with terms:* Congenital, Hereditary
Initiation codon, mutation of, of αglobin gene in HbH disease, 729-732
Injured bone marrow (BM), CAP and, 1180-1185
Injured red blood cells (RBCs), interaction with, 152-157
In (Lu) Lu(a-b-) erythrocytes, characterization of membrane protein defect of, 1475-1481
^{111}In-oxine platelets, survival of, in thrombocytopenia, 652-656
Interferon-α (IFN-α)
  and receptor-mediated monocytoid differentiation of promyelocytic cells by INF, 994-1002
  recombinant, *see* Recombinant interferon-α
Interferon-γ, *see* Recombinant interferon-γ
Interleukin 1 (IL-1)
  expression of myelomonocytic antigens on B-CLL cells correlated with ability to produce, 1750-1757

- Interleukin 1 (IL-1) (*Continued*)
  - secretion of, by AML cells inducing endothelial cells to secrete CSFs, 1218-1221
  - spontaneous production of IL-1 activity by B-CLL cells, 1851-1857
- Interleukin 1α (IL-1α), rTNF-α and -β compared with, in regulation of neutrophil migration and superoxide production, 979-984
- Interleukin 2 (IL-2)
  - ATL cell expansion dependent on, 1407-1411
  - dependent on T cells from patient with T-CLL and not infected with HTLV-I, 1069-1071
  - lymphocyte, production and responsiveness of, in primary MDS, 496-500
  - NK cells activated by, in BMTs with soybean lectin-separated and E rosette-depleted BM, 1893-1903
  - production of, and response to, by PB mononuclear cells after BMT, 1595-1603
- Interleukin 2 receptors (IL-2R)
  - expressed on acute leukemic B cells, 954-959
  - phorbol ester inducing, on cell surface of precursor thymocyte leukemia without TCR β and γ gene rearrangement, 1291-1297
  - serum, *see* Serum interleukin 2 receptors
- Interleukin 3 (IL-3)
  - AML progenitor cells stimulated by, 333-336
  - recombinant, *see* Recombinant interleukin 3
- Interleukin 4 (IL-4), effects of BSF-1 and, on hematopoietic progenitors, 254-263
- Intracellular HbS (hemoglobin S) gelation, sickling as indicator of, 1251-1253
- Intravenous gamma globulin (IV IgG), effects of high-dose, on responses to single-donor platelets in patients refractory to platelet transfusions, 1433-1436
- Iron
  - defective vesicle membrane transport of, in anemia, 38-44
  - homeostasis of, in β-thalassemia, 1462-1465
- Irradiation
  - laser-ultraviolet, for virus inactivation in blood products, 589-591
  - leukemia induced by, 905-908
  - and photoradiation therapy of BM for ABMTs, 484-489
  - total body, allogeneic BMT without, 1382-1388
- γ-Irradiation
  - in BM preparation for BMTs and its effects on recovery of contact hypersensitivity, 1910-1920
  - exposure to, increasing PMA-induced H_2O_2 production in macrophages, 694-701
- ITP, *see* Immune thrombocytopenic purpura
- IV IgG (intravenous gamma globulin), effects of, on responses to single-donor platelets in patients refractory to platelet transfusions, 1433-1436

- Juvenile chronic myelogenous leukemia (JCML) cells in peripheral blood during remission, 1466-1469

- K, *see* Potassium
- Ki-B3 MoAb, formalin-resistant antigen detected by, on normal and neoplastic B cells, 629-636
- Kinase, tyrosine, in promyelocytic leukemia cells and PMNs, 356-362
- Kinetics
  - and chemokinetics of locomotion by maturing promyelocytic leukemia cells, actin polymerization and, 363-367
  - of HbS gelation, 1248-1251
  - of new pre-B cell component of plasma cell myeloma, 932-942
  - and proliferative capacity of PMNs, age and, 1836-1841
- Kinin, coagulation-kinin pathway of plasma, 1-15
- Ku-812 cell, bipotential cell differentiation of, 612-619

- Lactoferrin (Lf), binding of, by leukemic cell lines, 264-270
- Lactoferrin (Lf) cDNA, isolation of, from myeloid library and expression of mRNA during normal and leukemic myelopoiesis, 989-993
- Large cell lymphoma (LCL; Richter's syndrome), antiidiotype antibody in analysis of patient with CLL and, 45-50
- Large granular lymphocytes (LGL), normal and leukemic, TCR gene rearrangements and expression in, 1500-1508
- Laser-ultraviolet (UV) irradiation for virus inactivation in blood products, 589-591
- L-BCGF (low molecular weight B cell growth factor), proliferation of ALL B cell precursors induced by, 132-138
- LCL (large cell lymphoma; Richter's syndrome) antiidiotype antibody in analysis of patient with CLL and, 45-50
- LCTAb (lymphocytotoxic antibody), measurement of, and response to nonmatched platelet transfusions by alloimmunized patients, 1727-1729
- LDA, *see* Limiting-dilution analysis
- Leukemia(s)
  - HLA antigens in, 227-232
  - radiogenic, 905-908
  - *See also specific types of leukemias*
- Leukemia virus, *see* HTLV-I; HTLV-II
- Leukemic cells and cell lines
  - 52-kD and 30-kD glucocorticoid receptor fragments produced by neutrophil elastase in cytosol of, 860-868
  - Lf binding by, 264-270
  - *See also specific types of leukemic cells and cell lines*
- Leukemic myelopoiesis, expression of Lf mRNA during, 989-993
- Leukocytes
  - defective synthesis of PAF by, in Zellweger patients related to age, 460-463
  - transfusions of platelet concentrates poor in, prepared by filtration with prostacyclin, 243-247
  - *See also specific leukocytes*
- Leukocytosis induced by rGM-CSF, 206-213
- Lf, *see* Lactoferrin
- LGL (large granular lymphocytes), normal and leukemic, TCR gene rearrangements and expression in, 1500-1508
- Limiting-dilution analysis (LDA)
  - in determination of leukemic cell frequencies after BM decontamination with merocyanine 540 or mafosfamide for ABMTs, 1543-1549
  - of effects of CSFs, phytohemagglutinin, and hydrocortisone on hematopoietic progenitor cell growth, 1611-1618
- Lipoproteins, plasma, factor VIIa-tissue factor complex inhibited by, 1947-1954
- Lithium, effects of, on growth factor production in LTMCs, 1136-1142
- Liver, as site of synthesis of factor XIII α-chain, 579-582
- Liver transplantations, production of Epo in adult recipients of fetal liver, 542-545
- LNH-80 protocol for aggressive lymphomas, 1394-1399
- Locomotion, and chemokinetics of maturing promyelocytic leukemia cells, actin polymerization and, 363-367
- Long-term marrow cultures (LTMCs)
  - adherent cells from, transformed by SV40, 464-474
  - effects of lithium on growth factor production in, 1136-1142.
- Low molecular weight B cell growth factor (L-BCGF), proliferation of ALL B cell precursors induced by, 132-138
- Low-proliferative potential colony-forming cells (LPP-CFCs), effects of rIL-3 on, 401-403

LT (lymphotoxin), *see* Recombinant tumor necrosis factor-β
LTMC's *see* Long-term marrow cultures
Lung carcinoma, advanced non-small-cell, following cisplatin-etoposide regimen, 1412-1417
Lupus anticoagulants, IgG, specificity and mechanisms of action of, 69-76
Lymphoblastic (and lymphocytic) leukemia, *see* Acute lymphoblastic (and lymphocytic) leukemia; Chronic lymphoblastic (and lymphocytic) leukemia
Lymphocytes
  homing receptors on, 1842-1850
  See also B cell(s); Large granular lymphocytes; T cell(s)
Lymphocyte interleukin 2 (IL-2), production and responsiveness of, in primary MDS, 494-500
Lymphocytotoxic antibody (LCTAb), measurement of, and response to nonmatched platelet transfusions by alloimmunized patients, 1727-1729
Lymphoid neoplasms, ocular adnexal, Ig and TCR β chain gene rearrangement in analysis of, 1519-1529
Lymphoid progenitors, B, expression and response of BCGF receptor of, 1020-1034
Lymphokine, activation of oxidative metabolism of U937 cell line mediated by, and enhanced by $1,25(OH)_2D_3$, 1639-1644
Lymphomas
  aggressive, chemotherapy in, 1394-1399
  diffuse, chromosome 18q21 gene rearrangement in, 90-95
  follicular , *see* Follicular lymphoma
  large cell, antiidiotype antibody in analysis of patient with CLL and, 45-50
  non-Hodgkin's, *see* Non-Hodgkin's lymphoma refinement of cytogenetics of, by major breakpoint region of chromosome 18q21, 1816-1823
Lymphoma cells and cell lines, FL-18, obtained from patient with follicular lymphoma, 1619-1623
Lymphotoxin (LT), *see* Recombinant tumor necrosis factor-β
Lysis, augmentation of neutrophil-mediated RBC, by cells derived from monocytes, 1743-1749
Lysosome-like granule protein, 53,000-molecular weight, exposed on surface of circulating activating platelets, 838-845

MAbs, *see* Monoclonal antibody(ies)
MAC-1 glycoprotein, impaired induction of, by chemotactic factors or secretagogues and abnormal stimulated adherence of NGs, 740-750
Macrophage(s)
  PMA-induced production of H_2O_2 in, increased by exposure to γ-irradiation, 694-701
  secretion of CSF for, by monocytes induced bty TNF-α, 1700-1703
  See also entries beginning with terms: Granulocyte-macrophage
Macrophage-like cells, differentiation between basophils and, by KU-812 MoAb, 612-619
Mafosfamide, LDA in determination of leukemic cell frequencies after BM decontamination with, for ABMTs, 1543-1549
Magnesium (Mg) modulating inhibition of volume-stimulated Cl^--dependent K^+ efflux in sickle cells, 1861-1866
MAIPA (monoclonal antibody-specific immobilization of platelet antigen), 1722-1726
Malonate, effects of, on RBC metabolism 1389-1393
Markers
  differentiation, of myelomonocytic lineage, oncoplacental protein SP_1 as, 1279-1283
  of hemostatic system in pathophysiology of prethrombotic state, 343-350
Marrow, *see* Bone marrow
Mastocytosis, cytogenetics of, 1928-1923
Matched platelet transfusions, *see* Platelet transfusions
MC-540 (merocyanine 540), LDA in determination of leukemic cell frequencies after BM decontamination with, for ABMTs, 1543-1549
MDS, *see* Myelodysplastic syndrome
Mechanically injured red blood cells (RBCs), endothelial cell interaction with, 132-137
MEG-01 (megakaryoblastic cell line), biosynthesis and secretion of protein S by, 300-306
Megakaryoblastic leukemia, acute, with Down's syndrome, *c-sis* gene expression in cells of patient with, 368-371
Megakaryocytes
  analysis of maturation of, 1509-1518
  effects of degree of thrombocytopenia on ploidy of, 177-185
  purification of, by FACS, 1735-1742
Megakaryocytic progenitors, BM-derived, effects of rIFN-α and rIFN-γ on, 1175-1179
Membrane-associated sickle Hb (hemoglobin), 1443-1449
Membrane skeleton (MS), abnormal RBC, in severe β-thalassemia, 158-164
Merocyanine 540 (MC-540), LDA in determination of leukemic cell frequencies after BM decontamination with, for ABMT's, 1543-1549
Messenger RNA, *see* mRNA
Metabolism
  oxidative, of U937 cell line activated by lymphokine and enhanced by $1,25\ (OH)_2D_3$, 1639-1644
  RBC, effects of malonate and oxalate on, 1389-1393
Mg (magnesium) modulating inhibition of volume-stimulated Cl^--dependent K^+ efflux in sickle cells, 1861-1866
Microenvironmental factors
  and age-related decline in neutrophil function, 1131-1135
  host origin of hematopoietic, following allogeneic BMT, 1966-1968
Microgranules, neutrophil, MPO in 1630-1638
Minimal residual disease (MRD) in AML, leukemic cell distribution during, 1073-1078
Minimally differentiated acute nonlymphoblastic leukemia (ANLL), 1400-1406
Mixed blood chimerism
  after BMT for hematologic malignancies, 1331-1337
  in T-cell depleted BMT recipients evaluated with DNA polymorphisms, 1692-1695
MM, *see* Multiple myeloma
MM4 MoAb, plasma cell-reactive, elimination of MM stem cells by, 1482-1489
MoAbs, *see* Monoclonal antibody(ies)
Molecular analysis
  of Burkitt's leukemia in two hemophilic brothers with AIDS, 1713-1717
  of clinical expression of HE and HPP, 766-772
  of defects in complex inherited thrombotic disorders, 347
  of fibrinolytic system defects in prethrombotic state, 347-348
  of hereditary ATIII deficiency, 1273-1278
  of $p210^{bcr\text{-}abl}$, in CML, 233-236
  of relapse in CML after allogeneic BMT, 873-876
Molecular species compositions of phosphatidylcholine, effects of, on cellular properties in normal and sickle RBCs, 1111-1118
Monoclonal antibody(ies) (MoAbs; MAbs)
  against activated circulating platelets, 838-845
  anti-plasma prekallikrein, inhibiting prekallikrein activation by factor XIIa, 1053-1062
  against cCLLa in CLL, 437-443

- Monoclonal antibody(ies) (MoAbs: MAbs) (*Continued*)
  - effects of, against vWF and GPIIb/IIIa on platelet retention test, 546-550
  - epitope mapping of functional domains of factor Va with, 139-146
  - flow cytometry in detection of hairy cells using, 1063-1068
  - IgA, recognizing neoantigen on GPIIa, 16-22
  - immunophenotyping of AML using, and alkaline phosphatase-antialkaline phosphatase technique, 83-90

- Myelomonocytic antigens, expression of, on B-CLL cells correlated with their IL-1 production ability, 1750-1757
- Myelomonocytic cell lines, oncoplacental protein SP$_1$ as differentiation marker of, 1279-1283
- Myeloperoxidase (MPO)
  - clinical significance of low levels of positivity of, in childhood ANLL, 51-54
  - in neutrophil microgranules, 1630-1638
  - posttranslation processing of, 1143-1150
- Myelopoiesis, expression of Lf cDNA during normal and leukemic, 989-993

- Natural killer (NK) cells
  - activated by IL-2, in BMTs with soybean lectin-separated and E rosette-depleted BM, 1893-1903
  - normal and leukemic, TCR gene rearrangement and expression in, 1500-1508
- Neoantigen, IgA MoAb recognizing, on GPIIa expressed on stored and activated platelets, 16-22
- Neonatal granulocytes (NGs), abnormal adherence of, 740-750
- Neoplastic cells
  - B, Ki-B3 detecting formalin-resistant antigen on, 629-636
  - *See also* Leukemic cells and cell lines *and specific types of neoplastic cells*
- Neutrophil(s) (PMNs)
  - age and function of, 1131-1135, 1836-1841
  - abnormalities of, in MDS and CML repaired with rG-CSF, 404-411
  - actin filament of, stimulated and primed by PAF, 1921-1927

Neutrophil(s) (PMNs) (*Continued*)
  and augmentation of neutrophil-mediated RBC lysis by cells derived from monocytes, 1743-1749
  CALLA/CD10 negative, chemotactic response of, to activated C, 1624-1629
  defensin in dense granules of, 757-765
  exposed to influenza virus, chemotactic defect in, 351-355
  migration of, rTNF-α and -β compared with rIFN-γ and IL-1α in regulation of, 979-984
  MPO in microgranules of, 1630-1638
  PB, activated by rGM-CSF, 206-213
  sialophorin expressed on, in Wiskott-Aldrich syndrome, 104-109
  tyrosine kinase and phosphotyrosine phoshatase activity in, 356-362
Neutrophil elastase, 52-kD and 30-kD glucocorticoid receptor fragments produced by, in cytosol of leukemic cells, 860-869
Neutrophil protease, regulation of factor V by, 846-851
Neutrophil surface protein, phagocytosis and changes in, 60-68
NGs (neonatal granulocytes), abnormal adherence of, 740-750
NHL, *see* Non-Hodgkin's lymphoma
Nitrous oxide (N_2O), and adenosine dialdehyde inducing HL-60 differentiation, 1161-1164
NK cells, *see* Natural killer cells
Non-anticoagulant heparin inhibiting degradation of ECM haparan sulfate mediated by heparanase, 551-557
Non-Hodgkin's lymphoma (NHL)
  B and T cell clones in, 287-292
  childhood, serum IL-2R levels related to advanced, and its poor outcome, 624-628
  carrying 14;18 translocation and associated with additional nonrandom chromosome changes, 444-447
  immunology and histology of, correlated with translocations, 1554-1564
Nonlymphoblastic leukemia, *see* Acute nonlymphoblastic (and nonlymphocytic) leukemia
Nonmatched platelet transfusions, *see* Platelet transfusions
Non-small-cell carcinoma of the lung (NSCLC), advanced, ANLL following cisplatin-etoposide regimen for, 1412-1417
Normal B cells
  flow cytometry of BM showing development of, 1316-1324
  Ki-B3 detecting formalin-resistant antigen on, 629-636
Normal cells, CD1 intermolecular complexes on, 676-685
Normal cellular counterparts of B-CLL, 418-427
Normal globin, equal stabilities of β°-39 mRNA in β-thalassemia, 293-301
Normal granulocytes, transcriptionally active *c-fos* in, 456-459
Normal hematopoietic cells, interaction of rTNF-α and all-*trans*-retinoic acid with leukemic and, 1940-1946
Normal individuals
  plasma and platelet HLA in, measured by ELISA, 282-286
  proteolytic degradation of vWF in, after DDAVP administration, 173-176
Normal lymphocytes
  histone H1° not synthesized by, 1203-1207
  large granular, TCR gene rearrangements and expression in, 1500-1508
  See also Normal B cells
Normal CALLA-positive B cell precursors, phenotypic similarities and differences between CALLA-positive ALL cells and, 814-821
Normal myelopoiesis, expression of Lf mRNA during, 989-993
Normal natural killer (NK) cells, T cell receptor gene rearrangements and expression in, 1500-1508
Normal peripheral blood (PB) monocytes, as sites of synthesis of factor XIII a-chain, 579-582
Normal platelet aggregation, prolonged BT and tests of, as indication of SPD, 620-623
Normal progenitor cells, dCyd protecting, from Ara-C cytotoxicity, 560-571
Normal red blood cells (RBCs)
  effects of molecular species composition of PC on cellular properties of, 1111-1118
  endothelial cell interaction with, 152-157
NSCLC (non-small-cell carcinoma of the lung), advanced, ANLL following cisplatin-etoposide regimen for, 1412-1417
N-terminal portion of vWF, localization of factor VIII binding domain on 34-kD fragment of, 1679-1682
Nucleotide sequence, cloning and, of RBC β-spectrin cDNA, 915-920

Ocular adnexal lymphoid neoplasms, Ig and TCR β chain gene rearrangement in analysis of 1519-1529
Oncogene(s)
  c-myc, rTNF regulating expression of, in HL-60 cells, 200-205
  ETS-1, identification of RFLP involving, on chromosome 11q23, 327-329
  HL-60, structure and expression of, 1237-1239
  See also Protooncogene
Oncoplacental protein SP_1, as differentiation marker of myelomonocytic lineage, 1279-1283
183-kD-myeloid-specific-DNA-binding protein, immunohistochemistry of, in B5, fixed, paraffin-embedded tissues and BM aspirates by BM-1 MoAb, 1124-1130
Oral anticoagulants, prothrombin activation suppressed by, 348-349
Outcome, *see* Prognosis
Oxalate, effects of, on RBC metabolism, 1389-1393
Oxidative metabolism of U937 cell line activated by lymphokine and enhanced by $1,25(OH)_2D_3$, 1639-1644
Oxidative stress hemolysis, RBC, genetic differences in influence of Hb on, 909-914
Oxygen delivery, HbS gelation and, 1255-1257

PA, *see* Plasminogen activator
PAF, *see* Platelet activating factor
PAI-1, *see* Plasminogen activator inhibitor, type 1
PB, *see* Peripheral blood
PC (phosphatidylcholine), effects of molecular species composition of, on cellular properties in normal and sickle RBCs, 1111-1118
p80 glycoprotein (GP), RBC, characterization of, and membrane protein defect of *In(lu)* Lu(a-b) RBC, 1475-1481
Peripheral blood (PB), juvenile chronic myelogenous leukemia cells in, during remission, 1466-1469
Peripheral blood (PB) B lymphocytes, evidence of involvement of, in MM, 1550-1553
Peripheral blood (PB) granulocyte-macrophage colonies (CFU-GM), response of, to PGE_1, 1792-1796
Peripheral blood (PB) monocytes, normal, as sites of synthesis of factor XIII a-chain 379-382
Peripheral blood (PB) mononuclear cells, response of, to IL-2 after BMT, 1595-1603
Peripheral blood (PB) neutrophils activated by rGM-CSF, 206-213
Peripheral blood (PB) T cells
  effects of herpes virus, cytomegalovirus and EBV on, 516-523
  in MM, 1550-1553

P. falciparum (Plasmodium falciparum), cytoplasmic factor required for entry of, into RBCs, 77-82

PGE$_1$ (prostaglandin E$_1$), PB and BM CFU-GM response to, 1792-1796

Ph chromosome, *see entries beginning with term:* Philadelphia

PHA (phytohemagglutinin), effects of, on hematopoietic progenitor cell growth, 1611-1618

Phagocytosis, and changes in neutrophil surface protein, 60-68

Phenotype
  analysis of, in ALL, at first presentation and at relapse, 1073-1078
  basophil, 1872-1879
  CD1 molecule, 676-685
  differences and similarities in, of CALLA-positive ALL cells and normal marrow CALLA-positive B cell precursors, 814-821
  erythroid, of HEL cells, 1764-1772
  HL-60, BM matrix modulation of, 1119-1123
  monocytic, *c-fos* expression in acute leukemias with, 1450-1457
  S--s--U blood group, δ glycophorin gene deletion in individuals homozygous for, 1830-1835
  α-thalassemia, Showa-Yakushiji ($_\beta$110 Leu-Pro) globin causing, 1688-1691
  See also Immunophenotyping

Philadelphia (Ph)-negative chronic myeloblastic leukemia (CML), establishment and characterization of myeloid cell lines from, in patient with MDS, 1670-1677

Philadelphia (Ph)-positive acute lymphoblastic leukemia (ALL)
  BMTs for, 587-588
  childhood, *see* Childhood Philadelphia-positive acute lymphoblastic leukemia

Philadelphia (Ph)-positive acute myelogenous leukemia (AML)
  c-*abl* expression in, 1584-1588
  with chromosome 22 breakpoint outside bcr, 1659-1664

Phorbol esters
  inducing IL-2R on cell surface of precursor thymocyte leukemia without T cell receptor β and γ gene rearrangement, 1291-1296
  platelets sensitized to activation by physiological agonists of, 1373-1381
  See also specific phorbol esters

Phorbol myristate acetate (PMA)
  exposure to γ-irradiation increasing H_2O_2 production in macrophages induced by, 694-701
  proliferation of B-PLL cells induced by, 670-675

Phosphatase
  and alkaline phosphatase-antialkaline phosphatase technique in phenotyping of AML, 83-90
  phosphotyrosine, activity of, in promyelocytic leukemia cells and PMNs, 356-362

Phosphatidylcholine (PC), effects of molecular species composition of, on cellular properties in normal and sickle RBCs, 1111-1118

Phosphorylation
  of 48-kD respiratory burst-associated protein enhanced by 1,25(OH)$_2$D$_3$, 1639-1644
  platelet protein, changes in, due to ADP, 511-515

Phosphotyrosine phosphatase, activity of, in promyelocytic leukemia cells and PMNs, 356-362

Phororadiation therapy (PRT) for clinical ex vivo treatment of BM for ABMTs, 484-489

Physiologic agonists of phorbol esters, platelets sensitized to activation by, 1373-1381

Physiologic regulation of renal Epo mRNA, 316-323

Phytohemagglutinin (PHA), effects of, on hematopoietic progenitor cell growth, 1611-1618

Plasma
  coagulation-kinin pathway of, 1-15
  vWF on platelet surface stimulated by ADP in, 1362-1366

Plasma anti-glycoprotein (GP) autoantibodies in chronic ITP, 1040-1052

Plasma cell myeloma, new pre-B cell component of 932-942

Plasma cell-reactive MM4 MoAb, elimination of MM stem cells by C and, 1482-1489

Plasma factor IX, HTLV-1 or HIV separated from, by immunoaffinity chromatography with conformation-specific antibodies, 1312-1315

Plasma HLA in normal individuals measured by ELISA, 282-286

Plasma lipoproteins, factor VIIa-tissue factor complex inhibited by, 1947-1954

Plasminogen activator (PA)
  DS-induced release of, 1858-1860
  tissue-type, fibrinolytic response to, 564-567

Plasminogen activator inhibitor, type I (PAI-1)
  conversion of active to latent, from endothelial cells, 1090-1098
  ECM of aortic endothelial cells containing, 721-728
  radioimmunoassay of concentration of plasma, during venous occlusion and platelet aggregation, 1645-1653

Plasmodium falciparum (P. falciparum), cytoplasmic factor required for entry of, into RBCs, 77-82

Platelet(s)
  activated, *see* Activated platelets
  ADP and, *see* ADP, platelets and dense tubular system of, [^{3}H]arachidonic acid uptake in, 832-837
  effects of degree of thrombocytopenia on volume of, 177-185
  Fg and, *see* Fibrinogen, platelets and; Fibrinogen-platelet binding
  FN required for adhesion of, on subendothelium and collagen surfaces, 1437-1442
  formation of TXA$_2$ on contact with, in calcium medium, 647-651
  FSBA as weak agonist of, 751-756
  ^{111}In-oxine, survival of, in childhood thrombocytopenia, 652-656
  sialophorin expressed on, in Wiskott-Aldrich syndrome, 104-109
  vWF and, *see* Von Willebrand factor, platelets and

Platelet activating factor (PAF)
  defective synthesis of, in Zellweger patients related to age, 460-463
  PMN actin filament assembly stimulated and primed by, 1921-1927

Platelet aggregation
  ADP and, *see* ADP, platelets and
  Fg and, *see* Fibrinogen, platelet aggregation and
  prolonged bleeding time and normal tests of, as indication of SPD, 620-623
  radioimmunoassay of plasma concentration of PAI-1 after, 1645-1653
  shear stress activation of GPIIb/IIIa plus vWF causing, 1354-1361
  surface expression of GPIIb/IIIa related to, 475-483

Platelet antigen, monoclonal antibody-specific immobilization, 1722-1726

Platelet-associated autoantibodies in chronic ITP, 1040-1052

Platelet HLA in normal individuals measured by ELISA, 282-286

Platelet membrane glycoprotein Ib (GPIb)
  botrocetin-induced vWF binding to, 985-988
  fibrin monomer inducing binding of vWF to glycocalicin portion of, 1589-1594
  pseudo-BSS due to autoantibody to, 428-431
  thrombin-induced changes in, 1678-1683
  vWF interaction with, 607

Platelet membrane glycoprotein IIa (GPIIa), IgA MoAb recognizing neoantigen on, expressed on stored and activated platelets, 16-22
Platelet membrane glycoprotein IIb/IIIa (GPIIb/IIIa)
  effects of MoAbs against, on platelet retention test, 546-550
  shear stress activation of, plus vWF causing platelet aggregation, 1354-1361
  surface expression of, induced by platelet activation, 475-483
  thrombin-induced changes in, 1673-1678
  vWF interaction with, 607
Platelet membrane glycoprotein IX (GPIX), thrombin-induced changes in, 1673-1678
Platelet proteins, changes in phosphorylation of, due to ADP, 511-515
Platelet retention test, effects of MoAbs against vWF and GPIIb/IIIa on, 546-550
Platelet surface, vWF on, stimulated in plasma by ADP, 1362-1366
Platelet transfusions
  assay for anti-HLA antibodies and selection of, 1495-1499
  effects of high-dose IV IgG on responses to single-donor platelets in patients refractory to, 1433-1436
  leukocyte-poor, prepared by filtration with prostacyclin, 243-247
  measurement of LCTAb, and response to, by alloimmunized patients, 1727-1729
  to refractory patients, crossmatching, ABO, and HLA matching for, 23-30
Platelet-type von Willebrand's disease (vWF), interactions of Asialo vWF with platelets in, 1804-1809
PLB-985 (myeloid leukemia cell line) with granulocytic and monocytic differentiating capacity, 372-378
PLL, *see* Prolymphocytic leukemia
Ploidy
  prognosis and hypoploidy in childhood ALL, 247-253
  megakaryocyte, effects of degree of thrombocytopenia on, 177-185
PMA, *see* Phorbol myristate acetate
PMNs, *see* Polymorphonuclear leukocytes
Polymer, fibrin 1, regulation of thrombin action on, in prethrombotic state, 347
Polymerization of actin, and its relationship to locomotion and chemokinetic response in maturing promyelocytic leukemia cells, 363-367
Polymorphisms, DNA, *see* Restriction fragment length polymorphisms
Polymorphonuclear luekocytes (PMNs)
  effect of flow cytometry on endothelial cell adhesion to, 1284-1290
  See also Basophils; Granulocyte(s); Neutrophil(s)
Polysaccharide antibody, deficiency in antibacterial, after allogeneic BMT, 779-785
Posttranslational processing of MPO, 1143-1150
Potassium (K)
  and deoxygenation inhibiting volume-stimulated Cl^--dependent K^+ efflux, 1861-1866
  transport of, inhibited by divalent cations in sickle RBCs, 1810-1815
Pre-B cell component, plasma cell myeloma, 932-942
Precommitted erythroid cells, enriched in Friend erythroleukemia cell cultures, 1565-1571
Precursor thymocyte leukemia, phorbol ester inducing IL-2R on cell surface of, without T cell receptor β and γ gene rearrangement, 1291-1296
Prekallikrein MoAb, anti-plasma, inhibiting prekallikrein activation by factor XIIa, 1053-1062
Prenatal conditions and interventions, *see entries beginning with term:* Fetal
Prethrombotic state, markers of hemostatic system activation in pathophysiology of, 343-350
Primary acquired sideroblastic anemia, *see* Acquired idiopathic sideroblastic anemia
Primary myelodysplastic syndrome (MDS), lymphocyte IL-2 production and responsiveness in, 496-500
Progenitor cells, *see specific progenitor and precursor cells*
Prognosis
  of aggressive lymphomas treated with LNH-80 protocol, 1394-1399
  and ALG therapy of aplastic anemia, disease severity and, 1046-1052
  of childhood ALL, hypoploidy and, 247-253
  childhood NHL, serum levels of IL-2R and, 624-628
Prolymphocytic leukemia (PLL), T-cell, cytogenetics of, 926-931
Prolymphocytic leukemia (PLL) cells, B, proliferation of, induced by PMA and native or rIFN-γ, 670-675
Promoter mutation, β globin gene on Chinese $\delta\beta$-thalassemia chromosome carrying, 1470-1474
Promyelocytic leukemia, acute, localization of G-CSF gene on chromosome 17 proximal to t(15;17) breakpoint in, 330-332
Promyelocytic leukemia cells
  actin polymerization and its relationship to locomotion and chemokinetic response in maturing, 363-367
  receptor-mediated monocytoid differentiation of, by TNF, 994-1002
  tyrosine kinase and phosphotyrosine phosphatase activity in, 356-362
  See also specific types of leukemia cells
Prostacyclin, leukocyte-poor platelet transfusions prepared by filtration with, 243-247
Prostaglandin E_1 (PGE_1), PB and BM CFU-GM response to, 1792-1796
Protease
  activity of cysteine, in serum of patients with TTP dependent on calcium, 1584-1588
  plasma, coagulation-kinin pathway interactions with, 6-7
  neutrophil, regulation of factor V by, 846-851
Protein(s)
  cleavage of, during contact activation of coagulation-kinin pathway, 4-5
  core and envelope HIV, antibodies to, 575-578
  53,000-molecular weight lysosome-like granule, exposed on surface of circulating activated platelets, 838-845
  48-kD respiratory burst-associated, phosphorylation of, enhanced by $1,25(OH)_2D_3$, 1639-1644
  183-kD-myeloid-specific-DNA-binding, immunohistochemistry of, in B5, paraffin-embedded tissues and BM aspirates by BM-1 MoAb, 1124-1130
  platelet, changes in phosphorylation of, due to ADP, 511-515
Protein S, biosynthesis and secretion of, by megakaryoblastic cell line, 301-306
Protein SP_1, oncoplacental, as differentiation marker of myelomonocytic lineage, 1279-1283
Proteoglycan, synthesis of, in stromal cell lines, 1777-1783
Proteolytic degradation of vWF after administration of DDAVP in normal individuals, 173-176
Prothrombin
  activation of, suppressed by oral anticoagulants, 348-349
  effects of warfarin on synthesis and secretion of, in HEP G2 cells, 773-778

- Rh alloantibodies, antiidiotypic IgG crossreactive with, in RBC autoimmunity, 710-715

Ribonucleic acid, messenger, *see* mRNA
Ribosylation inhibitors, inhibitors of GF-induced proliferation of ADP, 686-693
Richter's syndrome (large cell lymphoma), antiidiotypic antibody in analysis of patient with CLL and, 45-50
rIFN, *see* Recombinant interferon
rIL-3, *see* Recombinant interleukin 3
Ristocetin, vWF and, 898-900
RNA, messenger, *see* mRNA
rTNF, *see* Recombinant tumor necrosis factor

SCA (sickle cell anemia), HbF production in, 716-721
SCID (severe combined immune deficiency), haploidentical BMT for, and BM treated with CT-2 and C following, 664-669
Second remission, BMT for childhood ALL in, 324-326
Secretagogues, impaired induction of MAC-1 by, and abnormal stimulated adherence of NGs, 740-750
Sedimentation, RBC, 1572-1576
Seropositivity to HIV in hemophilia A and B, 276-281, 786-790
Serum
  capacity of, to depolymerize actin filaments, 524-530
  of HIV-infected patients, detection of HIV antigen and specific antibodies to HIV core and envelope proteins in, 575-578
  of patients with HCL, soluble IL-2R in, 1530-1535
  of TTP patients, cysteine protease activity dependent on calcium in, 1584-1588
Serum immunoreactive erythropoietin (siEp) in childhood cyanotic and acyanotic CHD, 822-826
Serum interleukin 2 receptors (IL-2R)
  high levels of, related to advanced childhood NHL and its poor outcome, 624-628
  soluble, *see* Soluble interleukin 2 receptors
Serum transferrin receptor, as index of erythropoiesis, 1955-1958
7p−;11p+ translocation [t(7p−;11p+)] involving short arm of chromosomes 7 and 11 and associated with AML, 1654-1658
7p−;12q translocation [t(7p−;12q)], recurrent abortion and hypofibrinogenemia associated with, 921-925
Severe aplastic anemia, allogeneic BMT as therapy of, 1325-1330
Severe combined immune deficiency (SCID), haploidentical BMT for, and BM treated with CT-2 and C following, 664-669
Severe β-thalassemia, abnormal RBC MS in, 158-164
Shear stress activation of GPIIb/IIIa plus vWF causing platelet aggregation, 1354-1361
Showa-Yakushiji ($_\beta$110 Leu-Pro) globin, α-thalassemia phenotype due to, 1688-1691
Sialophorin in Wiskott-Aldrich syndrome, 104-109
Sickle cell(s)
  Cl^--dependent K^+ efflux in, deoxygenation inhibiting volume-stimulated, 1861-1866
  effects of molecular species composition of PC on cellular properties of, 1111-1118
  endothelial cell interactions with, 152-157
  K transport inhibited by divalent cations in, 1810-1815
  membrane-associated sickle Hb and rigidity of, 1443-1449
  See also specific thalassemias
Sickle cell anemia (SCA), HbF production in, 716-721
Sickle cell disease, *see* HbS
Sickle trait, endothelial cell interaction with, 152-157
Sideroblastic anemia, *see* Acquired idiopathic sideroblastic anemia
siEp (serum immunoreactive erythropoietin), childhood cyanotic and acyanotic CHD, 822-826
sIL-2R, *see* soluble interleukin 2 receptors
Simian virus 40 (SV40), adherent cells from LTMC transformed by, 464-474
Single-donor platelets, effects of high-dose Iv IgG on responses to, in patients refractory to platelet transfusions, 1433-1436
Soluble interleukin 2 receptors (sIL-2F)
  levels of, in B-CLL, 396-400
  in patients with HCL, 1530-1535
S-100 β^+ T cells, characteristics and behavior of, under normal and pathologic conditions, 214-220
Soybean lectin-separated marrow
  IL-2-activated killer cells following BMT with E rosettle-depleted BM and, 1893-1903
  IL-2 production and response to IL-2 by PB mononuclear cells following BMT with, 1595-1603
Spanish $\gamma\beta^0$-thalassemia, 3′ ends of deletions of β globin gene in, 593-596
SPD (storage pool deficiency), prolonged bleeding time and normal aggregation tests as indication of, 620-623
β-Spectrin cDNA, nucleotide sequence of RBC, 915-920
S--s--U blood group phenotype, glycophorin gene deletion in individuals homozygous for, 1830-1835
Stem cell(s)
  elimination of, from MM cells by plasma cell-reactive MM4 and C, 1482-1489
  multipotent, *see* Multipotent stem cell(s)
Storage pool deficiency (SPD), prolonged bleeding time and normal aggregation tests as indication of, 620-623
Stored platelets, IgA MoAb recognizing neoantigen on GPIIa expressed on activated and, 16-22
Stromal cells
  B cell differentiation in close association with, in diffusion chambers, 1418-1424
  characteristics of, in adherent cells from LTMCs, 464-474
  proteoglycan synthesis in, 1777-1783
Structure-function relationship of vWF, 605-611
Subendothelium
  arterial, platelet adherence to, inhibited by Asialo vWF, 1084-1089
  FN required for platelet adhesion and thrombus formation on, 1437-1442
Superoxide, production of, rTNF-α and -β compared with rIFN-γ and IL-1α in regulation of, 979-984
Survival, *see* Prognosis
SV40 (simian virus 40), adherent cells from LTMC transformed by, 464-474

T-ALL (T cell acute lymphoblastic leukemia), TRGγ diversity and mRNA expression in, 637-646
TBI (total body irradiation), allogeneic BMT without, 1382-1388
T cell(s)
  clones of, in non-Hodgkin's lymphoma, 287-292
  PB, *see* Peripheral blood T cells
  sialophorin expressed on, in Wiskott-Aldrich syndrome, 104-109
  S-100$^+$, characteristics and behavior of, under normal and pathologic conditions, 214-220
T cell acute lymphoblastic leukemia (T-ALL), TRGγ diversity and mRNA expression in, 637-646
T cell chronic lymphocytic leukemia (T-CLL), IL-2 dependent on T cells from patient with, not infected with HTLV-L, 1069-1071
T-cell depleted marrow
  IL-2 production and response to IL-2 by PB mononuclear cells following BMT with, 1595-1603
  mixed blood chimerisms in transplantation with, evaluated with DNA polymorphisms, 1692-1695
  recovery of functional T cell frequencies in recipients of transplants with, 960-964

T cell leukemia cells
  adult, IL-2-dependent expansion of, 1407-1411
  CD1 antigen on, 676-685
T cell leukemia viruses type I and type II, human, *see* HTLV-I; HTLV-II
T-cell prolymphocytic leukemia (T-PLL), cytogenetics of, 926-931
T cell rearranging gene γ (TRGγ), diversity and mRNA expression of, in T-ALL, 637-646
T cell receptor (TCR) β chain gene rearrangement
  in occular adnexal lymphoid neoplasia, 1519-1529
  phorbol ester inducing IL-2R on cell surface of precursor thymocyte leukemia with, 1291-1296
T cell receptor (TCR) γ chain gene rearrangement
  in childhood ALL, 1933-1939
  phorbol ester inducing IL-2R on cell surface of precursor thymocyte leukemia without, 1291-1296
T cell receptor (TCR) gene(s), configuration of, in infant ALL, 536-541
T cell receptor (TCR) gene rearrangement, and expression in normal and leukemic LGL and NK cells, 1500-1508
TCR, *see entries beginning with term:* T cell receptor
Terminal transferase (TdT), HL-T cell line expressing, and secreting suppressor activity, 1151-1160
12-0-Tetradecanoylphorbol-13-acetate (TPA), synergistic action of A23187 and, on B-CLL cells, 1536-1542
TGs (transglutaminases) in vascular cells and tissues as alternate pathway for fibrin stabilization, 702-709
α-Thalassemia phenotype, Showa-Yakushiji ($_{\beta}$110 Leu-Pro) globin causing, 1688-1691
β-Thalassemia
  equal stabilities of normal β globin and β°-39 mRNA in, 293-301
  iron homeostasis in, 1462-1465
  mutation in IVS-1 sequence of β globin causing, 147-151
  permeability and concentration of calcium not impaired in, 804-808
  severe, abnormal RBC membrane skeleton in, 158-164
  ~300 bp deletion involving part of 5′ region of β globin gene, 583-586
$\gamma\beta^{\circ}$-Thalassemia, Spanish, 3′ ends of deletions of β globin gene in, 593-595
δ°-Thalassemia, homozygous, δ globin gene from patients with, functioning normally on transient expression of heterologous cells, 809-813
Therapy-related acute myeloblastic leukemia (AML), chromosome 5 long arm deletion and, 1707-1708
30-kD glucocorticoid receptor fragments produced by neutrophil elastase in cytosol of leukemic cells, 860-868
34-kD fragment of *N*-terminal portion of vWF, localization of factor VIII binding domain on, 1679-1682
3;21 translocation [t(3;21] associated with blast phase of CML, 1338-1342
~300 bp β globin gene deletion involving part of 5′ region in β-thalassemia, 583-586
Thrombin
  changes induced by, in GPIb, GPIX, and GPIIb/IIIa, 1673-1678
  regulation of action of, on fibrin I polymer in prethrombotic state, 347
  regulation of generation of, 344-345
Thrombocytopoienia
  childhood, ^{111}In-oxine platelet survival in, 652-656
  effects of degree of, on megakaryocyte ploidy and platelet volume, 177-185
  pseudo-BSS as, caused by autoantibody to GPIb, 428-431
Thrombocytopenic purpura
  immune, *see* Immune thrombocytopenic purpura
Thrombocytopenic purpura (*Continued*)
  thrombotic, cysteine protease activity in serum of patients with, dependent on calcium, 1683-1687
Thromboplastin, tissue, HTF1-788 inhibiting, 490-493
Thrombopoiesis, regulation of, 177-185
Thrombotic disorders
  inherited, 345-347
  See also specific disorders
Thrombotic thrombocytopenic purpura (TTP), cysteine protease activity in serum of patients with, dependent on calcium, 1585-1588
Thromboxane A$_2$ (TXA$_2$), formation of, on contact with platelets, 647-651
Thrombus, FN required for formation of, on subendothelium and collagen surfaces, 1437-1442
Thymocyte(s), sialophorin expressed on, in Wiskott-Aldrich syndrome, 104-109
Thymocyte leukemia, phorbol ester inducing IL-2R on cell surface of precursor, without TCR β and γ gene rearrangement, 1291-1296
Thymus cells, CD1 antigen phenotypes identified on, 676-685
Tissue factor (factor III; tissue thromboplastin), HTF1-788 MoAb inhibiting, 490-493
Tissue factor-factor VIIa complex inhibited by plasma lipoproteins, 1947-1954
Tissue localization of renal Epo mRNA, 316-327
Tissue-type plasminogen activator (tPA), fibrinolytic response to, 564-567
T-PLL (T-cell prolymphocytic leukemia), cytogenetics of, 926-931
TNF, *see* Tumor necrosis factor
Total body irradiation (TBI), allogeneic BMT without, 1382-1388
TPA (12-0-tetradecanoylphorbol-13-acetate), synergistic action of A23187 and, on B-CLL cells, 1536-1542
tPA (tissue-type plasminogen activator), fibrinolytic response to, 564-567
Transferase, terminal, HL-T cell line expressing, and secreting suppressor activity, 1151-1160
Transferrin receptors
  regulation of expression of, in myeloid leukemia, 852-859
  serum, as index of erythropoiesis, 1955-1958
Transferrin-transferrin receptor complex, reticulocyte-coated vesicles carrying, 1035-1039
Transfusions
  blood product, risk of AIDS for recipients of, from donors subsequently developing AIDS, 1604-1610
platelet, *see* Platelet transfusions
Transglutaminases (TGs) in vascular cells and tissues, as alternate pathway for fibrin stabilization, 702-709
Translocation(s)
  3;21, associated with blast phase of CML, 1338-1342
  7p–;11p+, involving short arm of chromosomes 7 and 11 and associated with AML, 1654-1658
  7p–;12q, recurrent abortion and hypofibrinogenemia associated with, 921-925
  14;18, histology of NHL carrying, associated with additional nonrandom chromosome changes, 444-447
  15;17, localization of G-CSF gene on chromosome 17 proximal to breakpoint of, in APL, 330-332
  histology and immunology of NHL and ATL correlated with, 1554-1564
  tdic(9;12), in childhood B-cell precursor ALL, 1962-1965
Transplantations
  adult recipients of fetal liver, Epo production in, 542-545
  See also Bone marrow transplantations

TRG γ (T cell rearranging gene γ), diversity and mRNA expression of, in T-ALL, 637-646

TTP (thrombotic thrombocytopenic purpura), cysteine protease activity in serum of patients with, dependent on calcium, 1683-1687

T200 antigen, relationship between expression of, and stages of B cell differentiation in resurgent hyerplasia of BM, 1165-1172

Tumor necrosis factor (TNF)
  recombinant, *see* Recombinant tumor necrosis factor
  sensitivity of G-CSF and GM-CSF to, 1773-1776

Tumor necrosis factor-α (TNF-α)
  recombinant, *see* Recombinant tumor necrosis factor-α
  secretion of CSF for macrophages by monocytes induced by, 1700-1703

Tumor necrosis factor (TNF) receptors
  on hematopoietic cells, 1730-1734
  monocytoid differentiation of promyelocytic cells mediated by, 994-1002

TXA_2 (thromboxane A_2), formation of, on contact with platelets, 647-651

Tyrosine kinase in promyelocytic leukemia cells and PMNs, 356-362

Ultraviolet (UV) irradiation, laser-, for virus inactivation in blood products, 589-591

Unfractionated marrow cells, ABMT using, cryopreserved in DMSO and HES, 974-978

U937 cell line, lymphokine-mediated activation of oxidative metabolism of, enhanced by $1,25(OH)_2D_3$, 1639-1644

Vascular cells and tissues, TGs in, as alternate pathway for fibrin stabilization, 702-709

Venous occlusion, radioimmunoassay of plasma concentration of PAI-1 during, 1645-1653

Vessel wall, vWF interaction with, 605

Viruses
  laser-ultraviolet irradiation for inactivation of, in blood products, 589-591
  See also specific viruses

Von Willebrand factor (vWF)
  collagen-interactive domain of, between amino acid residues Gly 911 and Glu 1,365, 1577-1583
  fibrin monomer inducing binding of, to glycocalicin portion of GPIb, 1589-1594
  localization of factor VIII binding domain on 34-kD fragment of *N*-terminal portion of, 1679-1682
  proteolytic degradation of, in normal individuals after DDAVP administration, 173-176
  structure-function relationship of, 605-611
  vWD and, 895-904

Von Willebrand factor (vWF), platelets and
  Asialo vWF, *see* Asialo von Willebrand factor botrocetin-induced binding of vWF to GPIb and, 985-988
  effects of calcium concentration on ability of, to support ADP-induced platelet aggregation, 827-831
  effects of MoAbs against vWF and GPIIb/IIIa on platelet retention test, 546-550
  interaction between, 605
  involvement of vWF in platelet adhesion to collagen, 1214-1217
  localization of surface vWF on resting and stimulated platelets, 1297-1302
  shear stress activation of GPIIb/IIIa plus vWF causing platelet aggregation, 1354-1361
  and vWF on surface of platelets stimulated in plasma by ADP, 1362-1366

vWD and vWF, *see* Von Willebrand factor; Von Willebrand's disease

Von Willebrand's disease (vWD)
  filter blockage and bleeding time in, 1354-1361
  platelet-type, interactions of Asialo vWF with platelets in, 1804-1809
  vWF and, 895-904; *see also* Von Willebrand factor

Warfarin, effects of, on prothrombin synthesis and secretion in HEP G2 cells, 773-778

Whole blood, detection of activated platelets in, using activation-dependent MoAbs and flow cytometry, 307-315

Wiskott-Aldrich syndrome (WAS), sialophorin in, 104-109

Zellweger syndrome, defective synthesis of PAF by leukocytes in, related to age, 460-465

INFORMATION FOR CONTRIBUTORS

SUBMITTING THE MANUSCRIPT

BLOOD, The Journal of The American Society of Hematology, provides an international forum for the publication of original articles, in English, describing basic laboratory and clinical investigations encompassed in the broad discipline of hematology. The scope of the journal covers all aspects of hematology, including disorders of leukocytes, both benign and malignant, erythrocytes, platelets, hemostatic mechanisms, and immunology, as well as major developments in clinical laboratory diagnosis and blood banking.

Manuscripts are accepted for consideration on the condition that they are contributed solely to BLOOD. No substantial part of a paper may have been or may be published elsewhere, except for an abstract of 500 words or less. Manuscripts will be critically reviewed by the Editor or an Associate Editor with appropriate independent referees drawn from the Editorial Board and other experts. Acceptance of papers for publication is based upon the originality of the observation or investigation, the quality of the work described, and the clarity of the presentation. Papers will ordinarily be published in the order in which they are finally accepted for publication and not in the order of submission. Acknowledgments to other investigators for advice or data must be substantiated by written authorization specifically granting permission to authors.

Concise Reports: BLOOD will consider for rapid editorial review and decision Concise Reports of original investigations of scientific importance within the broad discipline of hematology. The value to the scientific readership of rapid publication is a criterion for acceptance of Concise Reports. Such manuscripts must represent original and definitive studies and include adequate description of experimental methods, documentation of findings, and references to the literature. No case studies, methods papers, or preliminary reports will be considered. The Editors will provide decisions on such manuscripts within three weeks of receipt at the BLOOD Office. These decisions may not be accompanied by detailed reviewers' comments such as are returned with manuscripts handled in the ordinary manner. Request for consideration as a Concise Report should be made in the author's covering letter upon submission. Concise Reports cannot exceed ten typed pages, including tables, figures, and references (count two graphs or one photomicrograph as a typed page). Papers exceeding the ten-page limit will be delayed while the author is being contacted. Papers not accepted for rapid publication as Concise Reports may be resubmitted for consideration as regular manuscripts.

Letters to the Editor: Letters to the Editor are welcomed and will be published if appropriate. They should be typewritten, double spaced, and generally should be no more than two typewritten pages in length.

Editorials, Brief Reviews: Editorials and Brief Reviews may be solicited by the Editors. These manuscripts must be prepared in a manner appropriate for other papers and will be reviewed as are original articles submitted for consideration.

Authors must accept the responsibility of conforming to the instructions in "Information for Contributors." Articles, editorials, letters to the editor, and other text material in BLOOD represent the opinions of the authors and do not reflect the opinions of The American Society of Hematology, the publisher, or the institution with which the author is affiliated, unless the contrary is specified.

Authors submitting a manuscript do so with the understanding that if it is accepted for publication, copyright in the article, including the right to reproduce the article in all forms and media, shall be assigned exclusively to the Publisher. To comply with US copyright law and the requirements of the insurance carrier, authors of accepted manuscripts and letters will be requested to sign a copyright release form. The Publisher will not refuse any reasonable request by the author for permission to reproduce any of his or her contributions to the journal.

Submit papers, with a $50.00 (in US funds) check, money order, or institutional purchase order to cover the cost of manuscript handling, to:

John W. Adamson, MD, Editor
BLOOD
University District Building—Room 410
1107 NE 45th St
Seattle, WA 98105
(206) 545-8080

All checks and money orders must be marked with the first author's name, in order to avoid delay in processing. Receipt of a manuscript will be acknowledged by a card bearing the name of the Editor or Associate Editor who is assigned responsibility for the review process. All correspondence concerning the manuscript should be addressed to the Editor or Associate Editor. Effective January 1, 1987, all manuscripts submitted to BLOOD and subsequently accepted for publication will be assessed a $50.00 charge per published page. This charge is necessary to offset the increasing costs of publication.

Papers reporting human experimentation will be reviewed in accordance with the precepts established by the Helsinki Declaration. Copies of this declaration may be obtained by writing to the American Medical Association, 535 N Dearborn St, Chicago, IL 60610. Such papers must include a statement that the human investigations were performed after approval by a local Human Investigations Committee and in accord with an assurance filed with and approved by the Department of Health and Human Services where appropriate.

All manuscripts dealing with recombinant DNA research must include a description of the physical and biologic containment procedures practiced, in accord with the National Institutes of Health Guidelines for Research Involving Recombinant DNA Molecules. The Editors of BLOOD will assume that the authors of research papers published in BLOOD are prepared to distribute to bona fide academic investigators exclusively for their own research any clone of cells or DNA used in the experiments.

(Continued on following page)

(Continued from preceding page)

PREPARING THE MANUSCRIPT

The original and *two* complete copies of the manuscript (including letters to the Editor) must be submitted. Manuscripts must be typewritten, double or triple spaced on good quality 8½-by-11-inch white paper with margins of at least one inch. Please do not use erasable bond.

The first page of the manuscript should contain the following information: (1) title of the paper; (2) authors' names; (3) name of institution in which work was done; (4) acknowledgments for research support; (5) name and address of the author to whom communications regarding the manuscript should be directed.

The second page should contain an abstract of 200 words or less, summarizing the reason for the study, the methods used, the results, and the major conclusions. Do not include a summary at the end of the paper.

PREPARING ILLUSTRATIONS AND TABLES

Tables and illustrations must be cited in order in the text using arabic numerals. All line drawings should be submitted as clear, glossy, black and white photographs. Hand-drawn or hand-lettered illustrations are unacceptable. Legible copies may be used only with the duplicate manuscripts. Photomicrographs and other photographic illustrations must be submitted in triplicate; photocopies of photographs and line drawings are not acceptable. The name of the first author, figure number, and designation of the top of the illustration should be marked on the back of each illustration with a soft lead pencil. Authors should avoid mounting illustrations on boards unless mounting is necessary to insure proper placement. Legends for illustrations should be typewritten, double spaced, on a separate sheet, and included at the end of the manuscript. A legend must accompany each illustration. Contributors will pay all charges involved in processing and printing of color photographs.

Figures, especially charts, graphs, and line drawings, are generally reduced in size for publication (consult a recent issue of the journal for examples). To maintain legibility it is important that all numbers, letters, and symbols be large enough originally so that *when reduced* they will remain at least 1/12 inch (2 mm) high (ie, approximately the same size as used for this line of type). Figures not properly prepared will have to be returned to the contributor for revision or will be relettered by the printer and the cost charged to the contributor.

Each table should be typed on a separate sheet and appropriately numbered. Table legends should be typed on the same sheets as the tables.

Failure to comply with the specifications for preparing illustrations and tables may result in a delay of the review process.

REFERENCES

References should be compiled at the end of the article according to the order of citation in the text. They should be typewritten, double spaced, under the heading REFERENCES. Abbreviations for titles of medical periodicals should conform to those used in the latest edition of *Index Medicus.* (A "List of Journals Indexed in Index Medicus"—with abbreviations—is obtainable from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402, at a modest charge.) Name all authors. Supply only first page number for each reference. References to abstracts and letters must be identified as such.

Personal communications and references to publications in press by authors other than those submitting the paper must be substantiated by a letter from the investigator(s) concerned confirming the data or observations and granting the authors permission to cite the material.

PROOFREADING

Contributors are provided with galley proofs and are asked to proofread them for typesetting errors. Important changes in data are allowed, but authors will be charged for excessive alterations in proof. Galley proofs should be returned within 48 hours.

REPRINTS

Reprints of articles can be furnished to contributors when ordered in advance of publication. An order form, showing cost of reprints, is sent with proofs. Individuals wishing to obtain reprints of an article that appeared in BLOOD can do so by contacting the author at the address given in the journal.

ANNOUNCEMENTS

Announcements of meetings, conferences, and the like that are of interest to the readership of BLOOD should be sent to the Editor at least three months before the first day of the month of issue. Fees for announcements vary, depending on their size and the number of issues involved. Prices may be obtained by contacting the BLOOD office.

Color-enhanced scanning electron micrograph of *Pneumocystis carinii.*

Drug of Choice in *PCP*

Bactrim I.V. is the drug of choice for treatment of *Pneumocystis carinii* pneumonia (*PCP*).[1] Please note, though, that AIDS patients may not tolerate or respond to treatment in the same way as non-AIDS patients.

The incidence of side effects—particularly rash, fever and leukopenia—is greatly increased in AIDS patients. Discontinue therapy at the first sign of skin rash or any adverse reaction.

High survival rate after first episodes of *PCP* in AIDS patients

In a multicenter evaluation of 185 AIDS patients who received trimethoprim plus sulfamethoxazole for their first episodes of *PCP*, 58% completed therapy with this combination alone. Among these patients, the rate of immediate survival was 82%.[2]

Immediate survival with TMP/SMX alone
82%
88/107

100%

Adapted from report of a National Heart, Lung and Blood Institute Workshop.[2]

Bactrim™ I.V. Infusion

(16 mg trimethoprim and 80 mg sulfamethoxazole per mL)

ROCHE®

References: 1. *Medical Letter 28*(706):9-16, Jan 31, 1986. **2.** Murray JF, *et al*: *N Engl J Med 310*(25):1682-1688, Jun 21, 1984.

Drug of choice in *PCP*[1]

Bactrim™ I.V. Infusion

(16 mg trimethoprim and 80 mg sulfamethoxazole per mL)

Before prescribing, please consult complete product information, a summary of which follows:

CONTRAINDICATIONS: Hypersensitivity to trimethoprim or sulfonamides; documented megaloblastic anemia due to folate deficiency; pregnancy at term and during the nursing period; infants less than two months of age.

WARNINGS: FATALITIES ASSOCIATED WITH THE ADMINISTRATION OF SULFONAMIDES, ALTHOUGH RARE, HAVE OCCURRED DUE TO SEVERE REACTIONS, INCLUDING STEVENS-JOHNSON SYNDROME, TOXIC EPIDERMAL NECROLYSIS, FULMINANT HEPATIC NECROSIS, AGRANULOCYTOSIS, APLASTIC ANEMIA AND OTHER BLOOD DYSCRASIAS.

BACTRIM SHOULD BE DISCONTINUED AT THE FIRST APPEARANCE OF SKIN RASH OR ANY SIGN OF ADVERSE REACTION. Clinical signs, such as rash, sore throat, fever, arthralgia, cough, shortness of breath, pallor, purpura or jaundice, may be early indications of serious reactions. In rare instances a skin rash may be followed by more severe reactions, such as Stevens-Johnson syndrome, toxic epidermal necrolysis, hepatic necrosis or serious blood disorder. Perform complete blood counts frequently.

BACTRIM SHOULD NOT BE USED IN THE TREATMENT OF STREPTOCOCCAL PHARYNGITIS. Clinical studies have documented that patients with group A β-hemolytic streptococcal tonsillopharyngitis have a greater incidence of bacteriologic failure when treated with Bactrim than with penicillin.

Bactrim I.V. Infusion contains sodium metabisulfite, which may cause allergic-type reactions in susceptible persons, especially asthmatics or atopic nonasthmatic persons.

PRECAUTIONS:

General: Give with caution to patients with impaired renal or hepatic function, possible folate deficiency (*e.g.*, elderly, chronic alcoholics, patients on anticonvulsants, with malabsorption syndrome, or in malnutrition states) and severe allergies or bronchial asthma. In glucose-6-phosphate dehydrogenase deficient individuals, hemolysis may occur, frequently dose-related.

Local irritation and inflammation due to extravascular infiltration of the infusion have been observed. If these occur, discontinue infusion and restart at another site.

Use in the Elderly: May be increased risk of severe adverse reactions in elderly, particularly with complicating conditions, *e.g.*, impaired kidney and/or liver function, concomitant use of other drugs. Severe skin reactions, generalized bone marrow suppression (see WARNINGS and ADVERSE REACTIONS) or a specific decrease in platelets (with or without purpura) are most frequently reported severe adverse reactions in elderly. In those concurrently receiving certain diuretics, primarily thiazides, increased incidence of thrombocytopenia with purpura reported. Make appropriate dosage adjustments for patients with impaired kidney function (see DOSAGE AND ADMINISTRATION).

Use in the Treatment of Pneumocystis Carinii Pneumonitis in Patients with Acquired Immunodeficiency Syndrome (AIDS): Because of unique immune dysfunction, AIDS patients may not tolerate or respond to Bactrim in same manner as non-AIDS patients. Incidence of side effects, particularly rash, fever, leukopenia, with Bactrim in AIDS patients treated for *Pneumocystis carinii* pneumonitis reported to be greatly increased compared with incidence normally associated with Bactrim in non-AIDS patients.

Laboratory Tests: Perform appropriate culture and susceptibility studies before and throughout treatment. Complete blood counts should be done frequently; if a significant reduction in the count of any formed blood element is noted, discontinue Bactrim. Perform urinalyses with careful microscopic examination and renal function tests during therapy, particularly for patients with impaired renal function.

Drug Interactions: In elderly patients concurrently receiving certain diuretics, primarily thiazides, an increased incidence of thrombocytopenia with purpura has been reported. Bactrim may prolong the prothrombin time in patients who are receiving the anticoagulant warfarin. Keep this in mind when Bactrim is given to patients already on anticoagulant therapy and reassess coagulation time. Bactrim may inhibit the hepatic metabolism of phenytoin. Given at a common clinical dosage, it increased the phenytoin half-life by 39% and decreased the phenytoin metabolic clearance rate by 27%. When giving these drugs concurrently, be alert for possible excessive phenytoin effect. Sulfonamides can displace methotrexate from plasma protein binding sites, thus increasing free methotrexate concentrations.

Drug/Laboratory Test Interactions: Bactrim, specifically the trimethoprim component, can interfere with a serum methotrexate assay as determined by the competitive binding protein technique (CBPA) when a bacterial dihydrofolate reductase is used as the binding protein. No interference occurs if methotrexate is measured by a radioimmunoassay (RIA). The presence of trimethoprim and sulfamethoxazole may also interfere with the Jaffé alkaline picrate reaction assay for creatinine, resulting in overestimations of about 10% in the range of normal values.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenesis: Long-term studies in animals to evaluate carcinogenic potential not conducted with Bactrim I.V. Infusion. *Mutagenesis:* Bacterial mutagenic studies not performed with sulfamethoxazole and trimethoprim in combination. Trimethoprim demonstrated to be nonmutagenic in the Ames

BACTRIM™ I.V. Infusion (trimethoprim and sulfamethoxazole/Roche)

assay. No chromosomal damage observed in human leukocytes cultured *in vitro* with sulfamethoxazole and trimethoprim alone or in combination; concentrations used exceeded blood levels of these compounds following therapy with Bactrim. Observations of leukocytes obtained from patients treated with Bactrim revealed no chromosomal abnormalities.

Impairment of Fertility: Bactrim I.V. Infusion not studied in animals for evidence of impairment of fertility. Studies in rats at oral dosages as high as 70 mg/kg trimethoprim plus 350 mg/kg sulfamethoxazole daily showed no adverse effects on fertility or general reproductive performance.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Trimethoprim and sulfamethoxazole may interfere with folic acid metabolism; use during pregnancy only if potential benefit justifies potential risk to fetus. Nonteratogenic Effects: See CONTRAINDICATIONS section.

Nursing Mothers: See CONTRAINDICATIONS section.

Pediatric Use: Not recommended for infants under two months (see CONTRAINDICATIONS section).

ADVERSE REACTIONS: Most common are gastrointestinal disturbances (nausea, vomiting, anorexia) and allergic skin reactions (such as rash and urticaria). **FATALITIES ASSOCIATED WITH THE ADMINISTRATION OF SULFONAMIDES, ALTHOUGH RARE, HAVE OCCURRED DUE TO SEVERE REACTIONS, INCLUDING STEVENS-JOHNSON SYNDROME, TOXIC EPIDERMAL NECROLYSIS, FULMINANT HEPATIC NECROSIS, AGRANULOCYTOSIS, APLASTIC ANEMIA AND OTHER BLOOD DYSCRASIAS (SEE WARNINGS SECTION).** Local reaction, pain and slight irritation on I.V. administration infrequent. Thrombophlebitis rarely observed.

Hematologic: Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia, neutropenia, hemolytic anemia, megaloblastic anemia, hypoprothrombinemia, methemoglobinemia, eosinophilia. *Allergic Reactions:* Stevens-Johnson syndrome, toxic epidermal necrolysis, anaphylaxis, allergic myocarditis, erythema multiforme, exfoliative dermatitis, angioedema, drug fever, chills, Henoch-Schoenlein purpura, serum sickness-like syndrome, generalized allergic reactions, generalized skin eruptions, conjunctival and scleral injection, photosensitivity, pruritus, urticaria and rash. Periarteritis nodosa and systemic lupus erythematosus have been reported. *Gastrointestinal:* Hepatitis (including cholestatic jaundice and hepatic necrosis), elevation of serum transaminase and bilirubin, pseudomembranous enterocolitis, pancreatitis, stomatitis, glossitis, nausea, emesis, abdominal pain, diarrhea, anorexia. *Genitourinary:* Renal failure, interstitial nephritis, BUN and serum creatinine elevation, toxic nephrosis with oliguria and anuria, crystalluria. *Neurologic:* Aseptic meningitis, convulsions, peripheral neuritis, ataxia, vertigo, tinnitus, headache. *Psychiatric:* Hallucinations, depression, apathy, nervousness. *Endocrine:* Sulfonamides bear certain chemical similarities to some goitrogens, diuretics (acetazolamide and the thiazides) and oral hypoglycemic agents; cross-sensitivity may exist. Diuresis and hypoglycemia have occurred rarely in patients receiving sulfonamides. *Musculoskeletal:* Arthralgia, myalgia. *Respiratory:* Pulmonary infiltrates. *Miscellaneous:* Weakness, fatigue, insomnia.

DOSAGE AND ADMINISTRATION: CONTRAINDICATED IN INFANTS LESS THAN TWO MONTHS OF AGE. CAUTION—BACTRIM I.V. INFUSION MUST BE DILUTED IN 5% DEXTROSE IN WATER SOLUTION PRIOR TO ADMINISTRATION. DO NOT MIX WITH OTHER DRUGS OR SOLUTIONS. RAPID INFUSION OR BOLUS INJECTION MUST BE AVOIDED.

DOSAGE *(Children and Adults):*

PNEUMOCYSTIS CARINII PNEUMONITIS: Total daily dose is 15 to 20 mg/kg (based on the trimethoprim component) given in three or four equally divided doses every 6 to 8 hours for up to 14 days. One investigator noted that a total daily dose of 10 to 15 mg/kg was sufficient in 10 adults with normal renal function.

SEVERE URINARY TRACT INFECTIONS AND SHIGELLOSIS: Total daily dose is 8 to 10 mg/kg (based on the trimethoprim component) given in two to four equally divided doses every 6, 8 or 12 hours for up to 14 days for severe urinary tract infections and 5 days for shigellosis. Maximum recommended daily dose is 60 ml. *Renal Impaired:* Creatinine clearance above 30 ml/min, give usual dosage; 15-30 ml/min, give one-half the usual regimen; below 15 ml/min, use not recommended.

Method of Preparation: Bactrim I.V. Infusion must be diluted. EACH 5 ML SHOULD BE ADDED TO 125 ML OF 5% DEXTROSE IN WATER. After diluting do not refrigerate; use within 6 hours. If a dilution of 5 ml/100 ml of 5% dextrose in water is desired, use within 4 hours. If there is cloudiness or evidence of crystallization, discard solution and prepare a fresh one.

Multidose Vials: After initial entry into the vial, use remaining contents within 48 hours.

The following infusion systems are satisfactory: unit-dose glass containers; unit-dose polyvinyl chloride and polyolefin containers.

Dilution: ADD EACH 5 ML OF BACTRIM I.V. INFUSION TO 125 ML OF 5% DEXTROSE IN WATER.

NOTE: *When fluid restriction is desirable*, add each 5 ml to 75 ml of 5% dextrose in water; mix just prior to use and administer within two hours. If there is cloudiness or evidence of crystallization, discard solution and prepare a fresh one.

DO NOT MIX BACTRIM I.V. INFUSION—5% DEXTROSE IN WATER WITH DRUGS OR SOLUTIONS IN THE SAME CONTAINER.

ADMINISTRATION: Administer by I.V. infusion over 60 to 90 minutes. Avoid rapid infusion or bolus injection. Do not give intramuscularly.

HOW SUPPLIED: 5-ml ampuls, 5-ml vials and 10-ml vials—boxes of 10; 30-ml and 50-ml multidose vials—boxes of 1. Each 5 ml contains 80 mg trimethoprim (16 mg/ml) and 400 mg sulfamethoxazole (80 mg/ml) for infusion with 5% dextrose in water.

STORE AT ROOM TEMPERATURE (15°-30°C or 59°-86°F). DO NOT REFRIGERATE.

INTRONA: L'INTERFERON alfa-2b

FORME ET PRESENTATION :
Lyophilisat et solution pour usage parentéral : Boîte unitaire

COMPOSITION :
Lyophilisat : 23,8 mg p. flacon
Interféron alfa-2b 3 millions U.I.
ou 5 millions U.I. ou 10 millions U.I. ou 30 millions U.I.
Excipient : Sodium (hydrogénophosphate de) anhydre,
Phosphate monosodique monohydraté, Acide amino-acétique, Albumine humaine.
Solution : Eau pour usage parentéral : (1 ml).

SORT DU MEDICAMENT :
En sous-cutanée et intramusculaire, les pics sériques sont atteints en 8 et 6 h ; les demi-vies d'absorption en 4 et 3 h et les demi-vies d'élimination en 7 et 6 h.
En intraveineuse, le pic sérique est atteint à la 30e minute (fin de perfusion), la demi-vie d'élimination est d'environ 1 h.
Quelle que soit la voie d'administration, il n'est pas retrouvé d'interféron alfa-2b dans les urines.

PROPRIETES :
Introna, dont le principe actif est l'interféron alfa-2b (interféron alpha, sous type 2) produit par génie génétique, présente ces propriétés qui ont été mises en évidence lors des études précliniques :
1. L'ACTIVITE ANTIPROLIFERATIVE : dose-dépendante.
2. L'ACTIVITE IMMUNOMODULATRICE.
3. L'ACTIVITE ANTIVIRALE.

INDICATIONS :
- Leucémie à tricholeucocytes.
- Mélanome disséminé.
- Sarcome de Kaposi associé au syndrome d'immuno-déficit acquis (SIDA).

CONTRE-INDICATIONS :
- Sensibilité à l'interféron alfa-2b ou à l'un des excipients (albumine humaine entre autres).
- GROSSESSE : en raison de la spécificité d'espèce, les études de tératogénèse et de toxicité fœtale chez l'animal n'ont pas de valeur prévisionnelle pour l'espèce humaine ; il en résulte que l'innocuité de l'interféron alfa-2b pendant la grossesse n'a pu être établie.

MISE EN GARDE :
- Une réaction allergique sévère doit faire interrompre le traitement immédiatement.
- Une surveillance électrocardiographique doit être assurée chez les patients ayant des antécédents cardiaques (infarctus du myocarde et/ou troubles du rythme) et ceux ayant reçu des substances cardiotoxiques.
- Une hypotension peut survenir durant le traitement et jusqu'à 48 h après son arrêt.
- Tout effet secondaire sévère doit conduire à modifier voire arrêter le traitement.

PRECAUTIONS :
- Un état d'hydratation satisfaisant doit être maintenu pendant la durée du traitement.
- Les analgésiques centraux, les hypnotiques et les sédatifs administrés simultanément doivent l'être avec prudence.
- L'innocuité de l'interféron alfa-2b n'a pas été établie ni chez l'enfant ni chez l'adolescent de moins de 18 ans.
- La surveillance biologique porte sur : NFS plaquettes, fonctions hépatique et rénale.

INTERACTIONS MEDICAMENTEUSES :
Incompatibilités majeures :
Aucune substance médicamenteuse ne doit être associée à l'Introna dans la seringue ou le flacon de perfusion.
Ne pas mélanger à des solutions glucosées.

EFFETS INDESIRABLES :
D'une façon générale, les effets indésirables ont un caractère réversible en 72 h et sont dose-dépendants :

Cliniques :
Le plus fréquent est le syndrome pseudo-grippal qui peut être prévenu ou traité par l'administration de paracétamol.
Les autres principaux effets indésirables observés sont :
- Les troubles du système nerveux central.
- Les modifications cardiovasculaires.
- Les troubles gastro-intestinaux.

Biologiques :
leuconeutropénie, thrombopénie, élévation des enzymes hépatiques, troubles de l'hémostase.

MODE D'EMPLOI ET POSOLOGIE :
- La reconstitution doit être effectuée immédiatement avant l'
ploi avec les précautions d'asepsie d'usage.
Prélever la dose appropriée pour injection sous-cutanée
adjonction à 50 ml de soluté isotonique de NaCl pour adm
tration intraveineuse (perfusion de 30 minutes).
- Aucune substance ne doit être associée à Introna dan
seringue ou le flacon de perfusion.

Les posologies recommandées sont les suivantes :
- *Leucémies à tricholeucocytes*
2 millions d'Unités Internationales/m²/jour par voie sous-cuta
3 fois par semaine, 1 jour sur 2.
- *Mélanome disséminé*
5 à 10 millions d'Unités Internationales/m²/jour par voie s
cutanée, 3 fois par semaine, 1 jour sur 2.
- *Sarcome de Kaposi associé au SIDA*
50 millions d'Unités Internationales/m²/jour en perfusion
30 minutes, 5 jours consécutifs, 1 semaine sur 2 (intervalle
9 jours entre 2 cures).

Conservation : A conserver au réfrigérateur (de 2 à 8 °C).
Après reconstitution, conserver au maximum 24 h entre 2
30 °C.

Une demande a été faite pour étendre la validité de conserva
au réfrigérateur à 36 mois et à température ambiante à 18 m
conformément aux résultats des études de stabilité conduites
plusieurs dizaines de lots et approuvés par l'expert analyste.

SURDOSAGE :
Aucun cas de surdosage n'a été rapporté à ce jour, bien que doses de 200 millions d'Unités Internationales aient administrées.

TABLEAU A. A.M.M. :
328 992.3 3 millions U.I. – 328 991.7 5 millions U.I.
328 990.0 10 millions U.I. – 328 989.2 30 millions U.I.
Mis sur le marché en 1987.
Cette spécialité est strictement réservée à l'usage hospitalier.

PROGRESS IN HEMOSTASIS AND THROMBOSIS,

VOLUME 8

Edited by

Barry S. Coller, M.D.

Progress in Hemostasis and Thrombosis, Volume 8, carries on the tradition established for the series under Dr. Theodore Spaet's editorship, of publishing definitive reviews on major topics of current interest in the broad fields of hemostasis and thrombosis.

For the first edition under his editorship, Dr. Barry S. Coller has selected a rich mixture of both basic and clinical topics written by authors with outstanding international reputations. Several chapters deal extensively with the new therapeutic modalities, including thrombolysis with tissue plasminogen activators, intravenous gamma-globulin, and DDAVP. Among the other topics covered are: the hereditary thrombophilias; Factor VIII; Protein Kinase C; Transcellular Metabolism of Eicosenoids; Porcine von Willebrand's Disease; and Heparin-like Molecules of the Endothelium.

Progress in Hemostasis and Thrombosis, Volume 8, presents hematologists, cardiologists, basic scientists, and other interested professionals, with in-depth reviews of important topics in the field.

GRUNE & STRATTON, INC.

A uniquely valuable contribution to the field of transplantation medicine!

TRANSPLANTATION TODAY,

VOLUME IX

Pekka Häyry, M.D., Saija Koskimies, and **Felix T. Rapaport, M.D.**

This volume is the ninth in a series of biennial in-depth reviews of world transplantation and has become a classic in its field today.

Transplantation Today, Volume IX, provides a global overview of all that transplantation has to offer patients suffering from end-stage disease of vital organs. A full compendium of the new areas of research that have developed in the field is provided. The applications of new discoveries to clinical medicine are outlined in detail, including full representation by all of major research and clinical transplantation facilities throughout the world.

Comprised of over 1,000 contributions from physicians and scientists representing 47 different nations, this volume is the unique authoritative compendium for world transplantation. Special chapters are devoted to cellular and molecular mechanisms in transplant rejection, histocompatibility, experimental transplantation, immunosuppression and clinical transplantation of kidney, heart, lung, liver, pancreas, bone marrow and other organs.

Transplantation Today, Volume IX, offers the most informative and authoritative view of this field to date. It will be a valuable reference for nephrologists, cardiologists, hepatologists, metabolic disease experts, diabetes experts, endocrinologists, immunologists, internists, and experts in infectious diseases.

PARTIAL CONTENTS: The State of the Art of Transplantation. Cellular and Molecular Mechanisms. Clinical Transplantation. Current Controversies in Transplantation. Progress in Transplantation. Immunobiology. Regulation of Antigen Expression. Immunogenics and Histocompatibility. HLA Matching and Transplant Survival. Experimental Transplantation. Experimental Transplantation of Islets and Endocrine Tissue. Clinical Transplantation: Kidney. Living Donors. Clinical Transplantation: Other Organs. Pancreas and Islet Cell Transplantation. Bone Marrow Transplantation. Clinical Bone Marrow Transplantation. Transplantation Today and Tomorrow.

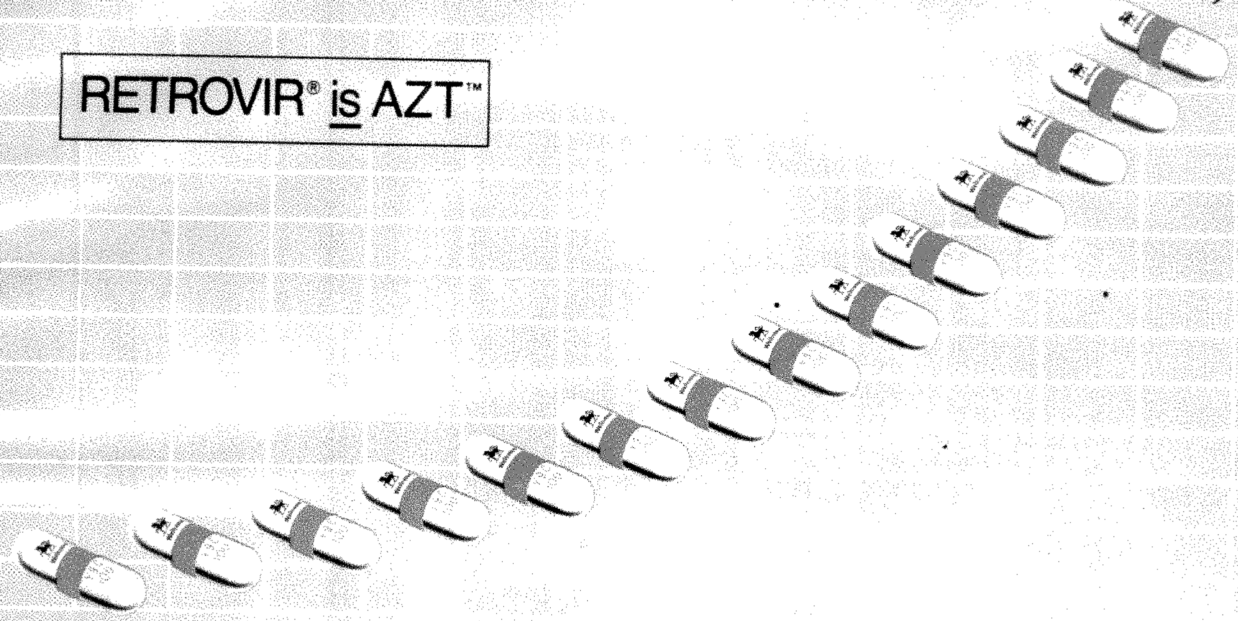
AIDS
UPDATE

A significant increase in the supply of RETROVIR® (zidovudine)

RETROVIR® is AZT™



All appropriate patients can now benefit from RETROVIR therapy

RETROVIR can now be prescribed just as any other medication

Since there is no longer a need for the RETROVIR enrollment program

Around-the-clock production of RETROVIR was implemented

Because of the growing number of AIDS and ARC patients in need of treatment

The supply of RETROVIR has been increased significantly

So that many more patients with AIDS and other serious HIV infections can now benefit from therapy

New clinical trials of RETROVIR are now under way

Because of our commitment to improving the treatment of HIV infections

IMPROVING LIVES THROUGH ANTIVIRAL RESEARCH

BURROUGHS WELLCOME CO.

Please see brief summary of prescribing information on other side of this advertisement.

RETROVIR® (ZIDOVUDINE) Capsules

WARNING: THERAPY WITH RETROVIR (ZIDOVUDINE) IS OFTEN ASSOCIATED WITH HEMATOLOGIC TOXICITY INCLUDING GRANULOCYTOPENIA AND SEVERE ANEMIA REQUIRING TRANSFUSIONS (SEE WARNINGS).

IN ADDITION, PATIENTS TREATED WITH ZIDOVUDINE MAY CONTINUE TO DEVELOP OPPORTUNISTIC INFECTIONS (OI'S) AND OTHER COMPLICATIONS OF THE ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS) AND AIDS RELATED COMPLEX (ARC) CAUSED BY THE HUMAN IMMUNODEFICIENCY VIRUS (HIV). THEREFORE, PATIENTS ON ZIDOVUDINE SHOULD BE UNDER CLOSE CLINICAL OBSERVATION BY PHYSICIANS EXPERIENCED IN THE TREATMENT OF PATIENTS WITH DISEASES ASSOCIATED WITH HIV. THE SAFETY AND EFFICACY OF ZIDOVUDINE HAVE BEEN ESTABLISHED ONLY FOR CERTAIN ADULT AIDS AND ADVANCED ARC PATIENTS (SEE "INDICATIONS AND USAGE").

INDICATIONS AND USAGE: Retrovir Capsules are indicated for the management of certain adult patients with symptomatic HIV infection (AIDS and advanced ARC) who have a history of cytologically confirmed *Pneumocystis carinii* pneumonia (PCP) or an absolute CD4 (T4 helper/inducer) lymphocyte count of less than 200/mm^3 in the peripheral blood before therapy is begun.

This indication is based primarily on the results of a randomized, double-blind, placebo-controlled trial conducted at 12 medical centers in the United States in which 281 patients with AIDS or advanced ARC were studied for an average of four and a half months. Additional data have been collected on approximately 80% of these patients who have received zidovudine in an open-label extension of this trial for an average of five more months.

The patient population of the controlled trial consisted of 160 AIDS patients (85 Retrovir and 75 placebo) who had recovered from their first episode of PCP diagnosed within the previous four months, and 121 ARC patients (59 Retrovir and 62 placebo) with multiple signs and symptoms of HIV infection, including mucocutaneous candidiasis and/or unexplained weight loss (> 15 lbs or > 10% of prior body weight). All patients had evidence of impaired cellular immunity with an absence of delayed cutaneous hypersensitivity and a decreased number of CD4 (T4) lymphocytes in the peripheral circulation. Two hundred twenty-one (79% of all patients) had fewer than 200 T4 cells/mm^3 at entry (95% of AIDS patients and 57% of ARC patients). All patients began therapy at a dose of 250 mg every 4 hours around the clock. This dosage was reduced or temporarily or permanently discontinued if serious marrow toxicity occurred. The trial was stopped because of a significant reduction in mortality before all patients had completed the planned 24 weeks of treatment. There were 19 deaths in the placebo group and 1 in the Retrovir group ($p < .001$). All deaths were apparently due to opportunistic infections (OI) or other complications of HIV infection. Treatment duration ranged from 12 weeks to 26 weeks, with a mean and median duration of 17 and 18 weeks, respectively.

Retrovir also significantly reduced the risk of acquiring an AIDS-defining OI in patients after 6 weeks of treatment ($p < .001$). In addition, patients who received Retrovir generally did better than the placebo group in terms of several other measures of efficacy including performance level, neuropsychiatric function, maintenance of body weight and the number and severity of symptoms associated with HIV infection. A modest increase in mean CD4 (T4) counts was seen in the zidovudine group but the significance of this finding is unclear as the CD4 (T4) counts declined again in some patients.

The most significant adverse reaction noted in the study was a depression of formed elements in the peripheral blood, which necessitated dose reduction or drug discontinuation in 49 of the 144 (34%) patients receiving Retrovir. Of those participants whose baseline CD4 (T4) lymphocyte counts were less than 200, 47% of those receiving Retrovir and 10% of those receiving placebo developed a granulocyte count of < 750/mm^3. Similarly, 45% of Retrovir recipients and only 14% of placebo recipients had a 25% or greater reduction in hemoglobin. (See ADVERSE REACTIONS.)

At the conclusion of the placebo-controlled trial, 127 Retrovir recipients and 100 placebo recipients elected to enroll in an uncontrolled extension protocol in which all patients received Retrovir at a dose of 200 mg every four hours. This dose was chosen because of concern about cumulative hematologic toxicity and to allow for greater flexibility in dosing. Over the subsequent five months, opportunistic infections continued to occur and additional patients died in both groups. Sixteen patients from the original placebo cohort died after the conclusion of the controlled trial. Four of these 16 never received Retrovir and seven expired during the first month of therapy. Ten additional deaths occurred among the original Retrovir recipients. With respect to these data, termination of the controlled trial precludes direct comparisons of mortality and morbidity between the original placebo and drug recipients. Long-term follow-up of these patients, however, will allow for examination of the natural history of prolonged zidovudine therapy.

CONTRAINDICATIONS: Retrovir Capsules are contraindicated for patients who have potentially life-threatening allergic reactions to any of the components of the formulation.

WARNINGS: Zidovudine has been carefully studied in limited numbers of seriously ill HIV-infected patients treated for a limited period of time. Therefore, the full safety and efficacy profile of zidovudine has not been completely defined, particularly in regard to prolonged use, and especially in HIV-infected individuals who have less advanced disease.

Zidovudine should be used with extreme caution in patients who have bone marrow compromise evidenced by granulocyte count < 1000/mm^3 or hemoglobin < 9.5 g/dl. In the placebo-controlled study, anemia and granulocytopenia were the most significant adverse events observed (see ADVERSE REACTIONS).

Significant anemia most commonly occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, and/or blood transfusions. Frequent (at least every 2 weeks) blood counts are strongly recommended in patients taking zidovudine. If anemia or granulocytopenia develops, dosage adjustments may be necessary (see DOSAGE AND ADMINISTRATION).

Coadministration of zidovudine with other drugs metabolized by glucuronidation should be avoided because the toxicity of either drug may be potentiated (see Drug Interactions under PRECAUTIONS). Zidovudine recipients who used acetaminophen during the controlled trial had an increased incidence of granulocytopenia which appeared to be correlated with the duration of acetaminophen use.

PRECAUTIONS:

General: Zidovudine is eliminated from the body primarily by renal excretion following metabolism in the liver (glucuronidation). There are currently no data available concerning the use of zidovudine in patients with impaired renal or hepatic function, and such patients may be at a greater risk of toxicity from zidovudine.

Drug Interactions: The interaction of other drugs with zidovudine has not been studied in a systematic manner. Coadministration of zidovudine with drugs that are nephrotoxic, cytotoxic, or which interfere with RBC/WBC number or function (e.g., dapsone, pentamidine, amphotericin B, flucytosine, vincristine, vinblastine, adriamycin, or interferon) may increase the risk of toxicity. Limited data suggest that probenecid may inhibit glucuronidation and/or reduce renal excretion of zidovudine. In addition, other drugs (e.g., acetaminophen, aspirin, or indomethacin) may competitively inhibit glucuronidation (see WARNINGS).

Some experimental nucleoside analogues which are being evaluated in AIDS and ARC patients may affect RBC/WBC number or function and may increase the potential for hematologic toxicity of zidovudine. Some experimental nucleoside analogues affecting DNA replication antagonize the *in vitro* antiviral activity of zidovudine against HIV and thus, concomitant use of such drugs should be avoided.

Some drugs such as trimethoprim-sulfamethoxazole, pyrimethamine, and acyclovir may be necessary for the management or prevention of opportunistic infections. In the controlled trial, increased toxicity was not detected with limited exposure to these drugs. However, there are two published reports of neurotoxicity (one of profound lethargy and one of seizure) associated with concomitant use of zidovudine and acyclovir.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term carcinogenicity studies of zidovudine in animals have not been completed. However, in an *in vitro* mammalian cell transformation assay, zidovudine was positive at concentrations of 0.5 µg/ml and higher.

No evidence of mutagenicity (with or without metabolic activation) was observed in the Ames *Salmonella* mutagenicity assay. In a mutagenicity assay conducted in L5178Y/TK$^{+/-}$ mouse lymphoma cells, zidovudine was weakly mutagenic in the absence of metabolic activation only at the highest concentrations tested (4000 and 5000 µg/ml). In the presence of metabolic activation, the drug was weakly mutagenic at concentrations of 1000 µg/ml and higher. In an *in vitro* cytogenetic study performed in cultured human lymphocytes, zidovudine induced dose-related structural chromosomal abnormalities at concentrations of 3 µg/ml and higher. No such effects were noted at the two lowest concentrations tested, 0.3 and 1 µg/ml.

Pregnancy: Pregnancy Category C. An oral teratology study in pregnant rats using doses up to 20 times the human dose has revealed no evidence of harm to the fetus due to zidovudine. It is not known whether zidovudine can cause fetal harm when administered to a pregnant woman or can affect reproductive capacity. Zidovudine should be given to a pregnant woman only if clearly needed.

Nursing Mothers: It is not known whether zidovudine is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions from zidovudine in nursing infants, mothers should be instructed to discontinue nursing if they are receiving zidovudine.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequent adverse events and abnormal laboratory values reported in the placebo-controlled clinical trial of oral zidovudine administration in 281 patients (144 patients zidovudine; 137 patients placebo) were granulocytopenia and anemia. The occurrence of these hematologic toxicities was inversely related to CD4 (T4) lymphocyte number, hemoglobin, and granulocyte count at study entry, and directly related to dose and duration of therapy. The frequency of granulocytopenia and anemia according to the patients' CD4 (T4) levels is shown in the following table.

	Pretreatment CD4 (T4) Levels			
	< 200/mm^3		> 200/mm^3	
Abnormality	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia (< 750/mm^3)	47%	10%	10%	3%
Anemia (Hgb < 7.5 g/dl)	30%	6%	3%	0%

Because many patients were anemic and/or granulocytopenic before starting therapy with zidovudine, examining the degree of change when compared to baseline, as shown in the table below, may be more informative.

		Pretreatment CD4 (T4) Levels			
		< 200/mm^3		> 200/mm^3	
Abnormality	% Decrease from Baseline	Zidovudine (n = 113)	Placebo (n = 105)	Zidovudine (n = 30)	Placebo (n = 30)
Granulocytopenia	> 50%	55%	19%	40%	13%
Anemia	> 25%	45%	14%	10%	10%

The anemia appeared to be the result of impaired erythrocyte maturation as evidenced by increasing macrocytosis (MCV) while on drug.

The 281 patients treated in this controlled trial had serious underlying disease with multiple baseline symptoms and clinical abnormalities. The following table summarizes those reported clinical adverse events which occurred in at least 5% of all patients treated with zidovudine. Severe headache, nausea, insomnia and myalgia were reported at a significantly greater rate in zidovudine recipients.

Percentage (%) of Patients with Clinical Events					
Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %	Adverse Event	Zidovudine (n = 144) %	Placebo (n = 137) %
BODY AS A WHOLE			MUSCULOSKELETAL		
Asthenia	19	18	Myalgia	8	2
Diaphoresis	5	4	NERVOUS		
Fever	16	12	Dizziness	6	4
Headache	42	37	Insomnia	5	1
Malaise	8	7	Paresthesia	6	3
GASTROINTESTINAL			Somnolence	8	9
Anorexia	11	8	RESPIRATORY		
Diarrhea	12	18	Dyspnea	5	3
Dyspepsia	5	4	SKIN		
GI Pain	20	19	Rash	17	15
Nausea	46	18	SPECIAL SENSES		
Vomiting	6	3	Taste Perversion	5	8

Clinical adverse events which occurred in less than 5% of all patients treated with zidovudine are listed below. Since many of these adverse events were seen in placebo-treated patients as well as zidovudine recipients, they may not be attributable to the drug.

Body as a whole: body odor, chills, edema of the lip, flu syndrome, hyperalgesia, back pain, chest pain, lymphadenopathy.
Cardiovascular: vasodilation.
Gastrointestinal: constipation, dysphagia, edema of the tongue, eructation, flatulence, bleeding gums, rectal hemorrhage, mouth ulcer.
Musculoskeletal: arthralgia, muscle spasm, tremor, twitch.
Nervous: anxiety, confusion, depression, emotional lability, nervousness, syncope, loss of mental acuity, vertigo.
Respiratory: cough, epistaxis, pharyngitis, rhinitis, sinusitis, hoarseness.
Skin: acne, pruritus, urticaria.
Special senses: amblyopia, hearing loss, photophobia.
Urogenital: dysuria, polyuria, urinary frequency, urinary hesitancy.

DOSAGE AND ADMINISTRATION: The recommended starting dose of Retrovir (zidovudine) is 200 mg (two 100 mg capsules) administered orally every four hours around the clock.

Hematologic toxicities appear to be related to pretreatment bone marrow reserve and to dose and duration of therapy. Careful monitoring of hematologic indices every two weeks is recommended to detect serious anemia or granulocytopenia. In patients with hematologic toxicity, reduction in hemoglobin may occur as early as 2 to 4 weeks, and granulocytopenia usually occurs after 6 to 8 weeks.

Dose Adjustment: Significant anemia (hemoglobin of < 7.5 g/dL or reduction of > 25% of baseline) and/or significant granulocytopenia (granulocyte count of < 750/mm^3 or reduction of > 50% from baseline) may require a dose interruption until some evidence of marrow recovery is observed. For less severe anemia or granulocytopenia, a reduction in daily dose may be adequate. In patients who develop significant anemia, dose modification does not necessarily eliminate the need for transfusion. If marrow recovery occurs following dose modification, gradual increases in dose may be appropriate depending on hematologic indices and patient tolerance.

North Carolina 27709

Copr. © 1987 Burroughs Wellcome Co. All rights reserved.

Large regional blood center with active research programs seeks M.D./Ph.D. with strong investigational interests, to develop a research area along with some clinical/operational responsibility. Several medical school collaborative research and teaching programs are ongoing and a university appointment can be arranged. Respond to:

JCO Box 10
P.O. Box 308
Park Ridge, NJ 07656

FELLOWSHIPS IN BLOOD BANKING. Applications are being accepted for training beginning July 1, 1988 in the joint program of the New Jersey Medical School and University Hospital of the University of Medicine and Dentistry of New Jersey (Eric J. Wake, M.D., Director of Blood Bank and Blood Bank Residency Training Program), and the North Jersey Blood Center (Harry L. Taylor, M.D., Medical Director). Trainees will receive instruction and have opportunities for basic and applied research in immunohematology, immunogenetics, transplantation immunology, hemostasis, transfusion therapy, pheresis procedures, automation, and computers in immunohematology. The trainees will participate in teaching activities and administrative aspects of blood banking, and ward rounds and administrative meetings. Must be eligible/certified in Clinical Pathology or other primary specialty board and eligible or licensed to practice medicine in New Jersey. Send resume to:

Stanley J. Robboy, M.D.
Professor & Chairman
Department of Pathology
UMDNJ-New Jersey Medical School
185 South Orange Avenue
Newark, New Jersey 07103-2757

For information call: Eric J. Wake, M.D., (201) 456-4083. An Equal Opportunity/Affirmative Action Employer m/f/h/v.

DIRECTOR HEMATOLOGY/ONCOLOGY

Full time position as Director of Hematology Oncology in a large Urban Teaching Hospital Affiliated with the University of Medicine and Dentistry of New Jersey. Successful candidate will be Board Certified in the Subspecialty of Hematology or Oncology or both. Responsibilities include Teaching, Clinical Practice, and Research. Please send CV to:

Hematology Oncology
Search Committee
United Hospitals Medical Center
c/o Office of Medical Affairs
15 South Ninth Street
Newark, New Jersey 07107

ACADEMIC HEMATOLOGIST

Full time tenure track position for faculty member to develop bone marrow transplantation program. Duties will include teaching medical students and house officers, independent research and superior clinical care. Academic rank appropriate to qualifications. Must be board certified. Competitive salary. Send c.v. and letter of interest to:

Joseph C. Allegra, M.D.
Professor and Chairman
Department of Medicine
University of Louisville
Louisville, KY 40292

EEO/AA

The Department of Hematology/Oncology, Children's Hospital National Medical Center
invites applications for the following positions from qualified candidates:

Bone Marrow Transplantation Physician. An MD with certification in Pediatrics and either Immunology or Hematology/Oncology and experience in clinical BMT is being sought. The candidate should have demonstrable capabilities in productive laboratory and/or clinical research.

Transplantation Immunologist. A scientist (Ph.D. or MD) is being sought to join the BMT program to collaborate in developing investigative approaches to current controversies in bone marrow transplantation. The candidate should have significant research experience and demonstrated scholarly productivity.

Oncologist. A pediatric hematologist/oncologist (BC/BE) with interests and expertise in both clinical and laboratory investigation, preferably in the biology of solid tumors.

Selected candidates would receive appropriate academic appointments in the Department of Child Health and Development, George Washington University School of Medicine and Health Sciences, and salaries commensurate with qualifications and experience. Candidates should send letter of interest and CV to: Gregory H. Reaman, M.D.
Chairman, Hematology/Oncology
Children's Hospital National Medical Center
111 Michigan Avenue, N.W.
Washington, D.C. 20010

LEUKEMIA RESEARCH FOUNDATION GRANTS

The Leukemia Research Foundation, Inc. announces funds are available to support research in the field of leukemia. Currently two types of grants are being funded; research grants, and postdoctoral fellowships.

The following guidelines apply:

1. Maximum limit is $35,000 for research grants, and $20,000 for postdoctoral fellowships.
2. Grants and fellowships are for a one-year period.
3. Institution of affiliation must provide both a report of the results of the research and a financial report.
4. No funds shall be applied to institutional overhead (indirect costs).
5. Preference will be given to researchers new to this field.
6. Deadline for receipt of completed grant applications is February 22, 1988.

For further information and for applications, contact:
Hollis R. Brownstein, Chairman
Medical Advisory Committee
Leukemia Research Foundation, Inc.
899 Skokie Blvd., Suite LL14
Northbrook, Illinois 60062
Phone: 1-312/480-1177

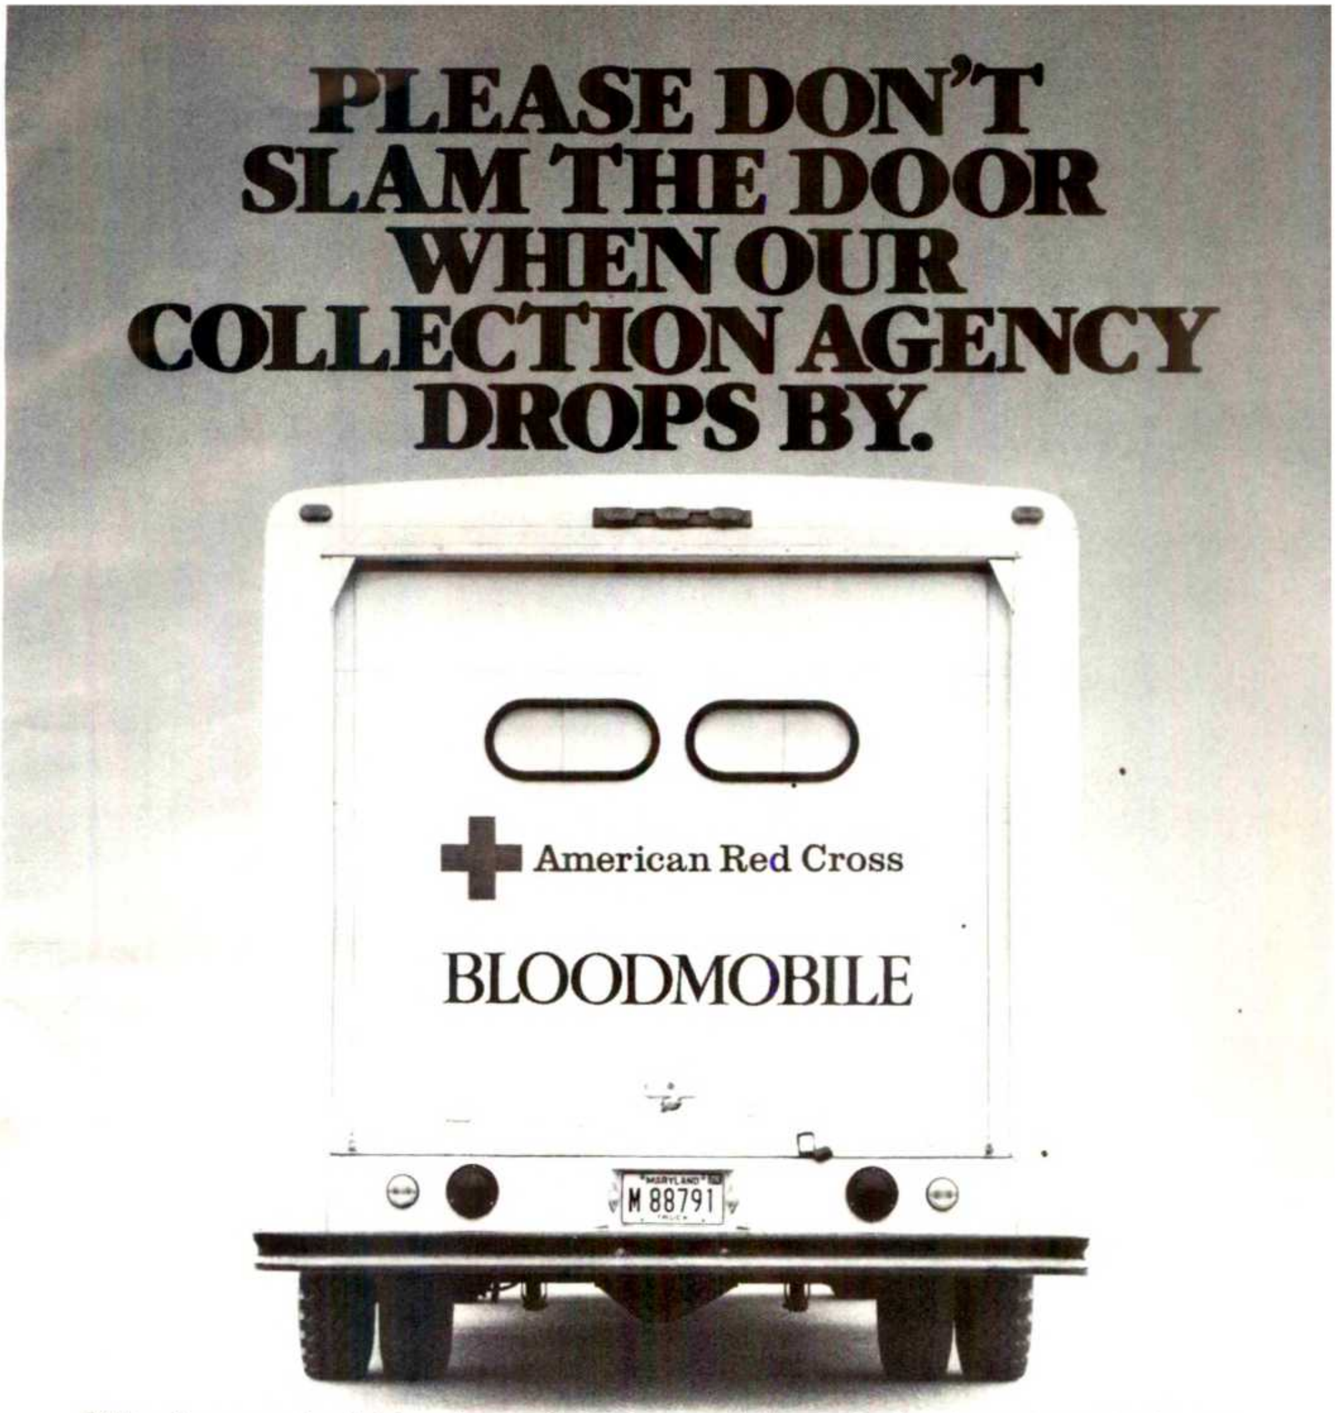
HUMAN GENETICS

Bruce L. Evatt, M.D., Director, the Division of Host Factors, Center for Infectious Diseases, Centers for Disease Control, invites applications for a research scientist in molecular genetics. Individuals with research interests in hematopoiesis or stem cell differentiation are particularly encouraged to apply. Responsibilities include the development and execution of program plans in coordination with the Division Director. A fully equipped laboratory and technical staff are provided. Prefer candidates with a Ph.D. and/or M.D. and a minimum of two years postdoctoral experience in molecular genetics. Salary ranges from $38,000-$72,000 depending on qualifications and personnel systems. Applications including curriculum vitae, a statement of future research interests, and the names with addresses of three references should be sent to: Sharlyn L. Wilkinson, Personnel Management Specialist, CDC, Bldg. 1, Room 1058, Atlanta, GA 30333. Applications must be received by March 15, 1988 to receive consideration.

CDC is an equal opportunity employer and has a smoke-free work environment.

Georgia—The Section of Hematology/Oncology, Department of Pediatrics, Medical College of Georgia is recruiting a fourth faculty member at the assistant/associate professor level. Board certification in pediatrics and subboard eligibility/certification in pediatric hematology/oncology required. Responsibilities include patient care, teaching, and research. The ideal candidate would have research interest in leukocyte or coagulation disorders. Contact P. Charlton Davis, M.D., Chief, Pediatric Hematology/Oncology, Medical College of Georgia, Augusta, GA 30912-3770, Phone (404) 721-3626. EOE/AAP

PLEASE DON'T SLAM THE DOOR WHEN OUR COLLECTION AGENCY DROPS BY.



50% of our nation's blood supply is donated through the American Red Cross.
Much of it comes from blood drives set up by companies just like yours.
So if you close your doors on our collection agency, you're closing the
doors on fellow human beings who need blood to live.
Don't slam the door. Call the Red Cross.
And arrange a blood drive tailored to your company.

Our new five-day platelet storage system gives you more than any other.

And one thing less.

Introducing the new Haemonetics Extended Storage Platelet $_{\text{ESP}}$ Pack. One less needle . . . and a lot more.

More Time

Now you have five full days to complete testing and deliver high quality platelets to the patients who need them. You also have the time you need to schedule donors and reduce weekend staffing demands.

More Convenience

The Extended Storage Platelet$_{\text{ESP}}$ Pack is the only single venipuncture, five-day platelet collection system. That means simpler apheresis, less donor anxiety and fewer donor deferrals due to access limitations. In addition, it eliminates the platelet resuspension exercise.

More Reliability

It's no surprise that the world's most advanced five-day platelet storage system was designed for the world's most versatile and reliable apheresis system . . . The Haemonetics V50 Apheresis System.

There's a lot more that makes our new Extended Storage Platelet$_{\text{ESP}}$ Pack and the V50 Apheresis System so unique. More safety features. More mobility. More support.

Call Haemonetics today, and we'll tell you more about it.

The new Extended Storage Platelet$_{\text{ESP}}$ Pack from Haemonetics. More of what you need . . . and one thing less.

HAEMONETICS®

Experience . . . that counts.

HAEMONETICS CORPORATION
